On chloral hydrate and alcoholate, see also B. H. Paul (*Pharm. J. Trans.* [3] i. 621; *Chem. Soc. J.* [2] ix. 134).

* **CHLORHYDRINS.** *Monochlorhydrin* is converted by sodium-amalgam into propylene glycol: $C^3H^3O^2.Cl + H^2 = HCl + C^3H^3O^2$ (Lourenco, *Compt. rend.* lii. 1043; Buff, *Bull. Soc. Chim.* [2] x. 123). It unites directly with trimethylamine, when heated with it, forming the compound $N(CH^3)^3.C^3H^3(OH)^2.Cl$, which

crystallises in slender needles soluble in water. The solution mixed with auric chloride forms orange-yellow needles of the gold-salt $N(CH_3)_2 \cdot C^3H^3(OH)_2Cl \cdot AuCl^3$ (V. Meyer, *Zeitschr. f. Chem.* [2], v. 439).

Dichlorhydrin, $C^3H^3(OH)Cl_2$, heated with potassium cyanide and alcohol to 100° in a closed vessel for 24 hours, is converted into dicyanhydrin, which when boiled with potash yields oxypyrotartaric acid, $C^3H^3O^3$:

and

(Maxwell Simpson, *Proc. Roy. Soc.* xiii. 44).

Dichlorhydrin dissolved in ether free from alcohol, but not dehydrated, is converted by sodium-amalgam into isopropyl alcohol (Buff, *loc. cit.*):

Trichlorhydrin or *Glyceryl Trichloride*, $C^3H^3Cl^3$, is formed, together with other products, by the action of phosphorus pentachloride on acrolein. A convenient mode of preparing it is to heat acrolein hydrochloride, $C^3H^3O \cdot HCl$, with 1 mol. phosphorus pentachloride as long as hydrochloric acid is given off, and submit the washed product to fractional distillation (Geuther, *Jahresb.* 1864, p. 333). It is also formed by the action of chlorine, or of a mixture of potassium chlorate and hypochlorous acid, on isopropyl iodide (Linnemann, *Jahresb.* 1865, p. 489). A solution of trichlorhydrin in 7 or 8 vol. alcohol, saturated with ammonia and heated to 130° – 140° for three or four days, is converted into chlorodiallylamine (Engler, p. 95):

Respecting the chlorhydrins corresponding to propylphycite, see that compound.

Epichlorhydrin. C^3H^3OCl .—Two rational formulæ have been assigned to this compound, viz.,

The first of these supposes that the oxygen is directly connected with two of the carbon-atoms; whereas the second supposes it to be joined to only one atom of carbon and to one atom of hydrogen—in other words, to be present as hydroxyl (ii. 896). That the former of these represents correctly the structure of epichlorhydrin is shown by the reaction of that compound with phosphorus trichloride and bromine. It appears indeed, from the experiments of Wichelhaus (*Ann. Ch. Pharm. Suppl.* vi. 277), that when organic bodies containing hydroxyl are thus treated, the ultimate products are a chlorinated organic compound, phosphorus oxychlorobromide, and hydrogen bromide, whereas bodies in which the oxygen is entirely combined with the carbon-atoms, like the ketones and oxides, yield as final products an organic bromide and phosphorus oxychloride. Now when epichlorhydrin is mixed with 1 mol. PCl^3 and 1 mol. bromine, (Br^2), is added by small portions to the cooled mixture, a product is formed which by repeated rectification may be separated into phosphorus oxychloride boiling at 110° , and dibromochlorhydrin, $C^3H^3Br^2Cl$ (i. 894), boiling between 195° and 200° :

If the epichlorhydrin molecule contained hydroxyl, the latter would be replaced by an atom of chlorine (Darmsstädt, *Ann. Ch. Pharm.* clii. 319).

Epichlorhydrin heated to 100° with acid sodium sulphite unites with it directly, *Sup.*

F F

forming the beautifully crystallised sodium salt of chlormethyl-isethionie or chlorhydroxypropyl-sulphonic acid, $C^3H^2Cl(OH)SO^2H$ (Darmstädter, *Zeitschr. f. Chem.* [2] iv. 342):

Epichlorhydrin heated with a concentrated solution of 2 mol. *neutral potassium sulphite* in a retort with upright condenser, yields the dipotassic salt of disulphoglyceric acid, $C^3H^2S^2O^2K^2 + 2H^2O$, together with free potash, the reaction probably taking place in two stages, as follows:

and

(Patzschko, *Zeitschr. f. Chem.* [2] v. 612.)

Epichlorhydrin unites directly with *hypochlorous acid*, when added to a cooled solution of that acid containing from 6 to 8 p. c. $ClOH$, and protected from light, forming the dichlorhydrin $(C^3H^4)^2(OH)^2Cl^2$, corresponding to the tetratomic alcohol, propylphycite, $(C^3H^4)^2(OH)^4$ (v. 894):

(Carius, *Ann. Ch. Pharm.* cxxiv. 71).

Epichlorhydrin unites directly with *acid chlorides* and *anhydrides*, forming chlorhydrins containing the corresponding acid radicles, the proportions in which the combination takes place varying according to the temperature and circumstances of the reaction. Thus with *acetyl chloride* at ordinary temperatures, after long standing, or more quickly at 100° , it forms *acetodichlorhydrin*, $C^3H^2\left\{ \begin{array}{l} OC^2H^3O \\ Cl^2 \end{array} \right. = C^3H^4OCl + C^3H^2OCl$. In like manner is formed *butyrodichlorhydrin*, $C^3H^2(OC^2H^4O)Cl^2$. With *benzoyl chloride* at 180° it forms *benzodichlorhydrin*, $C^3H^2(OC^2H^3O)Cl^2$.

Epichlorhydrin and acetic chloride heated for thirty hours to 100° in sealed tubes form (besides acetodichlorhydrin), *diglycerin-acetotetrachlorhydrin*, $\left(\begin{array}{c} C^3H^2 \\ C^3H^2 \end{array} \right)^2 \left\{ \begin{array}{l} OC^2H^3O \\ OC^2H^3O \\ Cl^2 \\ Cl^2 \end{array} \right.$ and *triglycerin-acetotetrachlorhydrin*, $\left(\begin{array}{c} C^3H^2 \\ C^3H^2 \\ C^3H^2 \end{array} \right)^3 \left\{ \begin{array}{l} OC^2H^3O \\ OC^2H^3O \\ OC^2H^3O \\ Cl^2 \end{array} \right.$, produced respectively by

the union of 2 or 3 mol. epichlorhydrin with 1 mol. acetyl chloride. Epichlorhydrin heated for four hours to 180° with acetic anhydride yields *diacetochlorhydrin*, $(C^3H^2)^2 \left\{ \begin{array}{l} OC^2H^3O \\ Cl \end{array} \right. = C^3H^4OCl + (C^2H^3O)^2O$; and when heated with acetic anhydride for 20 hours to 200° it forms (besides the last-mentioned compound) a body having the composition $\left(\begin{array}{c} C^3H^2 \\ C^3H^2 \end{array} \right)^2 \left\{ \begin{array}{l} OC^2H^3O \\ OC^2H^3O \\ Cl \end{array} \right. = C^3H^4OCl + 2(C^2H^3O)^2O$ (Truchot, *Bull. Soc. Chim.* [2] v. 447; vi. 481).

CHLORINE. The following methods of preparation on the large scale have been proposed as capable, under particular circumstances, of advantageously replacing the ordinary method of decomposing hydrochloric acid with manganese dioxide:

1. Binks and Macqueen (*Technologist*, 1862, p. 627) heat a mixture of 2 mol. magnesium chloride and 1 mol. manganese dioxide, whereby 2 mols. magnesia and 1 mol. manganous chloride are formed and 1 mol. chlorine is given off:

A similar method is described by Clemm (*Journal of Gas-lighting*, 1863, p. 385).

2. Schlösing (*Rép. Chim. pure*, iv. 378) proposes to heat a mixture of hydrochloric and nitric acids, suitably concentrated, with manganese dioxide, whereby chlorine, manganous nitrate, and water are produced. The manganous nitrate heated to between 150° and 195° yields manganese dioxide and nitrogen tetroxide; the latter under the influence of water and oxygen reproduces nitric acid, which, together with the manganese dioxide, may be used for the decomposition of a fresh quantity of hydrochloric acid. In one experiment, using 4 equivalents of nitric acid containing 50.5 p. c. N^2O_5 , and 3 eq. of hydrochloric acid containing 39.5 p. c. HCl , these acids being diluted with $\frac{1}{4}$ of their volume of water and heated to 122°, Schlösing obtained 91 p. c. of the chlorine contained in the hydrochloric acid, recovering at the same time 93.3 p. c. of the manganese and 91 p. c. of the nitric acid. This method seems therefore to promise well for application on the manufacturing scale.

3. Laurens (*Rép. Chim. app.* iv. 110) mixes cupric chloride, CuCl_2 , with half its weight of sand, dries the mixture, and heats it to 250°–300° in an earthen retort. The residue, consisting of cuprous chloride, Cu^2Cl^2 , is reconverted into cupric chloride by exposure to the air in contact with hydrochloric acid.

4. Mallet (*Bull. Soc. Chim.* [2] vii. 522) directs a current of air over cuprous chloride heated to 100°, whereby an oxychloride $\text{Cu}^2\text{Cl}^2\text{O}$ is formed, which is decomposed by hydrochloric acid into cuprous chloride, water, and free chlorine:

In a subsequent paper (*Compt. rend.* lxxi. 349) Mallet states that between 100° and 200°, and even at higher temperatures, cuprous chloride is almost instantly converted into oxychloride in a stream of moist air, and that the latter, if hydrochloric acid be slowly dropped upon it at the same time, may be converted into cupric chloride, which gives off chlorine when further heated.

5. H. Deacon finds that when a mixture of hydrochloric and oxygen gas is passed over cupric sulphate or other copper salt heated to 700°–750° F., the hydrochloric acid is completely decomposed, its hydrogen combining with the oxygen, and the chlorine being set free. The best way of conducting the process is to pass the mixed gases over pieces of brick soaked in solution of cupric sulphate and dried. Lead-salts, except the sulphate, act in the same manner, but require a higher temperature; also manganese salts, but less completely. The action of all these salts appears to be catalytic (*Chem. News*, September 30, 1870). This process is now carried out on the manufacturing scale. For other processes, see Richardson and Watts's *Chemical Technology*, pt. iii. p. 386.

In the ordinary method of preparing chlorine by oxidising hydrochloric acid with manganese dioxide, the waste still-liquors, consisting of solution of manganous chloride and ferric chloride, have always been an incumbrance to the manufacturer, and have hitherto been but little utilised. Methods of reconvertng the manganese contained in these liquids into dioxide have however been proposed, and to a certain extent carried out. Dunlop and Balmain neutralise the liquid with crude ammonium carbonate (from ammoniacal gas-liquor), which throws down ferric oxide, and then precipitate the decanted solution completely with a fresh proportion of ammonium carbonate, which throws down manganous carbonate. The latter dried and calcined in a muffle is converted into a mixture of dioxide and an intermediate oxide. Calcium carbonate may also be used instead of ammonium carbonate.—P. W. Hoffmann (*Dingl. pol. J.* clxxxi. 364) recommends the following process. The impure manganous solution neutralised with chalk or lime is precipitated with calcium sulphide (for which purpose the yellow liquid obtained by lixiviating soda-waste after exposure to the air may be used); and the precipitate of manganous sulphide and sulphur separated after 24 hours is dried at a gentle heat. It then contains about 57 p. c. sulphur, and forms a good material for burning in pyrites burners. Hoffmann obtained from it 41 p. c. sulphur in the form of sulphurous oxide, and a residue consisting of 75.4 p. c. manganous sulphate, 8.8 p. c. manganese dioxide, and 15.8 p. c. manganous oxide. The latter gently heated with sodium nitrate (2 mol. NaNO_3 to 1 mol. MnO or MnSO_4) yields, with evolution of nitrous vapours, a mixture of sodium sulphate and the higher oxides of manganese. The washed and dried product yields on the average a quantity of available oxygen equivalent to 55 p. c. MnO_2 . Any iron that may be present in the crude manganese solution may be separated before the precipitation, by addition of a small quantity of soda residue.

W. Weldon (*Laboratory*, i. 445) precipitates the crude manganese solution in the generating vessel with slaked lime, and passes a stream of air into the liquid in order to bring the manganese to a higher state of oxidation. The resulting solution of calcium chloride is decanted after subsidence. The oxide of manganese thus obtained is said to correspond to 55 p. c. dioxide. For a full description of this process, which is now largely employed, see *Chemical News*, Sept. 23, 1870.

Kuhlmann (*Compt. rend.* xlvii. 403) utilises the manganese residues for the preparation of barium chloride, by heating them, after evaporation to dryness, with a mixture of native barium sulphate and charcoal:

The barium chloride is extracted by lixiviation.

Lastly, these liquors, which contain free chlorine, as well as manganous, manganic, and ferric chlorides, are utilised by E. Kopp at Duenz for the recovery of sulphur from soda-waste. The sulphur which is contained in them as sulphide and hyposulphite of calcium, &c., is separated by the action of the manganese liquor, partly in the free state, partly as hydrogen sulphide: 10,000 litres of manganese liquor yield on the average 36 kilos. of pure sulphur. An additional quantity is recovered by burning the hydrogen sulphide with a limited supply of air (*Ann. Ch. Phys.* [1] vii. 5, 63; *Bull. Soc. Chim.* [2] iv. 335, 440; *Jahresb.* 1865, p. 779).

Physical Properties of Chlorine.—From the experiments of E. Ludwig (*Zeitschr. f. Chem.* [2] v. 172) it appears that chlorine does not conform to Gay-Lussac and Mariotte's laws till raised to temperatures considerably above its point of condensation. Its specific gravities at different temperatures were found to be as follows:

Temp.		Sp. gr.	Temp.		Sp. gr.
20°	.	2.4807	150°	.	2.4609
50	.	2.4783	200	.	2.4502
100	.	2.4685			

The density calculated from the atomic weight determined by Stas (35.457) is 2.45012.

Chlorine gas liquefies under a pressure of six atmospheres at 0°, and under eight and a half atmospheres at 12.5° (Niemann). Liquid chlorine boils under the ordinary atmospheric pressure at -33.6° (Regnault, *Jahresb.* 1863, p. 70). According to Loir and Drion (*Bull. Soc. Chim.* 22 juin 1850), chlorine does not liquefy under ordinary pressure at -34°; but at the temperature of -50°, obtained by blowing air over liquid sulphurous oxide, the liquefaction takes place.

CHLORIDES.

Hydrogen Chloride. Hydrochloric Acid. Among various methods suggested for the preparation of this acid on the manufacturing scale, may be mentioned the decomposition of calcium chloride by aqueous vapour at a high temperature. The calcium chloride obtained by treating the still-liquors of the chlorine manufacture with calcium carbonate (p. 435) may be utilised for this purpose (Pelouze, *J. Chim. ind.* [4] vi. 197; *Compt. rend.* lii. 1267). At present, however, by far the greater part of the hydrochloric acid used in the arts is obtained as a secondary product in the decomposition of common salt by sulphuric acid for the production of sodium sulphate in the soda manufacture, the vapour of hydrochloric acid thereby evolved being condensed by passing through towers filled with fragments of coke or stone, down which a continuous stream of water is made to flow (v. 610). For details, see Richardson and Watts's *Chemical Technology*, vol. i. pt. iii. pp. 204-215, and pt. v. pp. 235-244.

Hydrochloric acid free from arsenic may be readily obtained by distilling the crude commercial acid with fuming solution of stannous chloride, filtering after twenty-four hours from the precipitated metallic arsenic (p. 217), and distilling from a retort, the receiver being changed after the first tenth has passed over (Bettendorff, *Zeitschr. f. Chem.* [2] v. 493). P. W. Hofmann (*ibid.* 253) prepares pure hydrochloric acid by filling a bottle having a twice perforated stopper, to one-third of its volume, with the crude acid, and adding sulphuric acid of sp. gr. 1.848 through a stoppered funnel. Hydrochloric acid gas is then immediately evolved, and may be collected, after washing, in distilled water.

Gaseous hydrogen chloride is somewhat quickly decomposed by a glowing spiral of iron wire, or by the electric arc between iron points, white fumes of ferrous chloride being formed and the volume of the gas reduced to one-half; the decomposition is, however, not quite complete, even after the experiment has been continued for several hours. The induction-spark produces a scarcely perceptible diminution of volume even when continued for a long time (Buff and Hofmann, *Chem. Soc. Qu. J.* xii. 273).

When air mixed with vapour of hydrochloric acid is passed into a warm solution of potassium permanganate mixed with sulphuric acid, or through a mixture of manganese dioxide and sulphuric acid, the hydrochloric acid is oxidised to hypochlorous acid, HClO (Odling, *Pharm. J. Trans.* [2] i. 469).

Hydrochloric acid gas is absorbed by solid nitrogen tetroxide (iv. 76), forming a liquid which by repeated fractional distillation, may be separated into two liquid

compounds, one boiling at -5° , the other at $+5$. The former is Gay-Lussac's chloro-nitric acid, NOCl^{I} (iv. 116); the latter has the composition $\text{NO}^{\text{I}}\text{Cl}$ (R. Müller, *Ann. Ch. Pharm.* cxxii. 1).

Aqueous hydrochloric acid heated to 200° for sixteen hours with amorphous phosphorus gives off gas and yields a solution of phosphorous acid; apparently thus: $3\text{HCl} + \text{P}^{\text{I}} = \text{PH}^{\text{I}} + \text{PCl}^{\text{I}}$; and $\text{PCl}^{\text{I}} + 3\text{H}^{\text{I}}\text{O} = 3\text{HCl} + \text{PH}^{\text{I}}\text{O}^{\text{I}}$ (Oppenheim, *Bull. Soc. Chim.* [2] i. 163).

Anhydrous liquid hydrochloric acid is much less energetic in its chemical reactions than the aqueous acid: it does not attack magnesium, zinc, iron, lime, metallic sulphides, or certain carbonates. Potassium, sodium, tin, and lead are attacked, but without evolution of gas; aluminium dissolves in it quickly, with effervescence (Gore, *Phil. Mag.* [4] xxix. 541).

Metallic chlorides are decomposed by aqueous vapour at high temperatures, yielding metallic oxides and hydrochloric acid. With the chlorides of the heavy metals, especially those which are volatile, this decomposition takes place easily, also with the chlorides of aluminium and magnesium. The chlorides of calcium and strontium are decomposed more slowly, whereas those of barium, potassium, and sodium are not decomposed by aqueous vapour alone, but only in presence of silica; lithium chloride, on the other hand, is decomposed by aqueous vapour alone (Kuhnheim, *Jahresh.* 1861, p. 149).

The reactions of metallic chlorides with ammonia are described in the Dictionary under the chlorides of the respective metals: see also Deherain (*Compt. rend.* li. 734; *Rép. Chim. pure*, 1861, p. 215). On the action of nitric acid on metallic chlorides, see H. Wurtz (*Sill. Am. J.* [2] xxv. 371; *Jahresh.* 1858, p. 604); of phosphorus pentachloride (iv. 512).

TRANSFORMATION OF CHLORINATED INTO IODATED ORGANIC COMPOUNDS.

Ad. Lieben has made important experiments on this kind of transformation. Ethyl chloride, mixed in a sealed tube with three or four times its weight of strong hydriodic acid, sp. gr. 1.9, and heated for five hours to 130° , is almost wholly converted into ethyl iodide, according to the equation:

In like manner ethylated ethyl chloride (butyl chloride) and amyl chloride are converted by strong hydriodic acid into the corresponding iodides, without formation of secondary products. Ethylchlorinated ethyl oxide $\text{C}^{\text{I}}\text{H}^{\text{I}}(\text{C}^{\text{I}}\text{H}^{\text{I}}\text{Cl})\text{O}$ is converted, by an excess of strong hydriodic acid, chiefly into ethyl iodide and ethylated ethyl iodide (butyl iodide); but there are also some secondary products formed, viz. butyl chloride, alcohol, and a substance having a carbonaceous aspect, the quantity of these secondary products increasing as the hydriodic acid is less concentrated and present in smaller quantity. To determine whether the action of hydriodic acid is a simple double decomposition or a case of the action of masses, the converse reaction was tried by heating ethyl iodide with a considerable excess of hydrochloric acid in a sealed tube to 130° . A small quantity of ethyl-chloride was thereby obtained, together with hydriodic acid and free iodine, showing that the inverse of the first-described reaction does really take place; but the quantity of ethyl chloride which it yields is very small, even when the action is continued for fifty hours. The result of the two supplementary experiments, namely, the decomposition of ethyl chloride by hydrogen iodide, and of ethyl iodide by hydrogen chloride, may be represented, though somewhat crudely, in the following manner:

$$\begin{aligned} & (\text{Affinity of H for I}) + (\text{Affinity of C}^{\text{I}}\text{H}^{\text{I}} \text{ for Cl}) \\ & < (\text{Affinity of H for Cl}) + (\text{Affinity of C}^{\text{I}}\text{H}^{\text{I}} \text{ for I}). \end{aligned}$$

The decomposition of ethyl chloride and its homologues by the action of hydriodic acid, is analogous to the decomposition of silver iodide by the same reagent. As an example of the action of hydriodic acid on organic chlorides of other series, chloroform CHCl^{I} was introduced, together with eleven times its weight of hydriodic acid of sp. gr. 1.9, into a sealed tube, and heated for seven hours to 125° . The principal results of this reaction were hydrochloric acid, free iodine, and methylene iodide, $\text{CH}_2\text{I}^{\text{I}}$. Now, remembering the fact, demonstrated by Kekulé, that iodides submitted to the action of hydriodic acid undergo an inverse substitution, the reaction just described may be explained by supposing that the chloroform is in the first instance converted into iodoform, which is then converted into methylene iodide by the action of the hydriodic acid, thus:

and

In other cases, the action represented by the second equation goes so far as to remove all the iodine from the iodated product formed in the first instance, and convert it into the corresponding hydride. Such, indeed, is the case with compounds belonging to the aromatic series. Berthelot (*Bull. Soc. Chim.* [2] ix. 30) has shown that Jolin's chloride of carbon, or perchlorinated benzene, C^6Cl^{12} , is converted into benzene, C^6H^6 , when heated to 280° with a large excess of hydriodic acid; and Lieben finds that monochlorobenzene, $\text{C}^6\text{H}^5\text{Cl}$, heated to 235° , for fifteen hours, with from three to five times its weight of hydriodic acid, likewise yields benzene.

The action of hydriodic acid on organic chlorine-compounds appears, then, to exhibit two cases: 1. The chloride is easily converted into the corresponding iodide by double decomposition, whereas the transformation of the iodide into the corresponding hydride is difficult, and takes place only at high temperatures. In this case, if the experiment is well conducted, an iodide is obtained without a trace of hydride. Such is the case in the action of hydriodic acid on the chlorides of the series $\text{C}^n\text{H}^{2n+1}\text{Cl}$.—2. The chloride is attacked by hydriodic acid with difficulty, and only at a high temperature, whereas the conversion of the iodide into hydride takes place easily, and at a comparatively low temperature. In such cases, as with the chlorides of the aromatic series, the product of the reaction is a hydride without any trace of iodide. In some cases, as that of chloroform, intermediate products are obtained, only part of the iodine being removed by the inverse reaction (*Giornale di Scienze di Palermo*, v. 130).

CHLORINE, OXYGEN-ACIDS OF. These acids, with the exception of perchloric acid, are reduced by nitrous acid; chloric acid in the first instance to chlorous acid; chlorous and hypochlorous acids immediately to hydrochloric acid:

Perchloric acid is not altered by heating with nitrous acid, even in concentrated solution (Toussaint, *Ann. Ch. Pharm.* cxxvii. 114).

Hypochlorous Oxide, Acid, and Salts. Hypochlorous oxide gas is absorbed by sulphuric oxide, forming a dark red thickish liquid, which on cooling solidifies to a mass of slender needles consisting of $\text{ClO} \cdot 4\text{SO}^2$. This compound melts at about 55° , is instantly resolved by water into hypochlorous and sulphuric acids, acts upon iodine, with evolution of chlorine and formation of iodic acid, and as a powerful oxidising agent on sugar, alcohol, and other organic bodies. When quickly heated, it detonates. Hypochlorous oxide is likewise absorbed by liquid sulphurous oxide; but as soon as the containing vessel is removed from the freezing mixture, a rapid evolution of chlorine takes place, and a red viscid liquid is left, containing hypochlorous and sulphuric oxides in a proportion not yet determined (Schützenberger, *Compt. rend.* lii. 135).

Carius (*Ann. Ch. Pharm.* cxxvi. 129) prepares a 2 to 3 p. c. solution of hypochlorous acid containing mercuric oxychloride and excess of mercuric oxide, by agitating mercuric oxide, previously heated to 300° and suspended in a small quantity of water, with chlorine gas as free as possible from air (15 grms. HgO to 1 litre of chlorine) in a dark place, in bottles provided with glass stoppers and not holding more than a litre; with larger quantities, the preparation fails in consequence of the formation of mercuric chlorate. The aqueous acid thus obtained is mixed with a small quantity of precipitated mercuric oxide previously heated to 300° . Such a solution is better adapted for certain experiments on organic bodies than pure hypochlorous acid, which easily gives off chlorine even in very dilute solution.

Hypochlorous acid unites directly with many unsaturated organic compounds, e.g. with ethylene, forming ethylene oxychloride or glycolic chlorhydrin, $\text{C}^2\text{H}^4\left\{\begin{smallmatrix} \text{OH} \\ \text{Cl} \end{smallmatrix}\right.$; with amylenes in like manner, forming $\text{C}^3\text{H}^6\left\{\begin{smallmatrix} \text{OH} \\ \text{Cl} \end{smallmatrix}\right.$; with glyceric epichlorhydrin, $\text{C}^3\text{H}^5\text{OCl}$, forming the dichlorhydrin of propyl-phycite, $(\text{C}^3\text{H}^5)^2\left\{\begin{smallmatrix} (\text{OH})^2 \\ \text{Cl}^2 \end{smallmatrix}\right.$, &c. (Carius). With turpentine oil, it also forms a dichlorhydrin, $\text{C}^{10}\text{H}^{16}\left\{\begin{smallmatrix} (\text{OH})^2 \\ \text{Cl}^2 \end{smallmatrix}\right.$, which dissolves in the aqueous liquid and may be extracted therefrom by ether; and likewise a viscid liquid apparently containing di- and tri-chlorinated turpentine oil. With camphor it forms monochlorocamphor, $\text{C}^{10}\text{H}^{15}\text{ClO}$ (Wheeler, *Zeitschr. f. Chem.* [2] iv. 170).

Calcium Hypochlorite.—The constitution of bleaching powder has lately been examined by J. Kolb (*Ann. Ch. Phys.* [4] xii. 266; *Jahresb.* 1867, p. 192), who finds that the most concentrated preparation producible by saturating dry calcium hydrate with chlorine contains 38.5 p. c. bleaching chlorine, 45.8 lime, and 24.7 water, corresponding with the formula $3\text{CaH}^2\text{O}^2 + 4\text{Cl}$ or $\text{CaH}^2\text{O}^2 + 2(\text{CaO} \cdot \text{H}^2\text{O} \cdot \text{Cl}^2)$ or $\text{Ca}^2\text{H}^2\text{O}^4 \cdot \text{Cl}^4$. In this product, the water and the whole of the lime are essential constituents, which cannot be removed without complete decomposition of the compound. Commercial bleaching powder always contains a slight excess of water, as well as free lime, which gives it greater stability, an effect likewise produced by other inactive substances, such as carbonate and sulphate of calcium. Dry chloride of lime is decomposed by water, with separation of calcium-hydrate and formation of a solution containing chloride and hypochlorite of calcium:

This agrees with the result formerly obtained by Fresenius (iii. 237). Hence it appears that the solution of bleaching powder differs materially in constitution from the dry product, which does not appear to contain a ready-formed hypochlorite; in fact the dry compound and the solution differ materially in their modes of decomposition under the influence of free chlorine and of heat. (a) Dry bleaching powder is not altered at ordinary temperatures by an excess of chlorine; but the solution when thus treated becomes strongly acid; and on afterwards expelling the excess of chlorine from the solution by a current of carbon dioxide, the quantity of bleaching chlorine (that is in the form of hypochlorous acid) in the liquid is found to have doubled; thus:

This reaction may serve for the preparation of hypochlorous acid.

(b) Under the influence of heat (at 80° – 90° if it is poor, at 40° – 35° if it is rich) dry chloride of lime is converted into chlorate, becoming pasty in consequence of the separation of water: .

The dissolved chloride is much less alterable, and it is only at the boiling heat and when concentrated that it is converted into chlorate, with evolution of oxygen and chlorine. In direct sunshine, the dry chloride is decomposed in the same manner as when heated, though less quickly; the dissolved chloride is partly converted into chlorite.

Dry chloride of lime is completely decomposed by dry carbon dioxide, with evolution of chlorine, whereas from the aqueous solution, even the greatest excess of carbon dioxide precipitates only half the calcium as carbonate, and with separation of hypochlorous acid, which does not act upon the residual calcium chloride. The same behaviour is exhibited by solid chloride of lime in moist air, whence it appears that in the use of bleaching powder for disinfecting the air, the active agent is not free chlorine, but hypochlorous acid.

According to Scheurer-Kestner (*Bull. Soc. Chim.* [2] ix. 159), a slight elevation of temperature (to about 55°) consequent on the absorption of the chlorine is not disadvantageous in the production of bleaching powder; but an excess of chlorine actually diminishes the proportion of that element in the product available for bleaching, apparently in consequence of the formation of chlorite. When a rather thick layer of slaked lime is saturated with chlorine, the superficial portion is always inferior in bleaching power to the lower portions.

Solutions of bleaching powder or of pure calcium hypochlorite exposed to sunlight give off ordinary oxygen, yielding at the same time chlorite as well as chlorate of calcium.

For the analysis of bleaching powder Kolb (*loc. cit.*) estimates the bleaching chlorine volumetrically by Guy-Lussac's method with arsenious acid (i. 904), and the entire amount of chlorine present as chloride and hypochlorite, in another portion, by precipitation with silver nitrate, after previous warming with ammonia to convert the hypochlorite into chloride:

In perfectly normal chloride of lime, $\text{Ca}^2\text{H}^2\text{O}^4 \cdot \text{Cl}^4$, the two processes give the same result; but if part of the chlorine is in the form of chlorate, the second method will give an excess of chlorine. To determine the amount of chlorate present, a third portion is heated with ammonia, then strongly acidulated with sulphuric acid, metallic

sine is introduced, and the mixture is left for some hours, to convert the chlorate into chloride by the action of the nascent hydrogen. If after this treatment the amount of chlorine determined by precipitation with silver nitrate is greater than that given by the second method, the difference is to be estimated as chlorate.

Magnesium Hypochlorite.—According to Bolley a. Jokisch (*Bull. Soc. Chim.* [2] vii. 524), a solution of chloride of magnesia, obtained by precipitating a solution of chloride of lime with magnesium sulphate, or by passing chlorine into water in which magnesia is suspended, exerts a quicker and at the same time a milder bleaching action than the solution of chloride of lime. Bolley attributes this difference, partly to the more ready decomposibility of magnesium hypochlorite, partly to the fact that magnesia does not possess caustic properties.

Silver Hypochlorite. ClOAg .—When chlorine in excess is passed into water in which oxide or carbonate of silver is suspended, the silver is converted into chloride, and an aqueous solution of hypochlorous acid is formed without a trace of chlorate or chlorite. But if the silver oxide is in excess, and the liquid is repeatedly shaken during and after the passage of the chlorine, silver chloride and hypochlorous acid are formed indeed in the first instance as before, but the latter gradually reacts with the excess of silver oxide, forming silver hypochlorite, so that ultimately the liquid loses the smell of hypochlorous acid. The very soluble silver hypochlorite remains undecomposed, and the solution retains its transparency as long as the agitation with excess of silver oxide is kept up; but when left at rest, the hypochlorite is quickly resolved into chloride and chlorate. These reactions may be represented by the following equations:

Chlorous Oxide, Cl^2O^2 , and Acid, HClO^2 .—Schiel (*Ann. Ch. Pharm.* cix. 317) prepares chlorous oxide by means of a mixture of 3 pts. nitric acid of sp. gr. 1.3, 2 pts. potassium chlorate, 0.6 to 0.8 pt. cane-sugar (instead of the tartaric acid recommended by Millon), and 3 to 4 pts. water; it is not necessary to pulverise the chlorate or the sugar. The mixture is poured into a flask standing in a water-bath, in such quantity that the neck of the vessel above the bath may be half filled with the liquid when expanded by the heat. The mixture may be heated to 60° or even to 100° without danger of explosion, provided that the gas evolved from two separate flasks is not directed into the same absorption-vessel.

Brandau (*Ann. Ch. Pharm.* cli. 340) prepares chlorous oxide by reduction of chloric acid with sulphobenzolic acid, a method first practised by Carius (*Zeitschr. f. Chem.* [2] iv. 17). 10 pts. of pure benzene are dissolved in 100 pts. of hydrogen sulphate diluted with 100 pts. water, and when the mixture has cooled 12 pts. of pulverised potassium chlorate are added. The mixture is heated to 50° in a flask having a delivery tube fitted to its neck by grinding, and blown out here and there into small bulbs; and the gas, after passing through water contained in these bulbs, is conducted into a glass tube standing in a mixture of ice and salt. The condensed liquid deposits crystals of a hydrate of chlorous acid, and the supernatant liquid decanted immediately into a small cooled glass cylinder, forms nearly anhydrous chlorous oxide. The gaseous chlorous oxide prepared by the older methods is too much contaminated with free chlorine to admit of condensation by a mixture of ice and salt (i. 909).

Liquid chlorous oxide thus obtained is very mobile, has a deep red-brown colour, and when recently condensed, a sp. gr. of 1.330 to 1.387 at 0° , referred to water at 4° . A drop of the recently condensed liquid evaporates on a watchglass without residue even at temperatures below 0° . It boils a little above 0° , but the boiling point of the last portions rises to 8° ; the liquid also acquires a higher boiling point by keeping. A drop of this less volatile liquid leaves on evaporation a residue of chloric acid. Hence it appears probable that the condensed chlorous oxide contains a certain quantity of the compound Cl^2O^4 or chloroso-chloric anhydride $\begin{matrix} \text{ClO} \\ \text{ClO}_2 \end{matrix} \text{O}$. Liquid chlorous oxide explodes somewhat readily at a few degrees above 0° . The sp. gr. of gaseous chlorous oxide prepared from the recently condensed liquid was found to be 4.022 at 13° , and 4.070 at 9° , the formula Cl^2O^2 requiring 4.123 (Brandau).

When the gas is passed into water at 0° , the chlorous oxide separates in resinous drops or granules, which if agitated with the water after the passage of the gas has ceased, are converted into a yellow lamino-crystalline hydrate of somewhat variable

constitution: it may be heated to 10° without fusion, but volatilises slowly without residue even considerably below that temperature (Brandau).

According to Schiel, water dissolves about 10 times its weight of chlorous oxide, forming a deep golden-yellow liquid, which may be kept for some time without alteration, and possesses fourteen times the bleaching power of chlorine-water. According to Brandau, 100 grms. of water dissolve:

At 8.5°	and 752.9 mm. pressure,	4.7655 grm. chlorous oxide.
" 14°	" 756.3	" 5.0117 "
" 21°	" 764	" 5.4447 "
" 23°	" 760	" 5.6508 "

When the aqueous solution is heated to 50° , chloric and hydrochloric acids are abundantly formed, the latter acting further on the chlorous acid, with evolution of chlorine: hence it is not possible to obtain pure chloric oxide gas by heating the aqueous solution or by decomposing the solution of a chlorite. On mixing aqueous chlorous acid with potassium iodide and hydrochloric acid, iodine is separated according to the equation:

Most metals are without action on gaseous chlorous oxide; but *mercury* absorbs it at ordinary temperatures. Most of the non-metallic elements decompose it with detonation. It is decomposed very quickly by direct sunshine, more slowly by diffused daylight; the presence of a trace of moisture facilitates the decomposition (Schiel).

Gaseous chlorous oxide is absorbed by dry *glycerin*. After a certain time an explosion takes place, which, however, is not strong enough to break the vessel; afterwards the absorption becomes rapid, but not tumultuous. With *ethylic* and *amylic alcohols*, chlorous oxide produces ethylic acetate and amylic valerate; thus:

Urea dissolves in aqueous chlorous acid, evolving carbon dioxide, and probably nitrogen monoxide. If the proportion of chlorous acid present is such that the liquid remains sensibly greenish after warming, the solution evaporated at 100° leaves a crystalline compound containing $\text{Cl}^2\text{N}^2\text{ClO}$. The reaction is probably as follows:

With *uric acid*, chlorous acid forms chloraluric acid (i. 885), together with other products (Schiel, *Ann. Ch. Pharm.* cxii. 73).

Chlorates. For the quantitative estimation of chloric and of chlorous acid, Toussaint recommends a method founded on the reaction of these acids with nitrous acid already described (p. 438). The aqueous solution of the salt to be examined is mixed with a slight excess of lead nitrite acidulated with nitric acid, and the chlorine is then precipitated as silver chloride. Or it may be mixed with a titrated solution of lead nitrite, and the completion of the reaction indicated by addition of a quantity of silver nitrate more than sufficient for the complete precipitation of the chlorine. The solution of lead nitrite is prepared by treating the basic nitrite $\text{Pb}(\text{NO}^2)^2.3\text{PbO}.2\text{H}^2\text{O}$ suspended in water with carbonic acid, till it disappears completely and a yellow solution of the nitrite is formed which is no longer rendered turbid by carbonic acid. For the volumetric estimation, this solution is titrated with a normal solution of potassium chlorate, and diluted so that 1,000 c.c. of it shall correspond to 6.14 grms. potassium chlorate (*Ann. Ch. Pharm.* cxxxvii. 114; *Jahresb.* 1866, p. 787).

Stelling (*Zeitschr. anal. Chem.* vi. 32) estimates the chlorine in chlorates by heating the solution to boiling with ferrous sulphate and potash, and precipitating the chlorine from the filtered solution (after oxidation with nitric acid) with silver nitrate:

The same method serves for estimating the total amount of chlorine in hypochlorites.

Barium Chlorate, $(\text{ClO}^3)^2\text{Ba}$, is easily prepared as follows: Potassium chlorate is heated on the water-bath with commercial aluminium sulphate and sulphuric acid in rather more than equivalent quantities, whereby crystallised alum and chlorous acid are produced, the former separating on cooling:

The perfectly cooled mass is mixed with several times its volume of alcohol, filtered and washed with alcohol of 50 p. c; the alcoholic liquid is neutralised with barium hydrate; the greater part of the alcohol removed by evaporation; and the liquid

CHLOROFORM.

filtered. The residue contains barium sulphate and aluminium hydrate; the solution, pure barium chlorate (Brandau, *Ann. Ch. Pharm.* cli. 361).

Basic Cupric Chlorate is thrown down on adding cupric acid to a boiling solution of potassium chlorate, as a green precipitate which decomposes quickly in washing.

Potassium Chlorate. ClO^3K .—The solubility of this salt in alcohol of various strengths has been determined by Gerardin (*Ann. Ch. Phys.* [4] v. 129). The following table gives the weights w of the salt, dissolved at the temperatures t in 100 pts. by weight of spirit of the specific gravities on the first line:

Alcohol of sp. gr.	0.9904		0.9793		0.9573		0.9390		0.8967		0.8429	
	t	w	t	w	t	w	t	w	t	w	t	w
Potassium Chlorate	13°	4.9	14°	3.2	13°	1.9	14.5°	1.1	12°	0.46	25°	0.09
	25	7.5	26	5.4	20	2.7	28	2.2	31	1.28	34	0.12
	35	10.2	38	7.9	36	4.3	40	3.4	43	1.95	56	0.24
	44	13.6	51	12.2	55	7.9	50	4.3	58	3.10	64	0.32
	50	16.2	63	17.5	63	10.5	67	7.6				

Potassium chlorate affords a very delicate test for the presence of manganese in organic bodies. When any substance containing manganese is thrown into melting potassium chlorate, the saline mass on cooling exhibits a rose-red or peach-blossom colour. The commercial salt itself, however, is seldom quite free from traces of manganese. To test it, a small quantity is to be fused, and a piece of charcoal prepared from pure sugar thrown into it; if manganese is present, a reddish colour will be apparent on cooling (Böttger, *J. pr. Chem.* lxx. 433). On the catalytic decomposition of potassium chlorate by manganese dioxide, cupric oxide, &c., see Wiederhold (*Pogg. Ann.* cxvi. 171; *Jahresh.* 1862, p. 76); also Krebs (*Zeitschr. f. Chem.* [2] vi. 243).

Rubidium Chlorate (v. 131).

Silver Chlorate. ClO^3Ag .—To obtain this salt perfectly pure, Stas (*Jahresh.* 1867, p. 312) passes a slow stream of chlorine into water containing oxide or carbonate of silver in suspension; decants the liquid (in which the alkali always present in precipitated silver oxide has been converted into hypochlorite) after a while, repeating this operation till the evaporated residue no longer contains any perceptible quantity of alkali; washes the silver precipitate carefully; suspends it in water; again treats it during agitation with chlorine gas, till the greater part of the silver oxide has taken part in the reaction; then agitates the mixture till its odour is quite destroyed. The clear liquid is decanted, left at rest (best at 60°) till the hypochlorite of silver is converted into chlorate, and the solution of silver chlorate is evaporated over the water-bath. The salt then remains as a white powder, which does not alter either in dry or in moist air. Any hygroscopic tendency indicates the presence of perchlorate.

Strontium Chlorate.—The solution evaporated over sulphuric acid leaves the salt in small granular crystals containing $(\text{ClO}^3)^2\text{Sr} \cdot 5\text{H}^2\text{O}$ (Souclay, *Ann. Ch. Pharm.* cii. 381).

Thallium Chlorate (v. 754).

Yttrium Chlorate. $(\text{ClO}^3)^2\text{Y}$, is obtained in crystalline laminæ by decomposing barium chlorate with yttrium sulphate, separating the excess of barium with dilute sulphuric acid, and evaporating (Popp, *Jahresh.* 1864, p. 204).

CHLOROFORM. CHCl^3 . *Trichloromethane.* *Dichlorinated Methyl chloride.*—This compound boils at 60.16° (Regnault, *Jahresh.* 1863, p. 70). It is formed by the action of zinc and sulphuric or hydrochloric acid on carbon tetrachloride in a flask provided with an upright condensing tube, and is converted by the prolonged action of the same reducing agent into methylene chloride, CH_2Cl^2 (Geuther, *Ann. Ch. Pharm.* cvii. 212). It is also converted into methylene chloride and marsh gas by treating it in like manner with zinc and a little aqueous ammonia (Perkin, *Chem. News*, xviii. 106). Heated to 125° in sealed tubes for 7 hours with 11 pts. of strong hydriodic acid (sp. gr. 1.9), it yields methylene iodide, CH_2I^2 , together with hydrochloric acid and free iodine: probably iodoform is produced in the first instance, and then converted into methylene iodide; thus:

and

(Lieben, *Zeitschr. f. Chem.* [2] iv. 713). Chloroform-vapour passed over red-hot copper is partially converted into acetylene (Berthelot, *Compt. rend.* l. 805). The same compound is formed by the action of *potassium amalgam* on liquid chloroform (Kletzinsky, *Zeitschr. f. Chem.* [2] ii. 127). Heated with *alcohol* and *potash* in sealed tubes to 100° for a week, it yields a certain quantity of ethylene gas (Berthelot, *Compt. rend.* xlvii. 350). Heated with an alcoholic solution of *sodium ethylate*, it yields an ether, $\text{CH}(\text{OC}^2\text{H}^5)^2$, which may be regarded as chloroform having its chlorine replaced by an equivalent quantity of oxethyl, or as the triethyl ether of a triatomic alcohol, $(\text{CH}_3\text{CH}_2\text{O})_3$, homologous with glycerin:

(Williamson & Kay, *Chem. Soc. Qu. J.* vii. 224). According to Savitsch (*Bull. Soc. Chim.* avril 1860), this ether is more easily produced by the action of sodium on a cooled mixture of chloroform with excess of alcohol. According to Genther (*Jahresb.* 1862, p. 388), chloroform heated with alcoholic potash gives off carbon monoxide. According to C. Schacht (*Jahresb.* 1867, p. 539), pure chloroform is decomposed by exposure to light and air; but in the dark it remains unaltered in a vessel only half filled with it.

Chloroform is slowly attacked by *alkaline sulphites* at 160°–180°. On opening the sealed tube, carbon dioxide escapes, together with a gas which burns with a green-edged flame (methyl chloride?). The solution contains methyl-sulphuric acid and its chlorinated derivatives, together with methylene-disulphuric and methenyl-trisulphuric acids. The simplest reaction is that which gives rise to dichloromethylsulphuric acid:

In the formation of the other products, either an inverse substitution takes place, or the higher sulpho-acids at first produced are further decomposed, with separation of SO^2 (Strocker, *Zeitschr. f. Chem.* [2] iv. 214). Chloroform heated with an *alkaline cupric solution* throws down cuprous oxide:

The reaction is very delicate, one or two drops of chloroform shaken up with 100 c.c. of water immediately producing the red copper precipitate when warmed with the cupric solution. The same reaction is produced by all compounds which yield chloroform when treated with alkalis, such as chloral, trichloroacetic acid, the perchloric ethers, &c. (Baudrimont, *J. Pharm.* [4] ix. 410).

CHLOROGENINE. $\text{C}^{22}\text{H}^{20}\text{O}^4$.—A base obtained by O. Hesse (*Ann. Ch. Pharm. Suppl.* iv. 40; *Jahresb.* 1865, p. 458) from the bark of an Australian tree not named. The concentrated very bitter aqueous extract of the bark, acidulated with sulphuric acid and mixed with mercuric chloride, yields a precipitate consisting of the mercuriochloride of chlorogenine, while another base called *porphyrine* remains in solution. Chlorogenine separated from the mercury-compound, and precipitated by ammonia from the solution of its sulphate, is a coffee-coloured amorphous powder, easily soluble in acids when recently precipitated, soluble also in ammonia, fusel-oil, and especially in chloroform, with which it yields a solution red-brown by transmitted, green by reflected light. It is very bitter, and when swallowed produces uneasiness and tendency to vomit. It is the active and colouring principle of the bark, which contains 2½ p. c. of it. Its salts are amorphous.

CHLOROLITHINE. An altered felspar occurring in the old green porphyry of the Val Camonica. It is yellowish-green, of sp. gr. 2.92, and contains 47.3 p. c. SiO^2 , 22.2 Al^2O^3 , 9.8 Fe^2O^3 , 8.6 CaO , 0.7 MgO , 3.3 K^2O , 4.6 Na^2O , and 2.7 H^2O (Thermak, *Jahresb.* 1864, p. 869).

CHLOROPHYLL or *Leaf-green*. The nature of the green colouring matter of leaves is still but imperfectly known. According to Frémy (*Compt. rend.* l. 405; *Jahresb.* 1860, p. 633), it is composed of a blue substance, *phylloeyanin*, and a yellow substance, *phylloxanthin*, which may be separated by agitation with a mixture of ether and hydrochloric acid, the yellow substance dissolving in the ether, and the blue in the hydrochloric acid. *Phylloeyanin* is decolorised by alkalis, but regains its blue colour when treated with acids; hence also chlorophyll itself is turned yellow by alkalis and green again by acids. The blue and yellow constituents of chlorophyll may also be separated by boiling with *baryta-water*. On boiling the resulting precipitate with alcohol, uncombined *phylloxanthin* is dissolved, and there remains a *baryta-lake* from which the *phylloeyanin* may be separated by sulphuric acid and dissolved out by alcohol or ether. *Phylloxanthin* is a neutral substance insoluble in water, soluble in alcohol and ether, and crystallising therefrom in yellow

laminæ or red prisms resembling those of potassium dichromate. It possesses very great colouring power, and dissolves with blue colour in strong sulphuric acid, whereas the yellow colour of flowers is coloured red by that acid. *Phyllocyanin* is insoluble in water, dissolves with olive-green or bronze-red colour in alcohol and ether; its salts are brown and green; those of the alkali-metals are soluble in water. The solutions of phyllocyanin in sulphuric or hydrochloric acid are green, reddish-violet, or blue, according to the degree of concentration: the phyllocyanin is precipitated from them by water (Frémy, *Ann. Ch. Phys.* [4] vii. 78; *Jahresb.* 1865, p. 586). H. Ludwig also finds that chlorophyll may be separated into a blue and a yellow colouring matter (iv. 634). Stokes, on the other hand (*Proc. Roy. Soc.* xiii. 144), concludes, from the optical properties of the chlorophyll of land-plants, that it is a mixture of four different colouring matters, two green and two yellow. The solutions of the green (but not of the yellow) colouring matters exhibit strong red fluorescence; three of these substances are very easily decomposed by acids or salts, acid potassium oxalate for example. Frémy's phyllocyanin is, according to Stokes, merely a product of decomposition of the green bodies by acids; it dissolves in many acids with green or blue colour, and in neutral solutions exhibits very sharp absorption-bands. Phylloxanthin varies in its properties according to the manner of its preparation. When prepared by removing the green substances by means of aluminium hydrate and a little water (iv. 634), it is a yellow substance; but when obtained with hydrochloric acid and ether, it is a mixture of the same yellow body with the products of decomposition of one of the green substances by acids. Green marine plants (*Chlorospermeæ*) differ from land-plants only in the relative proportions of the colouring matters above mentioned; olive-coloured sea-plants (*Melanospermeæ*), on the other hand, contain (instead of one of the green and one of the yellow bodies above-mentioned) another green and another yellow body. Red sea-plants (*Rhodospereæ*) contain a red colouring matter in addition to the chlorophyll. Stokes further states that chlorophyll is easily distinguished from the green colouring matter of bile (biliverdin) by the fact that it exhibits very strong red fluorescence and very characteristic absorption-bands which are not exhibited by biliverdin.

According to Filhol (*Compt. rend.* lxi. 371; *Jahresb.* 1865, p. 586), chlorophyll dissolved in alcohol and cautiously treated is resolved into four substances: a brown azotised body insoluble in alcohol; a yellow non-azotised body soluble in alcohol; a blue substance formed only under the influence of an excess of hydrochloric acid; and a yellow body separated from the blue substance by ether. In a later investigation (*Compt. rend.* lvi. 1218; *Zeitschr. f. Chem.* [2] iv. 569) Filhol arrives at the following conclusions: 1. All methods of preparing chlorophyll by means of acids yield nothing but products of decomposition.—2. Organic acids, which act less strongly than mineral acids, destroy the green colour of chlorophyll solutions, and split up the chlorophyll into two substances, one of which separates in black flocks, while the other remains dissolved with fine yellow colour.—3. This yellow substance is further resolved by strong hydrochloric acid into a solid yellow body which separates, and a blue substance which remains dissolved. The latter turns yellow when the hydrochloric acid is neutralised.—4. The yellow body separated by hydrochloric acid, if boiled for a few minutes in an open vessel with a small quantity of potash, soda, or baryta, acquires the property of turning blue in contact with acids.—5. The green parts of plants always contain these two yellow substances in addition to chlorophyll; and the young shoots of various species of spindle-tree (*Eucalyptus*) contain only these two yellow bodies, without the smallest trace of chlorophyll.—6. The brown substance separated from an alcoholic solution of chlorophyll on addition of oxalic acid, is rich in nitrogen, and is identical with the substance described and analysed by Morot (i. 922).—7. The solutions of this brown substance have a high degree of dichroism, which is not exhibited by those of the yellow substance.—8. The solutions of the brown substance treated with caustic alkalis in contact with the air, assume an orange-red colour, which again disappears in consequence of absorption of oxygen, and gives place to a pure green colour.—9. Certain metallic oxides, especially zinc-oxide dissolved in potash, accelerate the oxidation of the brown substance. The splendid green colour thus produced may be precipitated on textile fabrics, but it is of no use as a dye, being quickly destroyed by light and air.—10. Leaves of plants which are coloured red, brown, or violet over their whole surface, are green in spring and yellow in autumn in the parts below the surface. This is easily shown by means of a mixture of sulphurous acid and ether, which dissolve the colouring matter of the superficial cells, and bring to light the green or yellow colour of those in the interior of the tissue.

Pfaundler (*Ann. Ch. Pharm.* cxv. 37; *Jahresb.* 1860, p. 531) adopts the opinion formerly expressed by Hlasiwetz (*Jahresb.* 1859, p. 527) that the colours of plants depend on the presence of quercitrin, æsculin, and other analogous principles, which

produce various shades of colour under the influence of alkalis, air, and salts of iron. In support of the assertion of Verdeil (*ibid.* 1851, p. 574) that the formation of leaf-green is essentially connected with the presence of iron, Pfaundler adduces a series of experiments by Salm-Horstmar (*Ueber die Nahrung der Pflanzen*, Braunschweig, 1856) showing that in plants grown in artificial soils not containing iron, the colour of the green parts was very pale, or even quite destroyed, whereas when iron was present the normal green colour was developed. Chlorophyll prepared by heating the juice of grasses to the boiling point, exhausting the coagulum with alcohol, distilling off the alcohol, dissolving the residual dark green jelly in hydrochloric acid, precipitating the filtered solution with hot water, and washing the green flocks thereby separated, forms when dry a dark blue powder, producing with alcohol and ether dark-coloured solutions, nearly blood-red by reflected light, yellow-green by transmitted light; with carbon bisulphide a brown-yellow, with hydrochloric acid a grass-green solution; soluble also in dilute potash, but separated by strong potash-ley in resinous lumps; not resolvable like quercetin, or reducible like indigo. It was free from nitrogen, gave 0.9 p. c. ash, in which iron could be distinctly detected, and gave by analysis 60 p. c. carbon and 6.4 hydrogen, calculated for the substance free from ash. Pfaundler further remarks that there may be several kinds of chlorophyll, and that the assumption of a single chlorophyll does not rest on very good grounds.

According to Phipson (*Compt. rend.* xlvii. 912), green leaves immersed in strong sulphuric acid assume a yellow autumnal colour; after prolonged contact, the yellow changes to emerald-green, and afterwards umic substances are formed. Yellow autumnal leaves immersed for a few seconds in sulphuric acid become emerald-green and afterwards brown.

According to Sachs (*Jahresb.* 1859, p. 561), vegetable plasma contains a colourless substance, *leucophyll*, possessing the constitution of leaf-green, and awaiting only a final chemical impulse to convert it into green chlorophyll. This impulse is given, not so much by light as by oxygen, in the active state, or rendered active by the influence of light. The still colourless cells of plants, in the state in which they would rapidly turn green on exposure to light, are instantly coloured green if immersed in sulphuric acid, whereas cells not in a state to be turned green by light are not thus altered by sulphuric acid.

According to Jodin (*Compt. rend.* lix. 857), solutions of chlorophyll, even in presence of alkali, retain their colour in the dark, whereas in sunlight they are decolorised in a few days, absorbing at the same time a quantity of oxygen equal to 0.72 of the weight of the colouring matter, and giving off carbonic acid. According to H. Vohl (*J. pr. Chem.* xcv. 219), the chloroform of horse-chestnut leaves is not decomposed by putrefaction of the leaves going on for several years.

CHLOROPICRIN, $(\text{CNO}^2\text{Cl})^2$. *Trichloronitromethane*. *Nitrochloroform*.—Formed by distilling chloral or metachloral with strong nitric acid, or with a mixture of nitric and sulphuric acids; also by distilling a mixture of methyl alcohol and sulphuric acid over a mixture of potassium nitrate and sodium chloride. These two modes of formation show that chloropicrin belongs to the methyl group (Kekulé, *Ann. Ch. Pharm.* cvi. 144). According to S. Priestley (*Chem. News*, ix. 3), chloropicrin may be prepared by adding nitric acid by small portions to a cooled pasty mixture of methyl alcohol and chloride of lime, and subjecting the whole to distillation. The mixture of chloropicrin, chloroform, and methyl alcohol which condenses in the receiver may be separated by fractional distillation, the chloropicrin, which is the least volatile, remaining behind.

For preparing chloropicrin in large quantity, Hofmann (*Ann. Ch. Pharm.* cxxxix. 107) mixes 45 kilo. of recently prepared chloride of lime, stirred up to a thick paste with cold water, in a capacious earthenware still surrounded by cold water, with a saturated solution of 45 kilo. of picric acid heated to 30°. A violent reaction takes place after a few minutes, and the greater part of the chloropicrin produced is driven over into the receiver, which should be connected by a conducting tube with the chimney to prevent the escape of the pungent vapours of chloropicrin. As soon as the first action is over, the water-bath is heated to boiling, to distil over the remainder of the chloropicrin. The chloropicrin thus obtained amounts to 114 p. c. of the picric acid used.

Chloropicrin boils at 112° (Hofmann).

Reactions.—1. Chloropicrin treated with iron filings and acetic acid, or with ferrous sulphate and excess of potash, is converted into methylamine:

(Geisse, *Ann. Ch. Pharm.* cix. 282; *Jahresb.* 1859, p. 437). See also the same paper for the action of alkaline sulphites on chloropicrin.

2. Heated to 100° for 24 hours with fuming *hydriodic acid*, chloropierin is decomposed in the manner represented by the equation :

(E. J. Mills, *Chem. Soc. J.* [2] ii. 153).

3. By heating with *sodium ethylate* (sodium and absolute alcohol), it is converted into ethylic orthocarbonate (Bassett, *Chem. Soc. J.* [2] iv. 238) :

4. Chloropierin heated with 9 mol. of fused *potassium acetate* and *alcohol* to 100°, is easily decomposed, yielding ethyl acetate, together with chloride, nitrite, carbonate, and acid acetate of potassium (Bassett, *Chem. Soc. J.* [2] ii. 31) :

5. Chloropierin heated with *potassium cyanide*, alcohol, and water, is converted into dicyano-nitro-chloromethane, $\text{C}(\text{NO}^2)\text{Cl}(\text{CN})^2$. This compound is soluble in water, alcohol, ether, and chloroform, very easily decomposable, and has not been obtained in the separate state, but only in combination with water, and with metallic oxides and salts. Lead acetate added to its aqueous solution forms a precipitate containing $\text{C}(\text{NO}^2)\text{Cl}(\text{CN})^2 \cdot 3\text{PbO}$; with silver nitrate a precipitate is formed consisting of $3\text{C}(\text{NO}^2)\text{Cl}(\text{CN})^2 \cdot 4\text{NO}^2\text{Ag} \cdot 8\text{H}^2\text{O}$ (Bassett, *Chem. Soc. J.* [2] iv. 352). For the details of the preparation, which requires particular precautions, we must refer to the original paper.

6. Chloropierin heated with *ammonia* in alcoholic solution is converted into guanidino-hydrochloride (Hofmann, *Chem. Soc. J.* [2] iv. 249; *Zeitschr. f. Chem.* [2] iv. 721) :

CHLOROSULPHOFORM. $\text{C}^2\text{Cl}^2\text{S}^2$.—W. N. Hartley (*Chem. Soc. J.* [2] v. 23) obtained this compound by treating a mixture of monochloride, dichloride, and trichloride of carbon with an alcoholic solution of potassium sulphhydrate. On precipitating the product with water, and distilling the washed product, the chlorosulphoform remained in the residue, together with sulphur, and was purified by repeated crystallisation from alcohol. It crystallises in needles, has an unpleasant odour, melts at about 250°, but begins to sublime at a lower temperature. It is insoluble in water, slightly soluble in alcohol and ether, more freely in carbon bisulphide, chloroform, the liquid chlorides of carbon, and oil of turpentine. When heated for several hours in sealed tubes with nitric acid, it yields sulphuric acid and a sulphuretted compound crystallising in white scales. It is produced in the above reaction entirely from the carbon monochloride, by direct addition of sulphur at the moment that the latter is set free (Hartley). As the so-called carbon monochloride, C^2Cl^2 , has been shown to be identical with hexachlorobenzene, C^6Cl^6 (p. 267), the formation of chlorosulphoform probably takes place in the manner shown by the equation $\text{C}^6\text{Cl}^6 + 9\text{S} = 3\text{C}^2\text{Cl}^2\text{S}^2$.

CHOLESTERIN. $\text{C}^{26}\text{H}^{44}\text{O}$.—This substance occurs, together with protagon (iv. 737), as an essential constituent of the nervous tissue, of the yolk of egg, of the seminal fluid, and of the red and colourless corpuscles of the blood (Hoppe-Seyler, *Med.-chem. Unters.* i. 140; *Jahresb.* 1866, p. 744). It has been found by Tolmatscheff (*Med.-chem. Unters.* i. 272) in human milk, to the amount of 0.0318 p. c.; by Marcet (*Ann. Ch. Phys.* [3] lix. 91) in the spleen, and abundantly in the excrements of the crocodile; by Hoppe-Seyler (*Jahresb.* 1863, p. 654) in guano; and by Piccolo a. Lieben (*Zeitschr. f. Chem.* iv. 646) in the *corpus luteum* of the cow. It is also found in vegetable substances, viz. in peas, and in certain fixed oils (Benneke, *Ann. Ch. Pharm.* cxxii. 249; Lindenmeyer, *J. pr. Chem.* xc. 321); in the fat of wheat-gluten and of rye (Ritthausen, *Jahresb.* 1863, p. 544; *Zeitschr. f. Chem.* [2] iv. 314); in that of barley (Leutner, *ibid.* 664); in maize-seeds; in the young shoots (eyes) of roses, and in wine-yeast (Hoppe-Seyler, *Jahresb.* 1866, pp. 698, 744).

To prepare cholesterolin from peas, the bruised seeds (5 lb.) are digested with an equal weight of alcohol of 94 p. c. at 36°–40°, and the extract, after standing for 24 hours, is filtered and evaporated. The brown-yellow glutinous residue (which exhibits with sugar-water the forms of myelin (iii. 1068) is dissolved in about 400 c.c. of water, and the solution is boiled with litharge (1 lb.) till the supernatant liquid becomes clear. The separated lead precipitate is then exhausted, first with cold and then with boiling alcohol, and the alcoholic solution is freed from lead by hydrogen sulphide. The filtrate, left to cool yields crystals of cholesterolin, a further quantity of

which is deposited as the alcohol evaporates. The portion still remaining in solution may be obtained by evaporating off the whole of the alcohol and boiling the aqueous solution of the residue with baryta-water; boiling the flocculent barium-compound which separates, with alcohol; and leaving the filtrate, freed from barium by sulphuric acid, to crystallise: 5 lb. of peas thus treated yield 1.5 grm. of cholesterol, identical in every respect with that obtained from animal substances (Benneke). Lindenmeyer (*J. pr. Chem.* xc. 321) exhausts the bruised peas repeatedly with alcohol containing ether; agitates the aqueous solution of the extract several times with ether; boils the residue left on evaporating the ether with alcoholic potash for an hour, ultimately evaporating to dryness; and repeatedly agitates the aqueous solution of the residue with ether. On evaporating the ether, the cholesterol remains, and may be freed from a yellow colouring matter by washing with cold alcohol. Lindenmeyer found that the dry substance of unripe peas, amounting to 36.6 to 38 p. c., contains from 0.024 to 0.026 p. c. cholesterol, whereas the dry substance of ripe peas, amounting to 84 to 89 p. c., contains from 0.051 to 0.059 p. c. cholesterol—consequently that the amount of cholesterol in peas increases considerably as they ripen.

The following process is given by Hoppe-Seyler for the simultaneous detection and estimation of cholesterol, protagon, and saponifiable fats in animal and vegetable substances: The substance is repeatedly exhausted with its own volume or with several volumes of ether; the clear decanted or filtered extracts, quite separated from the aqueous solution, are distilled over the water-bath; and the dried residue is weighed. Part or the whole of this residue is then boiled for several hours with an excess of clear concentrated alcoholic potash, the alcohol finally evaporated, the residue dissolved in water, and the solution repeatedly agitated with ether. This ethereal extract usually contains the cholesterol almost pure. In the contrary case, the residue, while still warm, must be shaken up with dilute potash, and after cooling again treated with ether, which then does not take up any of the soaps produced by the action of the alkali, unless the quantity of water or alkali present is deficient. The soap-solution freed from the cholesterol is strongly supersaturated with hydrochloric acid and repeatedly agitated with ether; the united ethereal extracts are distilled off; and the dried residue is weighed. The acid aqueous solution (freed from the fatty acids by ether) is evaporated to dryness in a platinum dish; the residue is fused with soda and nitro; and the aqueous solution of the fused mass, after acidulation with nitric acid, is precipitated by a solution of ammonium molybdate in nitric acid. In this precipitate, collected after standing for 24 hours, the phosphorus is estimated by solution in ammonia and precipitation with ammoniacal magnesia-solution, and from this the amount of protagon, $C^{12}H^{22}N^{10}O^{12}$, is calculated. The quantity of the saponifiable fats is found by deducting the weights of the protagon and cholesterol from the total weight of the original ethereal extract. Respecting the quantities of cholesterol thus found in the serum and corpuscles of blood, see p. 351.

Cholesterol rotates a ray of polarised light to the left, its specific rotatory power being -27.5° for red, and -34.5° for yellow light (Hoppe-Seyler, *Jahresb.* 1862, p. 567). Lindenmeyer (*ibid.* 1863, p. 542) has made the following determinations of the levogyrate power of cholesterol for the different fixed lines in the spectrum:

B	C	D	E	b	F	G
20.63°	25.51°	31.59°	39.91°	41.92°	48.65°	62.37°.

The rotatory power of cholesterol affords the means of quickly estimating its proportion in oil of almonds and cod-liver oil, and of distinguishing these oils from others which do not possess the levorotatory power (e.g. poppy, sesame, olive,* rape, &c.). For the estimation of cholesterol in peas, however, the chemical method above given must be resorted to, inasmuch as the peas likewise contain a dextrogyrate substance not yet isolated; 1 pt. of cholesterol dissolves in 6.85 pts. of *chloroform* at 20° (Lindenmeyer).

When a small quantity of cholesterol is evaporated at a gentle heat with a drop of nitric acid, a yellow spot is left, which turns red when touched with a drop of ammonia; and the red colour thus produced is not essentially altered by subsequent addition of a fixed alkali—a character which distinguishes this reaction from the similar one produced with uric acid. When cholesterol is treated with a mixture of 2 or 3 vol. strong hydrochloric or sulphuric acid and 1 vol. of moderately dilute solution of ferric chloride, and the whole is evaporated to dryness, a reddish-violet residue is obtained, changing to blue-violet at a somewhat higher, and to dull grey at a still higher temperature. This reaction, which is likewise produced with auric or

* According to Benneke, olive oil contains cholesterol.

platinic chloride, or with potassium dichromate and hydrochloric acid, is not exhibited by the colouring matter or any other constituent of the bile (H. Schiff, *Ann. Ch. Pharm.* cxv. 313).

Cholesterin Dibromide, $C^{26}H^{44}OBr_2$, is formed by the action of bromine on cholesterin, both dissolved in carbon bisulphide, and separates on leaving the solution to evaporate. After recrystallisation from hot ether-alcohol, it forms white needle-shaped crystals, insoluble in water, slightly soluble in alcohol, easily in ether. It melts and chars when heated, and is reconverted into cholesterin by sodium-amalgam. The same compound appears to be formed by the action of bromine on cholesterin in ethereal solution (Wislicenus a. Moldenhauer, *Ann. Ch. Pharm.* cxlvi. 175).

CHOLESTERIC ETHERS.—**Sodium cholesterate**, $C^{26}H^{42}NaO$, is formed, with evolution of hydrogen, when sodium is added to a saturated solution of cholesterin in petroleum (previously purified with sodium). The solid compound which separates melts at 150° , decomposes at 180° , and crystallises from petroleum, or from a strongly cooled solution in anhydrous chloroform, in silky needles which are slowly decomposed by water, more quickly by alcohol. When heated for some days with 1 mol. *ethyl iodide* to 100° , it yields, together with sodium iodide, a body crystallising from ether in tables melting at 141° , and apparently consisting, not of ethyl cholesterate or cholesteryl ethylate, but of cholesteryl oxide. By treating sodium cholesterate with cholesteryl chloride (*infra*) at 100° , another body is produced, insoluble in alcohol, and crystallising from ether like cholesterin, but melting at 71° . **Cholesteric acetate**, $C^{26}H^{42}(C^2H^3O)O$, produced by the action of acetyl chloride on sodium cholesterate, crystallises from ether (after the excess of cholesterin has been removed by boiling alcohol) in moss-like crystals, which are decomposed by boiling alcoholic potash, yielding potassium acetate.

Cholesteryl Chloride, $C^{26}H^{42}Cl$, is produced by the action of phosphorus pentachloride on cholesterin, and purified by pressure, boiling with water, and crystallisation from ether and alcohol. It dissolves readily in ether, sparingly in alcohol, melts at 100° , and exhibits just before solidification a bright violet colour by reflected, yellowish-green by transmitted light. It is not decomposed by aqueous potash, but with boiling alcoholic potash it yields potassium chloride and cholesterin (Planer, *Ann. Ch. Pharm.* cxviii. 25; Lindemeyer, *loc. cit.*).

CHOLINE or **NEURINE**. $C^5H^{12}NO^2 = \frac{C^5H^9OH}{(CH^3)^3}N.OH$ (Strecker, *Compt. rend.* lii. 270; *Ann. Ch. Pharm.* cxxxiii. 353; *Zeitschr. f. Chem.* [2] iv. 218, 438. Liebreich, *Ann. Ch. Pharm.* cxxxiv. 29. Baeyer, *ibid.* xli. 306. Dybkowsky, *J. pr. Chem.* c. 163; *Jahresb.* 1867, p. 493. Wurtz, *Ann. Ch. Pharm. Suppl.* vi. 116; *Compt. rend.* lxx. 1015; lxxviii. 1434; *Zeitschr. f. Chem.* [2] iv. 169; v. 481).—Strecker in 1861 obtained from pigs' bile, and afterwards from ox-bile, a base which he called choline. Liebreich in 1865, by decomposing protagon, the chief constituent of nervous tissue (iv. 737), with alkalis, obtained a similar base, which he termed neurine; and these two products were afterwards shown by Baeyer, Dybkowsky, and Strecker to be identical. The rational formula of this base was discovered by Baeyer, and confirmed by Wurtz, who has produced it synthetically.

Preparation: 1. *From Bile.*—The alcoholic solution of inspissated bile is precipitated by ether; the portion remaining dissolved is boiled (after the ether and alcohol have been driven off) for twelve to twenty-four hours with baryta-water; the excess of baryta is removed by carbonic acid; the strongly concentrated filtrate is mixed with absolute alcohol; and the alcoholic solution separated from the resulting precipitate is neutralised with hydrochloric acid. Taurine then separates out, and the liquid filtered therefrom gives with platinic chloride a yellow amorphous precipitate of choline platinochloride, which crystallises from water (together with more sparingly soluble octahedral crystals) in orange-red six-sided tables containing $(C^5H^{11}NOCl)^2.PtCl^4$ (Dybkowsky).

2. *From Brain.*—Fresh ox-brain is rubbed through a fine sieve; the pulp is exhausted with ether; the residue of the ethereal solution is boiled with baryta-water; and the preparation is completed as above. The crystals of the neurine platinochloride thus obtained have the same form and composition as those of the choline salt (Dybkowsky). According to Claus a. Keesé (*Zeitschr. f. Chem.* [2] iv. 46), choline appears to be likewise identical [or isomeric?] with sincaline (v. 311).

3. *By Synthesis.*—By heating trimethylamine (5 grms.) with glycolic chlorhydrin, (10 grms.) for 24 hours to 100° in a sealed tube, which then becomes filled with deliquescent prismatic crystals of trimethyl-oxethylammonium chloride, identical in composition with neurine chloride:

This salt dissolves abundantly in boiling alcohol, and separates partially on cooling from a very concentrated solution. The solution gives with auric chloride a yellow crystalline precipitate of the *aurichloride* $(\text{CH}^3)_2(\text{C}^2\text{H}^4\text{OH})\text{NCl} \cdot \text{AuCl}_3$, which exhibits under the microscope the same form (rhombic laminae) as the gold salt prepared with neurine from brain. The hydrate $(\text{CH}^3)_2(\text{C}^2\text{H}^4\text{OH})\text{NOH}$, obtained by treating the chloride with moist silver oxide, is a syrupy liquid which decomposes when heated, giving off an ammoniacal odour (Wurtz).

From these results it appears that choline or neurine has the constitution of trimethyl-oxethyl-ammonium hydrate. The same conclusion had previously been arrived at by Baeyer, who found that a concentrated solution of neurine hydrochloride, heated with strong hydriodic acid and a little amorphous phosphorus, yields an iodide, $(\text{C}^2\text{H}^5)_3\text{NI}^2$ or $(\text{C}^2\text{H}^5)_3\text{N} \cdot \text{HI}$, perfectly analogous in its reactions to the bromide $(\text{C}^2\text{H}^5)_3\text{NBr}^2$, which Hofmann obtained by treating trimethylamine with ethylene bromide, and producible from the same bromide by treatment with silver oxide and then with hydriodic acid. A solution of the bromide in hot hydriodic acid yields on cooling, crystals of the bromiodide $(\text{C}^2\text{H}^5)_3\text{NBrI}$; the latter treated with silver chloride yields the corresponding bromochloride; and this compound treated with platinum chloride yields the double salt $(\text{C}^2\text{H}^5)_3\text{NBrCl} \cdot 2\text{PtCl}_4$, identical with that obtained by Hofmann (iii. 1001).

Amyl-glycolic chlorhydrin heated with excess of ammonia yields the *chloride of hydroxamyl-ammonium*, isomeric with choline chloride:

and ethyl-glycolic chlorhydrin heated with triethylamine yields the *chloride of hydroxethyl-triethylammonium*, homologous with choline chloride:

Wurtz (*Compt. rend.* lxxviii. 1434; *Zeitschr. f. Chem.* [2] v. 481).

CHOLOIDIC ACID. According to Hoppe-Seyler (*J. pr. Chem.* lxxxix. 83), the substance thus designated, which is produced by boiling bile with acids, is nothing but a mixture of cholic acid, dyslysin, and cholonic acid, perhaps also containing undecomposed glycocholic and taurocholic acids.

CHONDRIIN. Optical rotatory power, in weak alkaline solution = -213.5° ; after addition of an equal volume of soda-ley = -552° ; and after addition of an equal volume of water = -281° (J. de Bary, *Med.-chem. Untera.* i. 71; *Jahresh.* 1866. p. 715). Fischer a. Bödeker (*Ann. Ch. Pharm.* cxvii. 1) found that pure rib-cartilage boiled with strong hydrochloric acid, yields a sugar, which reduces cupric oxide in alkaline solution, and is capable of fermenting with yeast; hence they inferred that chondrin contains a glucoside. De Bary, who designates the sugar thus obtained as chondroglucose, finds that it differs from grape-sugar in possessing levogyrate power (not varying with the temperature, and, according to one experiment, = -45.5° for yellow light); further, in being uncrystallisable or very difficult to crystallise; also in being difficultly fermentable, and splitting up thereby, like melitose, into a fermentable and a nonfermentable (levogyrate) sugar.

Otto (*Zeitschr. f. Chem.* [2] iv. 628) has confirmed the observation formerly made by Hoppe-Seyler (*J. pr. Chem.* lvi. 129) that chondrin yields considerable quantities of leucine when boiled with sulphuric acid, but does not yield glycocine by boiling either with sulphuric acid or with baryta-water.

CHROMIUM. Deville obtains this metal in the fused state by igniting a mixture of chromic oxide and sugar charcoal in a lime crucible intensely heated in a portable blast-furnace. The metal thus prepared is shining, has a steel-grey colour, a specific gravity of 6, and is hard enough to scratch glass. J. Loughlin (*Zeitschr. f. Chem.* [2] v. 113) prepares metallic chromium by exposing a mixture of chromic oxide and potassium cyanide to a white heat in a covered porcelain crucible. A solution of chromic chloride or other chromic salt treated with sodium-amalgam, yields an amalgam of chromium, which when heated in a stream of hydrogen, leaves metallic chromium in the form of a pulverulent sponge (Vincent, *Phil. Mag.* [4] xxiv. 328; Roussin, *Bull. Soc. Chim.* [2] vi. 23).

Detection and Estimation.—Chromic salts when very much diluted are somewhat difficult to distinguish from salts of nickel. In either case ammonium sulphhydrate produces no precipitate, but merely colours the liquid more or less dark brown. But on adding a few drops of hydrochloric acid to a small quantity of the solution in a porcelain capsule, and leaving the liquid to evaporate, the residue, if nickel

is present, turns first blue, then green, and finally yellow; but in the case of chromium, the sides of the capsule exhibit successively a blue, a violet, and a green colour, and finally a residue is left of a fine carmine-red colour, which is quickly decomposed by water, but is insoluble in cold alcohol and ether, and permanent; when strongly heated, it gives off white vapours and leaves a green residue; with lime it gives off ammonia. This reaction probably depends on the formation of a roseo-chromic salt analogous to the roseo-cobaltic salts (C. Hüsson, *Zeitschr. f. Chem.* [2] iv. 569).

Tincture of guaiacum is an extremely delicate test for chromic acid. Of a solution containing only 0.00001 grm. of chromic anhydride in a cubic centimetre, $\frac{1}{10}$ c.c. added to a few drops of guaiacum tincture (1 pt. of the resin to about 100 pts. of 60 p. c. alcohol) in a porcelain capsule, immediately produces a deep blue colour. This reaction serves to demonstrate the solubility of lead chromate and barium chromate in distilled water (Schiff, *Ann. Ch. Pharm.* cxx. 208; *Jahresb.* 1861, p. 253).

Chromic oxide is easily and quickly oxidised to chromic acid by a mixture of nitric acid and potassium chlorate. Even chrome iron ore and strongly ignited chromic oxide are oxidised in this manner more quickly than by the ordinary fusion process. The chromium is then easily estimated in the form of barium chromate (A. H. Pearson, *Zeitschr. f. Chem.* [2] v. 661).

For other methods of analysing chrome-ores see Genth, *Chem. News*, vi. 30; O'Neill, *ibid.* v. 199.

W. Gibbs (*Soll. Am. J.* [2] xxxix. 58) describes a method of separating chromic oxide from the oxides of iron, manganese, cobalt, nickel, and zinc, also from alumina and magnesia, founded on the conversion of chromic oxide into chromic acid by the action of chlorine, bromine, or dioxide of lead in alkaline solution. When chlorine or bromine is used, the solution is ultimately neutralised with acetic acid; and when sulphuric acid is absent, the chromic acid is precipitated by barium acetate. It is better however to pass chlorine into the *hot* neutral chromic solution mixed with sodium acetate, and neutralise the liberated acid from time to time with sodium carbonate. Alumina and ferric oxide are then separated at the boiling heat, while the other oxides remain dissolved, together with the chromic acid, which may be separated as lead or barium salt.

For the volumetric estimation of chromium in chromates, C. Rube (*J. pr. Chem.* xcv. 53) makes use of the conversion of potassium ferrocyanide into ferricyanide by the action of chromic acid:

The aqueous solution of the chromate (0.3 to 0.7 grm.), acidulated with hydrochloric acid and diluted to 150 c.c., is mixed with a solution of the ferrocyanide containing 40 grms. in a litre, till the whole of the chromic acid is reduced and a slight excess of ferrocyanide is present, which may be known by the production of a greenish instead of a brown colour on treating a drop of the liquid on a porcelain plate with strongly acid ferric chloride. From the number of burette-divisions of the solution used, so many are to be deducted as are required to produce the reaction on ferric chloride in an equal quantity of liquid.

In estimating chromic acid by the iodometric method, Zulkowsky (*Zeitschr. f. Chem.* [2] iv. 661), instead of distilling the chromate with hydrochloric acid, and determining the quantity of chlorine evolved by means of iodine, makes use of the reduction of chromic acid by hydriodic acid in aqueous solution, according to the equation:

The chromate to be analysed is dissolved in water, mixed with potassium iodide, hydrochloric acid, and starch-paste, and the iodine separated by the reaction is titrated with a $\frac{1}{10}$ normal solution of sodium hyposulphite.

Atomic or Equivalent Value.—Chromium is a hexad element, being sexvalent in the fluoride, CrF^{VI} (formerly regarded, according to the small atomic weight of chromium, 26, as a trifluoride); in the trioxide, CrO^{III} ; in the chromates, e.g. $\text{Cr}^{\text{VI}}\{\text{O}^{\text{II}}\}_4$, $\text{Mg}^{\text{II}}\{\text{O}^{\text{II}}\}_4$; in chromyl dichloride, $\text{CrO}^{\text{III}}\text{Cl}^{\text{I}}_2$, &c. In the chromic salts it is quadrivalent, these compounds, however, always containing two atoms of chromium, linked together so as to form a sexvalent group, like the two atoms of carbon in ethane, $\text{C}^{\text{IV}}\text{H}^{\text{I}}_4$: thus chromic chloride = $\text{Cr}^{\text{III}}\text{Cl}^{\text{I}}_3$; chromic oxide, CrO^{III} ; chromic sulphate, $\text{Cr}^{\text{III}}(\text{SO}^{\text{IV}})_4$, &c. In the chromous compounds it is bivalent, e.g. CrCl^{II} , CrO , &c.

Wanklyn (*Phil. Mag.* [4] xxix. 313) regards chromium as quadrivalent in all its compounds, and represents these compounds by formulæ of which the following may be taken as examples:

These formulæ are based on the analogy of chromic chloride to ferric chloride, on its boiling point, and on the boiling point and vapour-density of chlorochromic acid.

Chromic Oxy salts. Siewert (*Ann. Ch. Pharm.* cxxvi. 86; *Jahresb.* 1863, p. 223) has made observations on the variations of colour in chromic salts, tending to confirm the views of Krüger and Löwel (i. 950), that these changes of colour are due to the formation of compounds containing different proportions of base and acid.

H. Schiff (*Ann. Ch. Pharm.* cxxiv. 165; *Jahresb.* 1862, p. 151) has made the following observations on basic and polyacid salts of chromium. The dark green saturated solution of chromic hydrate in dilute sulphuric acid, evaporated at

50°-60°, leaves a similarly coloured soluble basic salt consisting of $\left\{ \begin{array}{l} (\text{Cr}^2)^{+1} \\ (\text{SO}^2)^- \\ \text{H}^2 \end{array} \right\} \text{O}^6 \cdot 2\text{H}^2\text{O}$

or $(\text{Cr}^2)^{+1} \left\{ \begin{array}{l} (\text{SO}^2)^- \\ (\text{HO})^2 \end{array} \right\} \cdot 2\text{H}^2\text{O}$. The solution of this salt in a small quantity of water is neutral, and may be boiled without decomposition; but on adding more water, a still more basic salt is precipitated; and if this precipitate be dissolved in a very small quantity of hydrochloric acid, the solution much diluted, and boiled for a few hours, decanted after cooling from a few flocks which may have separated, and incompletely precipitated by ammonia, light blue flocks are obtained, consisting of the salt $\text{Cr}^2 \left\{ \begin{array}{l} \text{SO}^4 \\ (\text{HO})^2 \end{array} \right\} \cdot 2\text{H}^2\text{O}$.

A *chromic hydroxychloride*, $(\text{Cr}^2)^{+1} \left\{ \begin{array}{l} (\text{HO})^4 \\ \text{Cl}^2 \end{array} \right\}$, is obtained by digesting the solution of chromic chloride for several days with excess of chromic hydrate, evaporating the resulting solution, and drying at 100° (Schiff, *Ann. Ch. Pharm.* cxxiv. 171). This compound was also obtained in the hydrated state, $\text{Cr}^2(\text{HO})^4\text{Cl}^2 \cdot \text{H}^2\text{O}$ [or $\text{Cr}^2\text{O}^3\text{Cl}^2 \cdot 3\text{H}^2\text{O}$], by Peligot (i. 954). With a smaller quantity of chromic hydrate the compound $\text{Cr}^2(\text{HO})^2\text{Cl}^4$ is produced.

Polyacid Salts.—The sulphate $\text{Cr}^2 \left\{ \begin{array}{l} \text{SO}^4 \\ (\text{HO})^2 \end{array} \right\}$ dissolves in nitric acid, forming a dark green liquid, which when evaporated at 80°-90° and dried at 100°, consists of *chromic sulphatotetranitrate*, $(\text{Cr}^2)^{+1} \left\{ \begin{array}{l} (\text{SO}^4)^- \\ (\text{NO}^3)^2 \end{array} \right\}$ or $\left\{ \begin{array}{l} (\text{Cr}^2)^{+1} \\ (\text{SO}^2)^- \\ (\text{NO}^3)^2 \end{array} \right\} \text{O}^6$. It dissolves completely in water, the solution being yellow-green in the cold, green at the boiling heat, and having an acid reaction. With barium chloride it forms only a slight cloud at ordinary temperatures, but a more copious precipitate at the boiling heat. *Chromic disulphatomitrate*, $\text{Cr}^2 \left\{ \begin{array}{l} (\text{SO}^4)^2 \\ (\text{NO}^3)^2 \end{array} \right\}$, is obtained by saturating the disacid sulphate with nitric acid. It is a green, tumefied, hygroscopic, saline mass, the solution of which has an acid reaction and astringent taste, and in other respects resembles that of the preceding salts.

Chromic diacetotetrachloride, $\text{Cr}^2 \left\{ \begin{array}{l} (\text{C}^2\text{H}^3\text{O}^2)^2 \\ \text{Cl}^4 \end{array} \right\}$, is obtained by dissolving the basic chloride $\text{Cr}^2(\text{HO})^2\text{Cl}^4$ in strong acetic acid; the *diacetodisulphate*, $\text{Cr}^2 \left\{ \begin{array}{l} (\text{C}^2\text{H}^3\text{O}^2)^2 \\ (\text{SO}^4)^2 \end{array} \right\}$, by dissolving the corresponding basic sulphate in acetic acid.

By dissolving the disulphate in cold hydrochloric acid, and evaporating at about 50°, a green amorphous mass is obtained, consisting of *chromic disulphatodichloride*, $\text{Cr}^2 \left\{ \begin{array}{l} (\text{SO}^4)^2 \\ \text{Cl}^2 \end{array} \right\} \cdot 2\text{H}^2\text{O}$. By dissolving the dihydroxytetrachloride, $\text{Cr}^2(\text{HO})^2\text{Cl}^4$, in nitric acid, the *dinitratotetrachloride*, $\text{Cr}^2 \left\{ \begin{array}{l} (\text{NO}^3)^2 \\ \text{Cl}^4 \end{array} \right\}$, is obtained, as a hygroscopic mass consisting of shining laminae. The *tetrahydroxydichloride*, $\text{Cr}^2(\text{HO})^4\text{Cl}^2$, dissolved in a small quantity of nitric acid, yields the *dinitratodichloride*, $\text{Cr}^2 \left\{ \begin{array}{l} (\text{NO}^3)^2 \\ (\text{HO})^2 \\ \text{Cl}^2 \end{array} \right\}$, as a light green, porous, hygroscopic mass, which crumbles to powder when stirred (Schiff).

The chromic acetates obtained by Schiff are described under ACETATES (p. 9).

Schützenberger has obtained a *chromic acetonitrate*, $\left(\begin{smallmatrix} \text{Cr}^{2+} \\ \text{H}^2\text{O} \\ \text{NO}^2 \end{smallmatrix}\right)^{\text{r1}} \text{O}^{\text{s}} \cdot 6\text{H}^2\text{O}$, by mixing

chromic nitrate and acetate in the required proportions and evaporating under the air-pump. A similar salt, crystallising in green laminæ or granules, is obtained on mixing 4 to 5 mol. of normal chromic acetate with 1 mol. of normal chromic nitrate, and evaporating at the boiling heat. When dried at 110° it has the composition $\left(\begin{smallmatrix} \text{Cr}^{2+} \\ \text{H}^2\text{O} \\ \text{NO}^2 \\ \text{H} \end{smallmatrix}\right)^{\text{r1}} \text{O}^{\text{s}} \cdot \text{H}^2\text{O}$. It dissolves easily in hot glacial acetic acid, and the solution

on cooling yields beautiful green laminæ, which after drying in a vacuum or at 100° have the composition $\left(\begin{smallmatrix} \text{Cr}^{2+} \\ \text{H}^2\text{O} \\ \text{NO}^2 \end{smallmatrix}\right)^{\text{r1}} \text{O}^{\text{s}} \cdot 4\text{H}^2\text{O}$. Heated to 200° , these crystals give off

water and acetic acid; at a higher temperature nitrous vapours are evolved, and the pulverulent mass assumes a yellow-brown colour. In this state it forms with water a dirty-brown solution, in which chromic acid may be detected. But at about 350° a somewhat violent reaction takes place, attended with evolution of gas, and there remains a light green, very finely divided, light powder, pyrophoric when heated. When very carefully prepared by heating the above-mentioned acetonitrate

with the vapour of boiling mercury, it has the composition $\left(\begin{smallmatrix} \text{Cr}^{2+} \\ \text{H}^2\text{O} \\ \text{NO}^2 \end{smallmatrix}\right)^{\text{r1}} \text{O}^{\text{s}}$. This

powder immediately takes up water, with rise of temperature, and is converted into a homogeneous deep green paste, which might perhaps be used as a pigment. The greater the quantity of water added, the more does this paste swell up, and finally it is converted into a green colloidal solution, which when mixed with an alkali deposits the whole of the salt. At about 400° the anhydrous powder gives off more acetic acid, without losing the power of uniting with water. At the temperature of boiling sulphur, complete decomposition takes place, anhydrous chromic oxide being left, mixed with charcoal.

Ammoniacal Chromic Salts.—Frémy, by the action of ammonia and ammoniacal salts on metachromic hydrate, obtained salts of a base $\text{Cr}^2\text{O}^3 \cdot 8\text{NH}^3$, which he called *roseochromammonia* (i. 951). Ammonio-chromic compounds of different composition have been obtained by Cleve (*J. pr. Chem.* lxxxvi. 47; *Jahresb.* 1862, p. 149). When the grey-green hydrate, precipitated by a slight excess of ammonia from a cold saturated solution of chrome-alum, is digested in a closed vessel with a saturated solution of ammonium chloride in ammonia, till it dissolves with deep rose-red colour, and the resulting solution is exposed to the air, a reddish-violet amorphous powder is precipitated, which dissolves with dark red colour in dilute hydrochloric acid. This solution gradually deposits a bright red crystalline powder, which dissolves in hydrochloric acid, and separates by slow evaporation in well-defined rhombic prisms, consisting of the salt $\text{Cr}^2\text{Cl}^6 \cdot 8\text{NH}^3 \cdot 2\text{H}^2\text{O}$, designated by Cleve as *tetramine-chromic chloride*. The crystals have a deep red colour and vitreous lustre, give off only hygroscopic water at 100° , but decompose at 200° with evolution of ammonia. They dissolve in water, forming a neutral solution which gives off ammonia when boiled, and is easily decomposed by alkalis. This salt forms double salts with platonic chloride and mercuric cyanide. The *platinum salt* $\text{Cr}^2\text{Cl}^6 \cdot 8\text{NH}^3 \cdot 2\text{H}^2\text{O} \cdot \text{PtCl}^4$ is a brown-red crystalline powder soluble in hot water. The chloride treated with sulphuric acid yields a *sulphato-chloride* of complex constitution. A *nitrate* is obtained by decomposing the chloride with an equivalent quantity of silver nitrate, in large, apparently hexagonal tables, which dissolve readily in water, are reconverted into the original chloride by hydrochloric acid, and are decomposed by heat into ammonia, ammonium nitrate, and chromic oxide.

Chromium Trioxide or Chromic Anhydride, CrO^3 , may be prepared by heating barium chromate with a large excess of nitric acid slightly diluted with water; decanting the boiling solution from the barium nitrate which separates, and from the further quantity which is deposited on cooling; distilling off the nitric acid till crystals of chromic anhydride separate out on the sides of the retort; then decanting the non-crystallised liquid, and evaporating it to dryness over the water-bath. By finally drying it over the open fire, with constant stirring, the anhydride is obtained in the form of a powder resembling ignited ferric oxide, almost black while hot, but becoming red again on cooling (Siewert, *Jahresb.* 1862, p. 146).

According to Schafarik (*Wien. Akad. Ber.* xlvii. [2] 256), chromic anhydride melts

at a temperature a little below the boiling point of strong sulphuric acid, a small quantity subliming at the same time. It deliquesces slowly on exposure to the air, dissolves without alteration in ether, and separates from the reddish-yellow solution in microscopic crystals. Phosphorus reduces it to chromic chromate (Oppenheim, *Jahresb.* 1864, p. 140).

Chromates. According to H. Schwartz (*Dingl. pol. J.* clxxvi. 31), chromates are but imperfectly decomposed by sulphuric acid, added in the proportion to form a neutral or acid sulphate. When 2 mol. sulphuric acid are added to a hot solution of 1 mol. potassium dichromate, the liquid on cooling deposits crystals of unaltered dichromate, and afterwards of a mixture of that salt with the tetrachromate (comp. Bolley, *Ann. Ch. Pharm.* lvi. 113). The chromates of lead and barium are only one-fourth decomposed by equivalent quantities of sulphuric acid; the lead-salt requires for decomposition 6 mol. sulphuric acid.

Ammonium Salts.—Siewert (*Jahresb.* 1862, p. 148) confirms the formula of the dichromate, $(\text{NH}_4)_2\text{O} \cdot 2\text{CrO}_3$ or $(\text{NH}_4)_2\text{CrO}_4 \cdot \text{CrO}_3$, given by Richmond & Abel (i. 932). Respecting the crystalline form of this salt, see Rammelsberg (*Pogg. Ann.* cxviii. 158; *Jahresb.* 1863, p. 225). The trichromate, $(\text{NH}_4)_2\text{O} \cdot 3\text{CrO}_3$, obtained by the action of strong nitric acid on the dichromate, forms shining deliquescent crystals of deep garnet-red colour, and generally isomorphous with potassium trichromate. It is resolved by water into chromic acid and the dichromate; becomes black-red at 100° – 120° , and detonates sharply at a stronger heat, leaving a greyish-black residue having the form of tea-leaves (Siewert).

Potassium Salts.—The solubility of the dichromate, $\text{K}_2\text{O} \cdot 2\text{CrO}_3$, in water at various temperatures, has been determined by Alluard (*Ann. Ch. Pharm.* cxxiii. 292):

$^\circ$	Salt dissolved by 100 pts. water	$^\circ$	Salt dissolved in 100 pts. water
0°	4.6	60°	45.0
10	7.4	70	56.7
20	12.4	80	68.6
30	18.4	90	81.1
40	25.9	100	94.1
50	35.0		

A saturated solution boils at 103.4° . Respecting the action of ammonium sulphocyanate on potassium dichromate, see v. 607.

The trichromate, $\text{K}_2\text{O} \cdot 3\text{CrO}_3$ or $\text{K}_2\text{CrO}_4 \cdot 2\text{CrO}_3$, is obtained pure and finely crystallised by leaving a solution of the dichromate in excess of aqueous chromic acid to evaporate over oil of vitriol (v. Hauer, *Jahresb.* 1860, p. 161). The tetrachromate, $\text{K}_2\text{O} \cdot 4\text{CrO}_3$ or $\text{K}_2\text{CrO}_4 \cdot 3\text{CrO}_3$, is obtained in shining red, thin prismatic laminae, by leaving a solution of the trichromate in excess of nitric acid over a heated sand-bath, and recrystallising the crusts which separate on cooling, from strong nitric acid (Siewert, *ibid.* 1862, p. 147).

Potassium Chromato-fluoride, $\text{KF} \cdot \text{CrO}_3$ or $(\text{CrO}_3)_2 \cdot \text{O} \cdot \text{K}$, analogous in composition to potassium chromato-chloride (i. 938) and chromium chromato-chloride (p. 456), is obtained by heating pulverised potassium dichromate with excess of concentrated hydrofluoric acid in a platinum dish. It crystallises on cooling in ruby-coloured translucent quadratic octohedrons, with terminal edges of 106° and lateral edges of 115° ; becomes dull and reddish-yellow on exposure to the air; cannot be kept in glass vessels; melts easily, when heated, to a dark brown liquid; and decomposes at a red heat in glass vessels, giving off oxygen and silicon fluoride. It dissolves easily in water, especially at the boiling heat, and the solution yields crystals of potassium dichromate, hydrofluoric acid remaining dissolved (Streng, *Ann. Ch. Pharm.* cxxix. 225):

Potassium Sulphato-chromate, $\text{K}_2\text{SO}_4 \cdot \text{CrO}_3$ or $(\text{CrO}_3)_2 \cdot \text{O} \cdot \text{K}$, analogous to Bolley's chromo-sulphuric acid (i. 968), is obtained by fusing potassium chromato-chloride, $\text{KCl} \cdot \text{CrO}_3$, at as low a temperature as possible, with neutral or acid potassium sulphate:

and

It is also found in the mass obtained by heating equivalent quantities of acid sulphate and dichromate of potassium, and is produced in the action of strong sulphuric acid on a concentrated solution of potassium dichromate in excess. It has the same colour as the dichromate, and is decomposed by water into free sulphuric acid, neutral sulphate, and dichromate of potassium, so that it cannot be purified by recrystallisation (Schiff, *Jahresb.* 1863, p. 226).

Sodium Dichromate, $\text{Na}_2\text{O} \cdot 2\text{CrO}_3 \cdot 2\text{aq.}$, crystallises in ruby-red or hyacinth-red prisms of $99^\circ 42'$ and $80^\circ 18'$ (Siowert, *Jahresb.* 1862, p. 147).

Lithium Chromate, $\text{Li}^2\text{CrO}_4 \cdot 2\text{H}_2\text{O}$, forms red-brown rhombic crystals, exhibiting the combination $\infty\text{P} \cdot \infty\text{P}2 \cdot \infty\text{P}3 \cdot \text{P}\infty \cdot \text{P}\infty \cdot \infty\text{P}\infty \cdot \infty\text{P}\infty$, the last three faces and $\infty\text{P}3$ being very subordinate. Axes $a : b : c = 0.6619 : 1 : 0.4663$. Easily soluble in water. The *dichromate*, $\text{Li}^2\text{CrO}_4 \cdot \text{CrO}_3 \cdot 2\text{H}_2\text{O}$, obtained by adding chromic or nitric acid to the solution of the neutral salt, and evaporating to a syrup, separates in deliquescent brown-black crystals, having some of their faces curved. *Lithio-ammonic chromate*, $\text{Li}(\text{NH}_4)\text{CrO}_4 \cdot 2\text{H}_2\text{O}$, crystallises from a solution of lithium dichromate saturated with ammonia, in slender red-brown deliquescent needles (Rammelsberg, *Pogg. Ann.* cxxviii. 311; *Jahresb.* 1866, p. 160).

Thallium Chromates (v. 754).

Cadmium Chromate (basic), precipitated on mixing the boiling solutions of cadmium sulphate and neutral potassium chromate (which, according to Malaguti a. Surzeau [i. 933], has the composition $\text{Cd}^2\text{Cr}_2\text{O}^{11} + 8\text{H}_2\text{O}$), is, according to Frees (*Zeitschr. f. Chem.* [2] vi. 31), a dicadmian salt, $\text{Cd}_2\text{CrO}_3 + \text{H}_2\text{O}$ or $2\text{CdO} \cdot \text{CrO}_3 + \text{H}_2\text{O}$, part of the chromium being, however, replaced by sulphur, unless the potassium chromate is added in great excess. The same is the case with the basic chromates of copper and zinc.

Calcium Chromate, $\text{CaCrO}_4 \cdot 2\text{H}_2\text{O}$, prepared by digesting aqueous chromic acid with excess of marble, crystallises by evaporation over sulphuric acid in yellow, apparently quadrate prisms, with quadratoctohedral summits. They assume a cinnamon-red colour when heated, but become yellow again on cooling; give off their water of crystallisation when strongly ignited; require for solution 241.3 pts. water at 14° ; but dissolve easily in aqueous chromic acid.

Cobalt Chromate, obtained by precipitating a boiling solution of the sulphate with neutral potassium chromate—to which Malaguti a. Surzeau assigned the formula $\text{Co}^2\text{CrO}_3 + 4\text{H}_2\text{O}$ or $3\text{CoO} \cdot \text{CrO}_3 + 4\text{H}_2\text{O}$ —is, according to Frees (*Zeitschr. f. Chem.* [2] vi. 31), a dicobaltous salt, $\text{Co}_2\text{CrO}_3 + 2\text{H}_2\text{O}$ or $2\text{CoO} \cdot \text{CrO}_3 + 2\text{H}_2\text{O}$.

Copper Chromates.—A *tricupric salt*, $3\text{CuO} \cdot \text{CrO}_3$ or $2\text{CuO} \cdot \text{CuCrO}_4$, is obtained (mixed with barium sulphate) by prolonged digestion of barium chromate with cupric sulphate at 30° – 35° ; from its solution in ammonia it is thrown down by nitric acid as a brown precipitate (Viefhaus, *J. pr. Chem.* lxxviii. 431). The same salt is obtained by precipitation of boiling cupric sulphate with neutral potassium chromate; also by digesting cupric carbonate with aqueous chromic acid, or cupric hydrate with potassium dichromate, and subsequent boiling with water: it contains 2 mol. water, which it gives up at about 260° , and recovers on exposure to moist air. This is the only definite basic chromate of copper; the green basic salts described by some authors are merely mixtures containing cupric hydrate or basic sulphate. *Potassio-cupric chromate* is formed, not only by digesting cupric hydrate with potassium dichromate (i. 933), but also by the mutual action of cold solutions of cupric sulphate and potassium dichromate. It is decomposed by boiling water, yielding potassium dichromate and tricupric chromate (Frees, *loc. cit.*).

Mercury Chromates.—The only *basic mercuric chromate* which appears to exist is the *trimercuric salt* (Frees).

Mercuric Chromato-sulphide, $\text{HgS} \cdot 2\text{HgCrO}_4$, is obtained by digesting precipitated mercuric sulphide for three or four hours with excess of a solution of recently precipitated mercuric chromate in chromic acid. It must be washed for a short time only, and dried at a temperature not above 30° . It is not attacked by the weaker acids, but sulphuric, nitric, and hydrochloric acid separate the chromic acid and form white compounds. Alkaline solutions change the ochre-coloured salt to orange, and ultimately to black; ammonia quickly converts it into a black powder. The compound detonates with great violence when rubbed, struck, or heated (Palm, *Jahresb.* 1862, p. 222).

Magnesium Salts.—A solution containing equivalent quantities of magnesium sulphate and potassium chromate deposits yellow crystals, having the form of the

double sulphates of the magnesium group with $6\text{H}^2\text{O}$, and containing variable quantities of chromic and sulphuric acids, always however rather less than 1 mol. chromic and rather more than 1 mol. sulphuric acid. A solution containing more than 1 mol. chromic acid and a proportionally smaller quantity of sulphuric acid yields, by crystallisation, the double salt $\text{MgK}^2(\text{CrO}^4)^2 \cdot 2\text{H}^2\text{O}$ (v. Hauer, *Jahresb.* 1860, p. 161).

Manganous Chromate (basic), $\text{Mn}^2\text{CrO}^4 + 2\text{H}^2\text{O}$; gives off half its water at about 180° , the rest above 300° (Frees).

Nickel Chromate (basic), obtained like the cobalt salt, consists, according to Frees, of $\text{Ni}^2\text{CrO}^4 + 3\text{H}^2\text{O}$ or $3\text{NiO} \cdot \text{CrO}^3 + 3\text{H}^2\text{O}$.

Zinc Chromates. A *bibasic* zinc chromate, $2\text{ZnO} \cdot \text{CrO}^3 + 2\text{H}^2\text{O}$, is formed by adding 2 mol. neutral potassium chromate to 3 mol. zinc sulphate, as a very light pulverulent orange-coloured precipitate, slightly soluble in water. The same salt with $\frac{1}{2}$ mol. water is obtained by adding chromic acid to water in which basic zinc carbonate is suspended. A *quadribasic salt*, $4\text{ZnO} \cdot \text{CrO}^3 + 3\text{H}^2\text{O}$ or $\text{Zn}(\text{CrO}^4) + 3\text{ZnH}^2\text{O}^2$, is obtained as a fine light-yellow powder, by adding zinc sulphate to an excess of neutral potassium chromate, and freeing the precipitate from potash by washing and repeated boiling with a large quantity of water. A *basic zinc-potassium chromate*, $5\text{ZnO} \cdot \text{K}^2\text{O} \cdot \text{CrO}^3 + 6\text{H}^2\text{O}$, is formed as an orange-yellow pulverulent precipitate on gradually pouring a solution of zinc sulphate into a large excess of neutral potassium chromate (Philippon a. Prüssen, *Ann. Ch. Pharm.* cxlix. 92). According to Frees, the precipitate formed on mixing cold solutions of zinc sulphate and neutral potassium chromate consists of $\text{Zn}^2\text{K}^2\text{CrO}^{14} + 3\text{H}^2\text{O}$ or $4\text{ZnO} \cdot \text{K}^2\text{O} \cdot 3\text{CrO}^3 + 3\text{H}^2\text{O}$, and is resolved by prolonged action of boiling water into potassium dichromate and the quadribasic salt $4\text{ZnO} \cdot \text{CrO}^3 + 3\text{H}^2\text{O}$.

An *ammonio-zinc chromate*, $\text{ZnCr}^2\text{O}^4 \cdot 4\text{NH}^3 + 3\text{H}^2\text{O}$, crystallising in square tables with octohedral summits, is formed by dissolving the bibasic zinc salt above mentioned in warm aqueous ammonia, precipitating with absolute alcohol, redissolving in ammonia, adding sal-ammoniac and alcohol, again dissolving the precipitate in warm aqueous ammonia, and leaving the solution to cool (Bieler, *Ann. Ch. Pharm.* cli. 223).

Chromic Chromate or *Chromium Dioxide*, $\text{CrO}^2 = \text{Cr}^2\text{O}^3 \cdot \text{CrO}^3 = \left\{ \begin{smallmatrix} \text{Cr}^2 \\ \text{Cr}^2 \end{smallmatrix} \right\} \text{O}^6$. This compound separates, according to A. Vogel (*J. pr. Chem.* lxxvii. 482; *Jahresb.* 1859, p. 171), from a solution of potassium dichromate, mixed with ammonia, or with alcohol, and exposed to sunshine. According to H. Schiff (*Ann. Ch. Pharm.* cxx. 207; *Jahresb.* 1861, p. 250), it is formed by the action of a solution of chloride of lime on chromic hydrate or violet chromic chloride. It may be quickly and easily prepared by stirring up an intimate mixture of equal parts of potassium dichromate and crystallised oxalic acid with strong nitric acid to a thick paste, heating this paste in a porcelain crucible to a temperature below the melting point of the resulting potassium nitrate as long as red vapours are given off, then pulverising the porous easily separating mass, and digesting it with cold water. The aqueous solution thereby obtained yields, on addition of ammonia, a further quantity of the brown oxide. This oxide is resolved by prolonged washing with water, into chromic acid and chromic oxide, whence it appears to consist of chromic chromate rather than of the dioxide. The same view is supported by the fact that it does not turn guaiacum tincture blue, a property exhibited by all true peroxides. The same view of its composition is taken by Elliot a. Storer (*Rép. Chim. app.* iii. 390; *Jahresb.* 1861, p. 251), who also find that it gives up chromic acid to water and to solution of sal-ammoniac. They obtained a brown oxide having the constant composition $\text{Cr}^2\text{O}^3 \cdot \text{CrO}^3$ by Vogel's method above described, and by that of Krüger (*Gmelin's Handbook*, iv. 114), which consists in oxidising chromic oxide at 200° – 210° in contact with the air. On the other hand, the brown oxides obtained by precipitating chrome-alum with neutral potassium chromate (5 eq. of the latter are required to produce a permanent precipitate), by treating chromic oxide with chlorine-water, and by heating chromium trioxide to 200° , as recommended by Traube (*Jahresb.* 1847–48, p. 416), proved to be mixtures of variable composition. Elliot a. Storer have endeavoured to replace the base in the compound $\text{Cr}^2\text{O}^3 \cdot \text{CrO}^3$ by an analogous sesquioxide. By adding 5 mol. neutral potassium chromate to a solution of 1 mol. common alum, a precipitate is formed consisting of *aluminium chromate*, $\text{Al}^2\text{O}^3 \cdot \text{CrO}^3$; the *ferric compound* formed in like manner contains $\text{Fe}^2\text{O}^3 \cdot \text{CrO}^3$, and an analogous compound containing both manganic and chromic oxides has been obtained by Fairrie (i. 936). Chromic chromate is also formed by passing the vapour of chromyl dichloride, mixed with hydrogen gas, through a red-hot glass tube (Schafarik, *Jahresb.* 1863, p. 226); and finally by boiling the solution of an acid chromate or of potassium-ammonium chromate with sodium hyposulphite (E. Kopp, *ibid.* 1864, p. 233).

Chromium Oxychlorides. 1. *Chromyl dichloride*, $(\text{CrO}^2)^+\text{Cl}^-$ or $\text{Cl}-\text{Cr}\begin{array}{c} \text{O} \\ || \\ \text{O} \end{array}-\text{Cl}$,

commonly called *Chlorochromic acid*.—According to Thorpe (*Chem. Soc. J.* [2] vi. 514), this compound boils at 116.8° under a pressure of 733 mm., a determination which agrees with that of Walter (i. 954), viz. 118° under a pressure of 760 mm. Its sp. gr. at 25° is 1.920 (Walter found 1.71 at 21°). Its specific volume calculated therefrom agrees with that of the analogously constituted sulphuryl chloride:

	Mol. weight	Sp. gr.	Sp. volume
SO^2Cl^2	136.0	1.66	81.8
CrO^2Cl^2	155.5	1.92	81.2

The vapour of chromyl dichloride imparts to the non-luminous flame of a Bunsen's burner a peculiar pale violet colour, and the spectrum exhibits three violet, eight green, one yellow, three orange, and two red lines, the brightest of which are the violet, and one of those situated in the green. When the flame is fed with a mixture of the vapour and oxygen gas, a spectrum of almost insupportable brightness is produced, the violet lines appearing peculiarly distinct. Neither chlorine gas nor chromic chloride nor chromous chloride introduced into the flame produces any similar spectrum. The deep red vapours of chromyl dichloride interposed before the slit of the spectral apparatus absorb all the light, excepting a narrow band of the red (Gottschalk a. Drechsel, *Bull. Soc. Chim.* [2] vi. 20).

2. *Chromium Chromato-chloride*. $\text{Cr}^2\text{Cl}^2\text{O}^4$ (Thorpe, *Chem. Soc. J.* [2] viii. 31).—Chromyl dichloride heated to 180° – 190° in a sealed tube for three or four hours is almost wholly resolved into this compound and free chlorine:

On opening the tube, the free chlorine escapes, and chromium chromato-chloride remains, mixed with unaltered chromyl dichloride, the greater part of which may be expelled by a gentle heat, and the rest by heating the substance to 120° in a current of carbon dioxide.

Chromium chromato-chloride is a black uncrystalline powder, which deliquesces rapidly in the air to a dark reddish-brown syrupy liquid smelling of free chlorine. It dissolves quickly in water, forming a dark brown solution which likewise evolves chlorine on standing. In strong hydrochloric acid it also dissolves with dark brown colour, and the solution when boiled gives off chlorine, becomes greenish-yellow, and ultimately exhibits the dark green colour peculiar to a solution of chromic oxide in hydrochloric acid. When the black compound is thrown into dilute ammonia, chromic acid is dissolved, together with all the chlorine, and a precipitate is formed consisting of chromium dioxide or chromic chromate, $\text{Cr}^2\text{O}^3 \cdot \text{CrO}^2$. When gently heated in hydrogen, it takes fire, the combustion proceeding rapidly through the mass, and is ultimately converted into chromic oxide, hydrochloric acid, and water:

Chromium chromato-chloride is analogous in composition to the compounds $\text{KCl} \cdot \text{CrO}^2$ and $\text{MgCl}^2 \cdot 2\text{CrO}^2$, obtained by Peligot (*Ann. Ch. Phys.* [2] lii. 267), and might be represented in like manner by the formula $\text{Cr}^2\text{Cl}^2 \cdot 2\text{CrO}^2$. But its reaction with hydrogen shows that the chlorine is not present in the form of chromous chloride, for that compound may be heated to fusion in hydrogen without forming hydrochloric acid.

The black chromium-compound and the corresponding magnesium-compound may perhaps be better represented by the following formulæ:

The *hydroxychlorides* $\text{Cr}(\text{HO})^2\text{Cl}^2$ and $\text{Cr}(\text{HO})^2\text{Cl}^2$ obtained by Schiff have been already mentioned (p. 451).

Chromic Sulphides. The sulphide obtained by fusing potassium chromate with liver of sulphur forms greenish-black friable crystals, of sp. gr. 2.79, is easily oxidised by nitric acid, and when ignited in the air burns with a glimmering light to chromic oxide having an alkaline reaction; but the sulphide produced by igniting chromic chloride in hydrogen sulphide forms grey-black, metallic, shining, flexible laminae, of sp. gr. 3.77; is not attacked by fuming nitric acid; and when ignited is converted, without alteration of form, into the green sesquioxide. The first-mentioned product is probably an alkaline double sulphide (Schafarik, *Jahresb.* 1863, p. 225).

CHRYSAMMIC ACID. $C^4H^2N^2O^8$.*—The following method of preparing this acid is given by Stenhouse & Müller (*Chem. Soc. J.* [2] iv. 319): 2 pts. of Socotrine aloes are added to 6 pts. of nitric acid of sp. gr. 1.36, heated nearly to boiling in a retort provided with a condensing arrangement, and the mixture is heated for about ten hours—the first portions of acid which pass over being poured back—till it is reduced to about half its original volume; 3 pts. more of nitric acid are then added; the digestion is continued for 6 or 7 hours longer; the greater portion of the nitric acid then distilled off; the residue mixed with 4 pts. water; and the mixture of picric and aloetic acids which remains undissolved is digested for six or eight hours with an equal weight of nitric acid of sp. gr. 1.45, and then washed by decantation with boiling water, till the wash-water, which is at first orange-yellow, exhibits a purple-red colour. The mixture of chrysammic and aloetic acid thus freed from picric acid is dried, again digested for about ten hours, with an equal weight of strong nitric acid; and the product, after washing with hot water, is repeatedly boiled with four times its weight of water till the filtrate is no longer purple-red, but light-red. After renewed boiling with water and a slight excess of chalk, the liquid becomes dark red or purple-red, and on cooling deposits calcium chrysammate, partly in needles, partly as a flocculent mass, which must be recrystallised from weak spirit. If much aloetic acid is still present, in consequence of imperfect transformation of the aloes, the calcium chrysammate crystallises only after repeated boiling with water, and cooling, whereby the more soluble aloetate is removed. The red wash-waters obtained in this process yield, when acidulated with nitric acid, a large quantity of impure aloetic acid, which by further treatment with strong nitric acid may be converted into chrysammic acid. Aloes thus treated yields from 3 to 4 p. c. calcium chrysammate: it is more economical however to make use of the otherwise worthless resinous portion of the aloes, which is insoluble in cold water, though the quantity of chrysammic acid obtained therefrom is not more than half of that yielded by the aloes itself. (Chrysammic acid is also produced, as shown by De la Rue & Müller (*Jahresb.* 1862, p. 324), by the action of nitric acid on chrysophane and other constituents of rhubarb.)

Chrysammic acid separated by nitric acid from the hot solution of the calcium salt forms large scales like lead iodide, quite insoluble in cold water. The acid suspended in water decomposes the neutral solutions of cupric acetate and nitrate, nickel sulphate, manganous chloride, and other salts. Treated with *potassium chlorate* and *hydrochloric acid*, it is slowly converted into chloropierin, without formation of chloranil. Heated with *benzoyl chloride*, it yields nearly insoluble benzoyl-chrysammic acid, $C^4H(C^6H^5O)N^2O^8$, which crystallises in prisms and is decomposed only by alcoholic potash into benzoic and chrysammic acids (Stenhouse & Müller). By *potassium cyanide* in aqueous solution it is converted into chrysocyanic acid (Finckh, *Ann. Ch. Pharm.* cxxxiv. 229):

Calcium Chrysammate, $(C^4H^2N^2O^8)_2Ca$ (at 145°), is easily soluble in boiling alcohol, less soluble in water, and crystallises from the latter in light red needles, which when dried in a vacuum give off water and turn brown. The *magnesium salt* $(C^4H^2N^2O^8)_2Mg$ (at 160°) crystallises in broad red tables. The *cupric salt* is prismatic and more soluble than the calcium salt. The *manganous salt* crystallises in scales having a blood-red colour by transmitted light, and a golden lustre; like most chrysammates, it is moderately soluble in weak spirit (Stenhouse & Müller).

Ethyl Chrysammate, $C^4H^2N^2O^8 \cdot C^2H^5$, is obtained by heating dry silver chrysammate to 100° with 5 pts. ethyl iodide. When purified by repeated crystallisation from benzol, and finally from ether, it forms pale red needles or yellow prisms nearly insoluble in carbon bisulphide, and only slightly soluble in ether (Stenhouse, *Chem. Soc. J.* [2] iv. 324).

* Graebe & Liebermann (*Zeitschr. f. Chem.* [2] iv. 508) regard chrysammic acid as *isotetrakis-benzo-anthraquinone*, $C^{16}H^2N^2O^8 = C^{16}H^2(RO)^4(RO)^4O^8$.

Hydrochrysammide, $C^2H^4N^3O^3$ (iii. 191), is easily formed by treating chrysammic acid with zinc and dilute acid, or with hydriodic acid (with addition of a little phosphorus), or with sodium-amalgam. The purple-red solution produced in the latter case becomes orange-coloured when shaken up with the amalgam in closed vessels, but recovers its original colour on exposure to the air (Stenhouse a. Müller, *loc. cit.*).

CHRYSANILINE. $C^{20}H^{17}N^3$ (iv. 473).—This base forms two picrates, of which the *dipicrate* $C^{20}H^{17}N^3[C^6H^4(NO^2)_2O]^2$ is the less soluble. It is obtained by precipitating a chrysaniline salt with an aqueous solution of picric acid, washing the precipitate, and dissolving it in alcohol. On mixing a cold-saturated solution of a chrysaniline salt with a cold-saturated solution of picric acid in alcohol, the dipicrate gradually separates in splendid ruby-coloured needles which retain 1 mol. water at 100° , but become anhydrous at 110° (Hofmann, *Deutsch. chem. Gesells.* Berlin, 1869, p. 379).

Trimethyl-chrysaniline. $C^3H^{14}(CH^3)^3N^3$.—The di-hydriodide of this base is obtained by heating 1 mol. chrysaniline with 4 mol. methyl-iodide to 100° for five or six hours, in shining needles which may be purified by washing with boiling alcohol, and recrystallisation from boiling water. It then separates in splendid needles having a colour intermediate between orange-yellow and carmine-red, and consisting when dried at 100° of $C^3H^{14}(CH^3)^3N^3 \cdot 2HI$. The solution of this salt dyes silk and wool deep orange-yellow, with a tinge of scarlet. The hot-saturated aqueous solution of this salt mixed with excess of ammonia becomes light yellow, and deposits on cooling interlaced yellow needles of the *monohydriodide* $C^3H^{14}(CH^3)^3N^3 \cdot HI$. The mother-liquors obtained in determining the iodine in these two salts, freed from silver by hydrochloric acid and mixed with platinum chloride, yielded the *platinum salt* $C^3H^{14}(CH^3)^3N^3 \cdot 2HCl \cdot PtCl_4$ in beautiful interlaced needles. The solution of either of the hydriodides warmed with silver-oxide yields the *base*, as a brown-yellow uncrystallisable powder, insoluble in water, soluble in alcohol. With acids it forms well-crystallised salts, most of which are very soluble; the nitrate and picrate however are sparingly soluble.

Triethyl-chrysaniline.—The dihydriodide $C^3H^{14}(C^2H^5)^3N^3 \cdot 2HI$ is prepared like the corresponding methyl-compound, which it resembles in every respect. When dried under the air-pump, it retains $1\frac{1}{2}$ mol. water, which it gives off at 100° . The *platinichloride* $C^3H^{14}(C^2H^5)^3N^3 \cdot 2HCl \cdot PtCl_4$ crystallises in needles slightly soluble in water.

The hydriodide of *triethyl-chrysaniline* has also been obtained in the crystalline form.

When chrysaniline is heated to the boiling point with excess of aniline and acetic acid, ammonia is given off and a dark brown solution is formed from which, after addition of alkali, the free aniline may be removed by a current of steam. From the brown residue, a dark brown hydrochloride of a phenylated chrysaniline may be prepared, which crystallises in four-sided tables (Hofmann, *Deutsch. chem. Gesells.* Berlin, 1869, p. 377; *Zeitschr. f. Chem.* [2] v. 634).

CHRYSANISIC ACID. Kellner a. Beilstein (*Ann. Ch. Pharm.* cxxviii. 179) represent this acid by the formula $C^7H^5(NO^2)^2$, according to which it is isomeric with trinitrotoluene. Cahours, by whom it was discovered, assigned to it the formula $C^7H^5(NO^2)_2O$, making it isomeric with trinitrocresol. The *ammonium salt* $C^7H^5(NO^2)^2 \cdot NH^4$ is easily soluble in water, and crystallises in light brown needles; the *silver salt* $C^7H^5(NO^2)^2 Ag$ is a bulky yellow precipitate. The *ethylic ether* $C^7H^5(NO^2)^2 \cdot C^2H^5$, produced by treating the alcoholic solution of the acid with hydrochloric acid gas, crystallises from alcohol in large laminae having a golden lustre, and remaining suspended in the liquid, with a sky-blue iridescence.

Amido-chrysanisic acid, $C^7H^5N^2O^4 = C^7H^5(NH^2)(NO^2)^2$, produced by the action of hydrogen sulphide on an alcoholic solution of chrysanisic acid supersaturated with ammonia, crystallises in red microscopic crystals, easily soluble in alcohol, sparingly soluble in hot water, insoluble in ether. Its *ammonium salt*, $C^7H^5N^2O^4 \cdot NH^4$, forms garnet-red monoclinic prisms with dihedral summits, having the axes $a : b : c = 1.0730 : 1 : 1.809$, and the angle $b : c = 77^\circ 32'$. The potassium salt and the barium salt crystallise in red needles; the salts of the heavy metals produce in the solution of ammonium amido-chrysanisate, orange-coloured or yellow precipitates.

Azo-amido-chrysanisic acid, $C^7H^5N^3(NH^2)(NO^2)^2$, separates on passing nitrous acid into the alcoholic solution of amido-chrysanisic acid, as a brass-yellow crystalline body, easily soluble in absolute alcohol and not decomposed by boiling with acids. It dissolves in ammonia, with evolution of nitrogen, forming a red liquid, from which

acids throw down a body which crystallises from hot water in yellow laminae and has the composition $C^{14}H^{12}N^2(NO^2)^2O$ (Kellner a. Beilstein).

CHRYSENE. $C^{18}H^{12}$.—This hydrocarbon, discovered by Laurent (i. 958), occurs, together with benzerythrene (p. 304), in the least volatile portion of crude anthracene (the mixture of solid hydrocarbons which remains in the distillation of coal-tar after the naphthalene has passed over). It is contained also in larger quantity in the reddish-yellow product which passes over last in the destructive distillation of dry fir-wood tar (*brui see*) (Berthelot, *Jahresb.* 1867, p. 606). It is formed, together with diphenyl and many other hydrocarbons, when the vapour of benzene is passed through a porcelain tube heated to bright redness (p. 261). The formation of diphenyl and chrysene may be represented by the equations,

Chrysene is also formed, together with benzene (probably from phenylene as intermediate product), when diphenyl is heated for an hour with hydrogen in a sealed tube (Berthelot, *ibid.* pp. 542, 544):

A mixture of chrysene vapour and hydrogen gas passed through a red-hot tube is converted into benzene and diphenyl:

and a mixture of chrysene and ethylene similarly treated yields benzene and anthracene, with a small quantity of naphthalene (Berthelot, *ibid.* p. 546):

and

Chrysene added to a hot alcoholic solution of picric acid (saturated at 20° – 30°) forms a yellow granular precipitate of *chrysene picrate*, consisting of scaly groups of microscopic needles. If benzerythrene is also present, the scales are changed into brown spherical aggregates of needles (Berthelot, *ibid.* 1867, p. 604). According to Gollatly (*Chem. News*, x. 243), chrysene picrate, $C^{18}H^{12}.C^6H^3(NO^2)^3O$, crystallises from a hot solution of its components in Bughead naphtha, in reddish-brown needles often half an inch long.

CHRYSENIC ACID. A yellow colouring matter contained in the buds of *Populus nigra* and *P. pyramidalis*. (See POPULAR-BUDS, v. 688.)

CHRYSOCYANIC ACID. $C^8H^2N^2O^6$ (C. Finck, *Ann. Ch. Pharm.* cxxxiv. 229).—An acid allied to isopurpuric acid, produced by heating chrysamnic acid with aqueous potassium cyanide:

The *potassium salt* resulting from the reaction, after being purified by repeated precipitation with potassium carbonate, and finally by recrystallisation from hot water, separates on cooling as a dark-coloured salt containing $2C^8H^2N^2O^6.K.3H^2O$, and giving up its water at 120° . The *ammonium salt* $2C^8H^2N^2O^6.NH^4.3H^2O$ forms dark green needles less soluble in water than the potassium salt. The *barium salt* $(C^8H^2N^2O^6)^2Ba$, the *calcium salt* $(C^8H^2N^2O^6)^2Ca$, the *lead salt* $(C^8H^2N^2O^6)^2Pb$, and the *silver salt* $(C^8H^2N^2O^6)Ag$, are red-brown precipitates which acquire metallic lustre by trituration, and detonate when heated. The *acid* $2C^8H^2N^2O^6.3H^2O$ separated from the potassium salt by nitric acid, is insoluble in water, soluble in alcohol, and exhibits metallic lustre when dry.

CHRYSOGEN (Fritzsche, *Compt. rend.* liv. 910; further, *Bull. Soc. Chim.* [2] vi. 474).—An orange-coloured hydrocarbon contained in small quantity in crude anthracene, separable therefrom by repeated crystallisation from light coal-tar naphtha, and finally purified by treatment with alcohol and ether. It dissolves in 2,500 pts. of cold benzol, and in 500 pts. at the boiling heat; very sparingly also in alcohol and ether; and separates from the hot-saturated solutions in groups of orange-coloured tables or laminae, which appear gold-green in the liquid by reflected light, and are converted by ether into an orange-coloured powder. It contains 94.3 to 96.0 p. c. carbon and 5.7 to 4.7 p. c. hydrogen; melts at 280° to 290° ; sublimes with partial decomposition; dissolves without alteration in strong sulphuric acid; and

yields a crystalline product with strong nitric acid. When mixed, even in traces, with colourless hydrocarbons, it imparts to them a fine yellow colour. Its solution when exposed to sunshine quickly becomes colourless, and then yields a crystallisable colourless body, which becomes orange-yellow when fused.

CHRY SOPHANE. $C^{16}H^{10}O^4$.—An orange-red bitter substance contained, according to Kubly (*Bull. Soc. Chim.* [2] x. 293), in the alcoholic extract of rhubarb, and resolvable by acids into chrysophanic acid and sugar.

CHRY SOPHANIC ACID. H. Grothe (*Pogg. Ann.* cxiii. 190) has obtained this acid from the root of *Rheum pyramidalis*, also of *Rumex Patientia*, *R. palustris*, *R. acutus*, *R. aquaticus*, and *R. Hydrolapathum*, and regards it as nearly allied to the yellow colouring matter of buckwheat. J. B. Batka (*Chem. Centr.* 1864, p. 622) prepares it by treating rhubarb or the leaves or petals of senna with caustic potash, precipitating the filtrate, and dissolving the washed and dried precipitate in chloroform, which on evaporation leaves the acid in granular crystals of a pure yellow colour. The substances obtained from rhubarb-root, and known in commerce as phaeoretin and erythrorutin, are, according to Batka, nothing but impure chrysophanic acid, the former in a half-charred condition, the latter contaminated with rheitannic acid.

The composition of chrysophanic acid has been represented by the formulæ $C^{16}H^{10}O^3$ and $C^{16}H^{10}O^{12}$ (i. 959). According to Rochleder (*Zeitschr. f. Chem.* [2] v. 576), chrysophanic acid prepared from rhubarb usually contains emodin. On boiling it with soda-ley and filtering at the boiling heat, the emodin dissolves, with blood-red colour, whilst nearly all the chrysophanic acid remains undissolved, and when further purified by crystallisation from alcohol of 90 p. c. gives by analysis numbers agreeing with the formula $C^{16}H^{10}O^4$. According to Graebe a. Liebermann (*ibid.* iv. 503), chrysophanic acid is isomeric with alizarin, $C^{14}H^{10}O^4$, and when treated with zinc-dust is converted into anthracene (p. 177).

A solution of chrysophanic acid in *benzoyl chloride* heated nearly to the boiling point of the latter, gives off hydrochloric acid and yields dibenzoyl-chrysophanic acid, $C^{16}H^{12}(C^7H^5O)^2O^3$ or $C^{16}H^{12}(C^7H^5O)^2O^4$, [$C^{16}H^{12}(C^7H^5O)^2O^4$] according to Graebe a. Liebermann), as a fibro-crystalline mass, which dissolves sparingly in alcohol, and crystallises from benzol, or, better, from a mixture of benzol and absolute alcohol or amyl alcohol, in long irregularly hexagonal prisms. It melts at 200° , gives off at higher temperatures, yellow vapours smelling like bitter almond oil, and is not decomposed by ammonia; with potash-ley of sp. gr. 1.5 it gives the characteristic red colour only after long boiling; by alcoholic potash or strong sulphuric acid it is immediately resolved into benzoic and chrysophanic acids. With *acetyl chloride* chrysophanic acid yields acetyl-chrysophanic acid, which is crystallisable, but difficult to purify. Gently heated with *phosphorus pentachloride* it yields a body which reacts like chrysophanyl chloride, being converted into chrysophanic acid by boiling with water. A solution of chrysophanic acid in *fuming nitric acid* deposits after a few days large laminar crystals of chrysammic acid (p. 457) identical in every respect with that obtained from aloes (De la Rue a. Müller, *Jahresb.* 1862, p. 323).

CHRY SOPICIN. Syn. with VULPIC ACID (v. 1007).

CHRY SOTOLUIDINE. $C^{21}H^{11}N^2$.—A yellow base related to toluidine in the same manner as rosaniline to a mixture of 2 mol. toluidine and 1 mol. aniline. It is found, together with other bases, among the secondary products formed in the industrial preparation of rosaniline (p. 165), being produced by the action of dehydrogenising agents on toluidine, 3 mol. of that base giving up 3 mol. hydrogen:

Toluidine. Chrysotoluidine.

By the exchange of 3 at. hydrogen for 3 at. tolyl, phenyl, or ethyl, it is capable of yielding new colouring matters: e.g.,

(De Laire, Girard a. Chapoteaut, *Compt. rend.* Lxiii. 964.)

CHURCHITE. A hydrated calcio-cerous phosphate from Cornwall, occurring on a quartz-rock as an incrustation resembling wavellite, consisting of fan-shaped

* In the first edition the formula is erroneously printed $C^{16}H^{10}O^3$.

groups of small prisms, apparently monoclinic. Colour, pale smoke-grey, with a tinge of flesh-red; hardness, rather more than 3; sp. gr. (approximate) = 3.14. Analysis gave 51.87 p. c. CeO , 5.42 CaO , 28.48 P_2O_5 , and 14.93 water containing a little hydrofluoric acid, whence the formula:

(Church, *Chem. Soc. J.* [2] iii. 259). C. Greville Williams (*Chem. News*, xii. 183) has found by optical examination that the mineral also contains didymium.

CINCHONA-BARK. When a bark containing quinine or cinchonine is heated in a test-tube, a characteristic red vapour is given off, which condenses to an oily liquid having a splendid carmine-red colour. This reaction is not exhibited by false cinchona-barks, or by the true barks after the alkaloids have been removed from them by acids (Grahe, *Chem. Centr.* 1858, p. 97; see also Batka, *ibid.* 1859, p. 866).

Quantitative Estimation of the Alkaloids.—1. Claus (*Russ. Zeitschr. Pharm.* i. 585; *Jahresb.* 1863, p. 707) exhausts the bark, dried at 100° , with cold dilute sulphuric acid; evaporates the extract with excess of magnesia; dissolves out the quinine from the residue with ether, and the other bases with alcohol.—2. De Vrij (*Pharm. J. Trans.* [2] vi. 50) mixes the pulverised bark, dried at 100° , with one-fourth of its weight of slaked lime; boils the mixture for about five minutes with 10 pts. alcohol of sp. gr. 0.85; and then exhausts it on a filter with a large quantity of boiling alcohol. The alcoholic solution acidulated with acetic acid is next evaporated, and the residue repeatedly treated with water, as long as the filtrate becomes turbid on addition of alkali. The bases are thereby dissolved, whilst quinonic acid, fats, and resinous substances remain on the filter. The bases are then precipitated from the concentrated aqueous solution by milk of lime; and the precipitate is washed with a little water, and then exhausted at the boiling heat with alcohol of sp. gr. 1.82. The alcoholic solution, when evaporated, yields the whole of the bases, sometimes contaminated with a small quantity of resinous matter insoluble in acetic acid. The bases are redissolved in acetic acid, and the solution is agitated in a closed tap-funnel with a slight excess of caustic soda and with ether (at least 15 pts.), and the ethereal solution is separated after standing for six hours. This solution when evaporated leaves the whole of the quinine, together with traces of cinchonidine, quinidine, and cinchonine, and frequently of a fusible base. The bases insoluble in ether are redissolved in dilute acetic acid. If quinidine is present, the resulting solution, mixed with a few drops of concentrated aqueous potassium iodide, yields a sandy precipitate of quinidine hydriodide, $\text{C}_9\text{H}_9\text{N}^+\text{O}_2^- \cdot \text{HI}$, which must be weighed after drying at 100° . The filtrate yields with caustic soda a precipitate consisting of cinchonine, or of a mixture of cinchonine and cinchonidine. The presence of the latter can be determined with certainty only by its behaviour to polarised light (i. 971).

3. According to Van der Burg (*Zeitschr. anal. Chem.* iv. 273; *Jahresb.* 1865, p. 736), the extraction of the bases of cinchona-bark by lime and alcohol is not complete unless the treatment be repeated several times at the boiling heat; moreover, a certain quantity of the lime is always dissolved, increasing the total weight of the alkaloids obtained, and being ultimately reckoned as cinchonine. For the estimation of the total quantity of the bases, Van der Burg recommends the following method: The bark is exhausted by repeated boiling with alcohol, with addition of calcium hydrate; the solution is mixed with acetic acid and evaporated; and the filtered aqueous solution of the residue is precipitated with caustic soda. The precipitate is freed from colouring matter, in the manner recommended by Rabourdin (*Jahresb.* 1861, p. 533), viz. by solution in hydrochloric acid and fractional precipitation with ammonia; the pure precipitate is finally dissolved in alcohol, the solution evaporated in a platinum capsule, and the residue weighed. This gives the total amount of organic bases in the bark. As quinine and quinidine are perceptibly soluble in pure water, it is advisable, after precipitating with soda-ley and washing the precipitate, to collect the wash-water separately as soon as it ceases to exhibit alkaline reaction, agitate it with ether, and add the residue obtained by evaporating the ethereal solution to the quantity of the bases obtained by precipitation.

4. For the estimation of quinine in cinchona-barks, the following volumetric method is given by Glénard a. Guillermond (*Compt. rend.* xlvi. 831; *J. Pharm.* [3] xxxvii. 5): The finely pulverised bark (10 grms.), intimately mixed with an equal weight of slaked lime, is exhausted in a well-closed vessel with a determinate quantity (100 c.c.) of ether free from water and alcohol, and a portion (10 c.c.) of the ethereal solution is agitated with a known and excessive volume of titrated sulphuric acid [10 c.c. of which contain 0.0302 grms. H^+SO_4 , equivalent to 0.2 grms. quinine, on the supposition that the salt produced by saturation has the composition $(\text{C}_9\text{H}_9\text{N}^+\text{O}_2^-)_2 \cdot \text{H}^+\text{SO}_4$];

and the unsaturated acid is determined by titration with ammonia; the quantity of quinine which saturates the rest of the acid may then be calculated. To determine the point of saturation, Glénard a. Guillermond use, instead of litmus, an ethereal solution of the colouring matter of Campeachy wood. In a subsequent memoir (*J. Pharm.* [3] xli. 40), the same authors recommend, instead of normal sulphuric acid, an aqueous solution of oxalic acid (4.0806 grm. of the air-dried crystallised acid in a litre), and replace the aqueous ammonia by an aqueous (not alcoholic) solution of pure potassium or sodium hydrate; for determining the point of saturation they use an alcoholic extract of St. Martha wood, which, in contact with free alkali, immediately assumes a bright red colour.

From the investigations of De Vrij (*Pharm. J. Trans.* [2] v. 593; vi. 15), it appears that the root-bark of various species of cinchona cultivated on the Neilgherry mountains in British India is richer in organic bases than the stem-bark, and that the amount of these bases in the bark may be increased by careful management, inasmuch as the bark of a young stem of *C. succirubra* scarcely two years old, which had been covered with moss to accelerate the thickening of the bark, was found to contain 8.409 p. c. of cinchona-bases. In the leaves of *C. succirubra* growing at a height of 1,600 feet above the sea-level, De Vrij found 2.06 p. c. quinic acid; the same species at the height of 5,200 feet was found to contain only 1.3 p. c. quinic acid. Respecting the proportions of quinin or quinin-bitter in various parts of cinchona-trees, see QUINOVIN (v. 32).

The bark of *Cinchona macrocalyx*, Pav., known in commerce as 'China de Cuenca,' contains, according to J. K. Fischer (*Zeitschr. f. Chem.* [2] ii. 256), 2.38 p. c. organic bases, of which 0.59 p. c. consists of quinine and 1.79 p. c. of cinchonine.

De Vrij regards it as probable that cinchona-barks originally contain an amorphous base which yields amorphous salts, inasmuch as he obtained such a base from barks grown in Java, which had been dried and exhausted with acetic acid in the dark (*Jahresb.* 1866, p. 471).

Howard (*Pharm. J. Trans.* [2] vi. 584) has described and delineated the crystallised constituents of cinchona-bark (*C. succirubra*).

Respecting a brown humus-like substance obtained from certain cinchona-barks, see LIXONIN (iii. 695).

Cinchona Cultivation in India.—The cultivation of cinchona-trees has within the last ten years been carried on with great success in British India. The chief seat of the cultivation is Ootacamund, in the Neilgherries, from which it extends nearly to the southern point of Hindostan, in some places at heights of 7,000 to 8,000 feet above the sea-level. The cinchonns were first introduced at Ootacamund in 1860; in 1862 there were upwards of 72,000 plants under cultivation, more than half of which consisted of *C. succirubra*, and 1,000 of *C. Calisaya*, both valuable species. In May 1866 the numbers of different species growing at Ootacamund were as follows:

<i>Cinchona succirubra</i>	297,000
<i>Calisaya</i>	37,000
<i>officinalis</i>	758,000
Species yielding grey barks	29,000
<i>C. lancifolia</i> and <i>C. pitayensis</i>	198
<i>C. Pahudiana</i>	425

Altogether, including a few other species occurring in small numbers, 1,123,000 plants.

The cultivation was also introduced at Hakgalla in the central mountain-land of Ceylon in 1861, and at Darjeeling in the south-eastern Himalaya in 1862. Hakgalla in 1863 possessed 22,000 cinchona-trees, and in November 1865 more than 500,000, principally *C. succirubra* and *C. officinalis*. Darjeeling and Rungbee in Sikkim possessed in May 1866 more than 300,000 plants, chiefly of the same two species. From these plantations young cinchona-trees have been transplanted to other parts of India, as the Punjab, Assam, Rangoon, and Bengal, also to the islands of Mauritius and Réunion, and to Australia, New Zealand, Jamaica, and other localities where the climate and soil appear to be adapted to their cultivation (Flückiger's *Pharmakognosie des Pflanzenreiches*, Berlin, 1867, p. 422).

CINCHONA-RED (i. 969) is formed, together with sugar, by boiling quino-tannic acid with dilute sulphuric acid. When dissolved in ammonia, precipitated by hydrochloric acid, and dried at 130°, it has the composition $C^{10}H^{10}O^{14}$. Its barium-compound precipitated from the ammoniacal solution contains $C^{10}H^{10}O^{14}Ba$; the calcium-compound $C^{10}H^{10}O^{14}Ca$. Fused with potash, it yields a brown humous product, chiefly protocathechuic acid, together with a little acetic acid. The liquid

separated from the cinchona-red contains glucose (Rembold, *Ann. Ch. Pharm.* cxliii. 270).

CINCHONIDINE. $C^{20}H^{24}N^2O$.—This base and its salts have been examined by Hesse (*Ann. Ch. Pharm.* 325), with results differing in many respects from those given in vol. i. p. 971. The pure base is obtained by mixing the preparation containing quinine-salt with sodio-potassic tartrate, dissolving the resulting precipitate in hydrochloric acid, and precipitating with ammonia. On treating the bases thereby separated with ether, the cinchonidine chiefly remains undissolved, and may be purified by recrystallisation of its neutral hydrochloride.

Cinchonidine crystallises in large anhydrous prisms soluble at 10° in 76.4 pts. ether, in 19.7 pts. of 80 p. c. alcohol (in 15.3 pts. at 20°), in 1680 pts. of cold and a somewhat smaller quantity of hot water. It melts at 206.5° , and resolidifies in the crystalline form at 190° (comp. i. 971).

SALTS OF CINCHONIDINE.—The *hydrochloride*, $C^{20}H^{24}N^2O.HCl$ + aq., crystallises in large monoclinic double pyramids, dissolving at 10° in 325 pts. ether and 30.5 pts. water (at 20° in 20.1 pts.). On boiling down the solution, the salt separates in yellowish drops, which solidify in the cold to a radio-crystalline mass. The *aurochloride*, $C^{20}H^{24}N^2O.HCl.AuCl_3$, is a pulverulent mass of a fine yellow colour, melting at about 100° . The *platinochloride*, $C^{20}H^{24}N^2O.2HCl.PtCl_3$, is a pale orange-yellow crystalline powder nearly insoluble in cold water. The *dihydriodide*, $C^{20}H^{24}N^2O.2HI$ + aq., forms lemon-yellow prisms. The *nitrate*, $C^{20}H^{24}N^2O.NHIO_3$ + aq., crystallises in large prisms, melting and giving off water at about 100° , and dissolving in 70.5 pts. water at 10° . The *hypophosphite* is more soluble than the corresponding quinine salt. The *acetate*, $C^{20}H^{24}N^2O.C_2H_3O_2$ + aq., is easily soluble in water, and crystallises in nodular groups of needles. The *benzoate*, $C^{20}H^{24}N^2O.C_6H_5O_2$, forms short white prisms soluble in 340 pts. water at 10° .

Sulphates.—The neutral sulphate, $2C^{20}H^{24}N^2O.SH_2O^4$ + 6aq., forms white prisms, becoming anhydrous at 100° ; insoluble in ether, but dissolving in 97.5 pts. water at 12° . The anhydrous salt is also crystallisable under certain circumstances, and exhibits the peculiarity of producing other anhydrous salts by double decomposition. The *acid salt*, $C^{20}H^{24}N^2O.SH_2O^4$ + 5aq., crystallises in long striated efflorescent prisms easily soluble in water and in alcohol. The *hyperacid salt*, $C^{20}H^{24}N^2O.2SH_2O^4$ + 2aq., separates from the solution of the preceding salt in dilute sulphuric acid, by evaporation over sulphuric acid, in short prisms insoluble in ether and dissolving but slowly in cold water. The *hyposulphite*, $C^{20}H^{24}N^2O.S_2H_2O^4$ + 2aq., forms thin prisms which dissolve at 10° in 221 pts. water, become anhydrous at 110° , but reabsorb their entire amount of water on exposure to the air. The *neutral oxalate*, $2C^{20}H^{24}N^2O.C_2H_2O^4$ + 6aq., crystallises in long asbestos-like prisms, soluble in 252 pts. of water at 10° ; the anhydrous salt in white nodules. The *succinate* forms prisms soluble in 582.5 pts. water at 10° . The *neutral tartrate*, $2C^{20}H^{24}N^2O.C_4H_4O^8$ + 2aq., is a white crystalline precipitate perfectly insoluble in potassio-sodic tartrate, separating from hot water in prisms, requiring for solution 1265 pts. water at 10° . As neutral tartrate of cinchonine is soluble in 35.6 pts. water at 16° , cinchonine and cinchonidine may be easily separated from one another in the form of tartrates. *Cinchonidine-antimonious tartrate* is easily soluble in hot water and in alcohol, and crystallises in prisms. The *citrate* forms prisms which are converted by water into a basic salt. The *hydroferricyanide* is an egg-yellow precipitate composed of spherical crystalline aggregates, or of laminae.

CINCHONINE. $C^{20}H^{24}N^2O$.—Hesse (*Ann. Ch. Pharm.* cxxii. 226) has shown that the base called β -cinchonine, obtained by Schwabe from commercial quinoidine (i. 974), does not differ in any respect from ordinary cinchonine.

Cinchonine sublimes partially at 220° and melts at 240° – 250° (Hesse); 1 pt. of it (dried at 100°) dissolves in 2118 pts. ether at 170° (Van der Burg, *Zeitschr. anal. Chem.* iv. 273). From a solution containing tartaric acid it is not precipitated by acid sodium carbonate at ordinary temperatures; but on heating the liquid, carbon dioxide escapes and cinchonine is precipitated. Some of the neutral salts, as the acetate and citrate, are decomposed, and yield a precipitate of the base, even when heated with water (Hesse). According to Schützenberger (*Compt. rend.* xli. 1065), cinchonine treated with zinc and sulphuric acid takes up H^2O and is converted into a new base, $C^{20}H^{24}N^2O^4$.

SALTS OF CINCHONINE (Hesse, *Ann. Ch. Pharm.* cxxii. 226; cxxiv. 326).—The *hydriodide*, $C^{20}H^{24}N^2O.HI$ + aq., separates on adding potassium iodide to a solution of the hydrochloride, partly as a pale yellow oil which solidifies to a crystalline mass, partly in slender white crystals. The *hydrochloride*, $C^{20}H^{24}N^2O.HCl$ + 2aq.,

crystallises in the form described by Schwabe (for the so-called β -salt, i. 975). The crystals are permanent in the air, effloresce over sulphuric acid, give off their water at 100° , and melt at 130° . Sp. gr. of the powder = 1.234. One part of the salt dissolves at 10° in 24 pts. water; at 16° in 1.3 pts. alcohol and 273 pts. ether. The *stannouschloride*, $C^{20}H^{21}N^2O \cdot 2HCl \cdot SnCl_2$, separates in heavy yellow prisms from a mixture of the hydrochloride with acidulated stannous chloride. The *zincchloride*, $C^{20}H^{21}N^2O \cdot 2HCl \cdot ZnCl_2 + aq.$, separates in flattened prisms from an alcoholic solution of cinchonine mixed with zinc chloride, and then with sufficient hydrochloric acid to redissolve the precipitate. A solution of this salt in excess of hydrochloric acid deposits the easily soluble salt $2(C^{20}H^{21}N^2O \cdot 3HCl)ZnCl_2 + 3aq.$ The *aurochloride*, $C^{20}H^{21}N^2O \cdot 2HCl \cdot AuCl_3$, is a heavy light-yellow powder, melting at a little above 100° to a dark yellow mass. The *nitrate*, $C^{20}H^{21}N^2O \cdot NHO^3 + \frac{1}{2}aq.$, forms monoclinic twin-crystals soluble in 26.4 pts. water. The *benzoate*, $C^{20}H^{21}N^2O \cdot C^7H^5O^2$, crystallises in stellate groups of anhydrous prisms soluble in 163 pts. water at 15° . The *sulphate*, $2C^{20}H^{21}N^2O \cdot SH^2O^4 + 2aq.$, dissolves in 65.5 pts. water at 13° and in 5.8 pts. alcohol (of 80 p. c.) at 11° . The *hyposulphite*, $2C^{20}H^{21}N^2O \cdot S^2H^2O^3 + 2aq.$, forms rhombic prisms m.p. ∞ . $\rho P (?)$, soluble in 157 pts. water at 16° . The *chromate*, $2C^{20}H^{21}N^2O \cdot CrH^2O^4$, is deposited on mixing the hydrochloride with a gently warmed solution of potassium dichromate, in small ochre-yellow prisms, which decompose in the moist state on exposure to light. The *phosphate*, $2C^{20}H^{21}N^2O \cdot PH^2O^4 + 12aq.$, forms concentrically grouped prisms easily soluble in water. The *arsenate*, $2C^{20}H^{21}N^2O \cdot AsH^2O^4 + 12aq.$, forms long prisms, easily soluble in water (Hesse). An aqueous solution of a cinchonine salt gives with *sodium sulpharsenate* a bulky precipitate soluble in excess of the reagent (Mosing, *Zeitschr. f. Chem.* [2] v. 353). The *oxalate*, $2C^{20}H^{21}N^2O \cdot C^2H^2O^4 + 2aq.$, crystallises in large prisms soluble in 101 pts. water at 10° . The *acid succinate*, $C^{20}H^{21}N^2O \cdot C^4H^3O^4$, crystallises in long oblique-angled needles containing $\frac{1}{2}H^2O$, or in large thick crystals with H^2O , both forms melting at 110° , and dissolving easily in water. The *acid tartrate*, $C^{20}H^{21}N^2O \cdot C^4H^3O^6 + 4aq.$, forms small prisms dissolving in 101 pts. water at 16° with acid reaction. The *neutral tartrate*, $2C^{20}H^{21}N^2O \cdot C^4H^3O^6 + 2aq.$, is less fusible than the acid salt, has a slight alkaline reaction, and when dehydrated, quickly reabsorbs its full amount of water on exposure to the air. *Cinchonine-antimonious tartrate*, obtained by decomposing the sulphate with bario-antimonious tartrate, crystallises from water, partly in white, easily efflorescing nodules containing 24.7 p. c. water, partly in large crystals resembling salt-petre and containing from 9.8 to 10 p. c. water. The compound dried at 100° contains 26.2 to 26.5 p. c. antimony and 47.48 p. c. cinchonine. The *acid citrate*, $2C^{20}H^{21}N^2O \cdot C^6H^5O^7 + 4aq.$, forms small prisms soluble in 55.8 pts. water at 15° . The *neutral citrate*, $3C^{20}H^{21}N^2O \cdot C^6H^5O^7 + 4aq.$, separates on evaporating its alcoholic solution, as a colourless oil which solidifies in long concentrically grouped prisms. The *picrate*, $2C^{20}H^{21}N^2O \cdot 3C^8H^3(NO^2)_2O$, is obtained as a yellow precipitate resembling lead iodide, on mixing cinchonine hydrochloride with a gently warmed solution of picric acid (Hesse).

Action of Potassium Permanganate on Cinchonine (Caventou a. Willm, *Zeitschr. f. Chem.* [2] v. 517).—When a cold-saturated solution of potassium permanganate is added by drops to a solution of about an equal quantity of cinchonine sulphate, likewise kept cool and acidulated with sulphuric acid, carbon dioxide is evolved, and the following products are formed:

1. Hydrocinchonine, $C^{20}H^{21}N^2O$.—2. Cinchotennine, an indifferent body which unites both with acids and with bases, but without forming well-defined compounds.—3. Carboxycinchonic acid.—4. A substance which reduces cupric oxide in alkaline solution. The last three are products of oxidation.

Hydrocinchonine, $C^{20}H^{21}N^2O$, melts at 268° , deflects the plane of polarisation to the left, but less strongly than cinchonine; it is insoluble in water; a litre of 90 p. c. alcohol dissolves 7.25 grm. of it at 15° ; at higher temperatures it is more soluble and separates on cooling in small silky needles. It forms well-crystallised salts, soluble in water and having a bitter taste. The *platinchloride*, $C^{20}H^{21}N^2O \cdot 2HCl \cdot PtCl_4$, forms rather large shining crystals. It is but slowly attacked by potassium permanganate.

1. *Cinchotennine*, $C^{20}H^{21}N^2O^3$, the most abundant of the oxidation products, separates from a boiling aqueous solution in silver-white silky crystals, but slightly soluble in cold water and in alcohol, even at the boiling heat. It turns the plane of polarisation to the left, but less strongly than cinchonine. It has a neutral reaction, and dissolves both in acids and in alkalis, but is insoluble in strong potash-ley. From its solution in baryta-water it is precipitated by carbonic acid. It forms a crystallisable platinchloride. With silver nitrate it forms a white precipitate and reduces the silver when heated. It is but slowly attacked by potassium permanganate even with aid of heat.

Carboxycinchonio acid, $C^{11}H^{11}N^2O^4$, is formed from cinchonine by addition of water, as well as by oxidation. Its formation appears to take place only when the evolution of carbon dioxide becomes energetic, and is perhaps analogous to that of benzoic acid by oxidation of benzene. It is moderately soluble in water, especially when hot, and crystallises in hard shining anhydrous prisms. 100 pts. alcohol dissolve 1·8 pts. of it in the cold, somewhat more than 3 pts. at the boiling heat. It is bibasic, and forms with the alkalis and with baryta, easily soluble salts, difficult to crystallise. The *cupric salt* $C^{11}H^{11}N^2O^4Cu$ is formed as an amorphous blue-green precipitate, which quickly becomes crystalline and deep blue. The *silver salt* $C^{11}H^{11}N^2O^4Ag^2$ is a very permanent crystalline precipitate. The acid likewise dissolves in hydrochloric, sulphuric acid, &c., and forms a *platinochloride* crystallising in orange-yellow laminae sparingly soluble in water.

CINCHOTENINE. See the last article.

CINNAMENIN. Benzyl Cinnamate. (See CINNAMIC ETHERS, p. 470.)

CINNAMENE or **CINNAMOL.** $C^{10}H^8$.—According to Berthelot (*Compt. rend.* lxiii. 518), cinnamene produced by the dry distillation of cinnamates is not identical in its physical properties with styrol from storax. Styrol is optically active, turning the plane of polarisation 3° to the left in a layer 100 mm. thick, whereas cinnamene is optically inactive. Moreover, styrol is more easily converted than cinnamene into polymerides under the influence of heat and of chemical reagents; and when mixed with $1\frac{1}{2}$ times its weight of strong sulphuric acid it gives off a larger quantity of heat, viz. 30,000 heat-units for the molecule $C^{10}H^8$, whereas cinnamene gives only three-fourths of that quantity. But the difference between the two is purely physical; in chemical properties and reactions, and therefore doubtless in the arrangement of the atoms in their molecules, they are absolutely identical.

Cinnamene (or styrol) is produced: 1. By polymerisation of acetylene. It has in fact the composition of tetracetylene, $(C^2H^2)^4$, and is formed, together with other polymerides, when acetylene is heated in a sealed glass tube over mercury to the softening point of the glass. It constitutes about $\frac{1}{2}$ of the liquid product thus obtained, passes over on fractionally distilling that liquid between 135° and 160° , and is identical in every respect with the cinnamene obtained from cinnamates (Berthelot, *Compt. rend.* lxii. 905, 947; see also ACETYLENE, p. 32).

2. When a mixture of ethylene and benzene or diphenyl is passed through a red-hot tube (Berthelot, *Jahresb.* 1866, pp. 545, 546):

and

3. Together with benzene and several other hydrocarbons, when ethylene alone is passed through a red-hot porcelain tube (Berthelot, *Zeitschr. f. Chem.* [2] iv. 384).

4. Together with other hydrocarbons, by passing the vapour of ethyl-benzene (p. 292) through a red-hot tube (Berthelot, *Zeitschr. f. Chem.* [2] iv. 689):

5. By abstraction of HBr from styryl bromide, (C^8H^7Br) (produced by the action of bromine-vapour on ethyl-benzene at the boiling heat), which may be effected by heating the bromide with alcoholic potash to 180° . Under these circumstances, the cinnamene is at first converted into metacinnamene, and the product when distilled yields, above 300° , a mixture of cinnamene with an oxidised body (probably styrylic ether, $C^8H^{10}O$); by a second distillation the cinnamene is obtained pure. Cinnamene is also obtained, in small quantity and as a secondary product, when styryl bromide is heated with sodium, or when it is made to act on certain salts (alkaline acetates and benzoates) at 180° (Berthelot, *loc. cit.*).

Reactions.—1. Cinnamene-vapour passed through a red-hot tube is partly resolved into benzene and acetylene (or its products of condensation), according to the equation $C^{10}H^8 = C^6H^6 + C^2H^2$.—2. When heated in a sealed tube filled with *Hydrogen*, it is resolved into benzene and ethylene; thus:

(Berthelot, *Jahresb.* 1866, p. 544).—3. A mixture of cinnamene and *ethylene* passed through a red-hot tube yields large quantities of benzene and naphthalene, the first produced by breaking up of the cinnamene molecule, as above; the second according to the equation:

Sup.

H H

4. A mixture of cinnamene and benzene vapours similarly treated yields anthracene as principal product, together with smaller quantities of naphthalene and a hydrocarbon resembling diphenyl (Berthelot, *ibid.* p. 545):

Cinnamene. Benzene. Anthracene.

5. Cinnamene shaken up with an alkaline solution of potassium permanganate is converted into benzoic and carbonic acids (Berthelot, *ibid.* 1867, p. 337):

6. Cinnamene treated with 80 pts. of saturated aqueous hydriodic acid yields as principal product octane, C^8H^{18} , boiling at 115° – 120° , together with small quantities of ethane and septane:

Cinnamene.

Octane.

Cinnamene.

Ethane. Septane.

With 20 pts. of the acid, it is converted for the most part into styryl hydride, C^8H^{10} (ethyl-phenyl?), while benzoic, ethane, and a resinous hydrocarbon of high boiling point occur as secondary products:

(Berthelot, *Jahresb.* 1867, p. 449).

7. When cinnamene is agitated with a concentrated solution of iodine in potassium iodide, and the liquid is then diluted with water, a beautifully crystallised iodide of cinnamene separates, which dissolves easily in ether and in hydrocarbons, is not decomposed by sulphurous acid and sodium carbonate, but splits up spontaneously after some time into iodine and a resinous substance (Berthelot).

8. With bromine, cinnamene forms the crystallised bromide $C^8H^8Br^2$ (i. 982).

9. With chlorine, cinnamene yields a liquid product, which is quickly converted by strong sulphuric acid into polymerides, partly volatilising without decomposition when heated above 300° , and therefore not identical with metacinnamene (Berthelot).

10. Fuming nitric acid acts strongly on cinnamene, separating a resinous body, and forming a solution which on evaporation deposits a similar resinous substance, insoluble in ether, remaining behind for the most part when distilled with water, and not yielding any volatile basic product by distillation with iron-filings and acetic acid. Other polymerides of acetylene exhibit a similar reaction with nitric acid (Berthelot).

The last four reactions, together with the conversion into metacinnamene by heating in closed vessels, are recommended by Berthelot (*Bull. Soc. Chim.* [2] vi. 295) for the detection and isolation of cinnamene.

For the detection of cinnamene in coal-tar—in which it is likely to occur in consequence of its formation, as above described, from benzene and other hydrocarbons at high temperatures—the crude light coal-naphtha, not yet treated with strong sulphuric acid, is agitated with soda-ley and with dilute sulphuric acid; then washed and fractionally distilled; and the portion collected after frequent rectifications between 144° and 150° is heated to 200° for several hours in a sealed tube. The contents of the tube are then distilled at about 300° , and the residue is more strongly heated, whereby a mixture of regenerated cinnamene and difficultly volatile hydrocarbons is obtained, from which the cinnamene may be separated by renewed distillation and tested as above. The liquid passing over between 144° and 150° was found to contain 2 p. c. cinnamene. Coal-tar naphtha purified in the ordinary way with strong sulphuric acid cannot contain cinnamene, since this hydrocarbon is thereby converted into polymeric modifications, which remain in the less volatile residue (Berthelot, *loc. cit.*).

Dicinnamene or *Distyrol*, $C^{16}H^{16}$, is produced, together with carbon dioxide, by heating cinnamic acid to 150° – 240° with aqueous hydrobromic acid (sp. gr. 1.35), with hydrochloric acid (sp. gr. 1.12), or with sulphuric acid diluted with 2 pts. water. It unites with bromine, forming the crystalline compound $C^{16}H^{16}Br^2$. It is not converted into metacinnamene by prolonged heating to 200° (Erlenmeyer, *Ann. Ch. Pharm.* cxxxv. 122).

CINNAMIC ACID. $C^8H^8O^2$.—Produced: 1. According to Harnitz-Harnitzky (*Ann. Ch. Pharm.* cxi. 192), by the action of chlorethylidene (obtained by the action of carbonyl chloride on aldehyde) on barium benzoate:

CINNAMIC ACID.

Kraut (*Zeitschr. f. Chem.* [2] v. 147) did not obtain cinnamic acid by this reaction.
 —2. By the action of carbon dioxide and sodium on bromocinnamene dissolved in ether (just as benzoic acid is formed from bromobenzene):

(Th. Swarts, *Ann. Ch. Pharm.* cxxxvii. 229; *Bull. Soc. Chim.* [2] vi. 61).

3. By the action of bromine on hydrocinnamic acid (Glaser, *Jahresb.* 1866, p. 367):

The decomposition of cinnamic acid by fusion with potash into benzoic and acetic acids, with evolution of hydrogen (i. 984), according to the equation

is analogous to that of the acrylic acids (p. 41), and shows that cinnamic acid may be regarded as phenyl-acrylic acid:

This view of its constitution is also in accordance with its formation from acetyl chloride and benzoic aldehyde (i. 983), and from chlorethylidene and barium benzoate.

Reactions.—1. Cinnamic acid shaken up with water and sodium-amalgam, in the proportion of 1 at. sodium to 1 mol. cinnamic acid, is converted into hydrocinnamic acid, $\text{C}^6\text{H}^5\text{O}^2$ (Erlenmeyer, *Ann. Ch. Pharm.* cxxxvii. 227).—2. It is also converted into hydrocinnamic acid by heating it to 100° with very strong aqueous hydriodic acid (Popoff, *Zeitschr. f. Chem.* [2] i. 111):

3. When gradually heated to 190° – 200° with hydrochloric acid, it yields an indifferent chlorinated oil, probably $\text{C}^6\text{H}^5\text{Cl}$, together with carbon dioxide; and reacts in like manner with hydrobromic acid (Schwartz, *loc. cit.*). According to Erlenmeyer, hydrochloric acid of sp. gr. 1.12 and hydrobromic acid of sp. gr. 1.35 convert it at 150° – 240° into dicinnamene, $\text{C}^{12}\text{H}^{14}$.

4. Heated with water to 180° – 200° for about a week, it is decomposed, with formation of cinnamene (Schwartz). According to Erlenmeyer, it is not decomposed by heating with water to 230° , but when heated in the dry state to 240° , it slowly gives off carbon dioxide.

5. Bromine-vapour is absorbed by cinnamic acid at ordinary temperatures or at 100° , with formation of dibromo-hydrocinnamic acid, $\text{C}^6\text{H}^5\text{Br}^2\text{O}^2$ (A. Schmitt, *Ann. Ch. Pharm.* cxxvii. 319).

6. Cinnamic acid unites directly with hypochlorous acid, forming phenyl-chlorolactic acid, $\text{C}^6\text{H}^5\text{ClO}^2$:

With free cinnamic acid this reaction does not take place very readily; but when chlorine is passed in a slow stream into a dilute solution of cinnamic acid in sodium carbonate till the liquid loses its alkaline reaction and acquires bleaching properties, phenyl-chlorolactic acid is easily formed. The solution freed from excess of chlorine and hypochlorous acid by sulphurous acid, and then treated with hydrochloric acid, yields phenyl-chlorolactic acid in prismatic crystals. This acid treated with sodium-amalgam is converted into phenyl-lactic acid, $\text{C}^6\text{H}^5\text{O}^2$, or phenyl-oxypropionic acid, $\text{C}^6\text{H}^5(\text{HO})\text{O}^2$, which, when treated with hydrochloric, hydrobromic, or hydriodic acid, takes up Cl, Br, or I in place of HO, forming phenyl-chloropropionic acid, $\text{C}^6\text{H}^5\text{ClO}^2$, $\text{C}^6\text{H}^5\text{BrO}^2$, or $\text{C}^6\text{H}^5\text{IO}^2$, &c. In like manner, phenyl-chlorolactic acid, $\text{C}^6\text{H}^5\text{ClO}^2$, or $\text{C}^6\text{H}^5(\text{HO})\text{ClO}^2$, treated with hydrochloric acid, takes up Cl in place of HO, forming phenyl-dichloropropionic acid, $\text{C}^6\text{H}^5\text{Cl}^2\text{O}^2$; and similarly with hydrobromic acid it forms phenyl-chlorobromopropionic acid, $\text{C}^6\text{H}^5\text{ClBrO}^2$. Lastly, phenyl-chlorolactic acid, treated with alkalis, yields a chloride of alkali-metal, together with phenyl-oxyacrylic or oxycinnamic acid:

The relation of these several derivatives to cinnamic acid is exhibited by the following formulae:

Phenyl-acrylic (cinnamic) acid	$C^6H^5 \cdot C^8H^7O^2$
Phenyl-chlorolactic acid	$C^6H^5 \cdot C^8H^7(ClHO)O^2$
Phenyl-dichloropropionic acid	$C^6H^5 \cdot C^8H^7(Cl^2)O^2$
Phenyl-bromochloropropionic acid	$C^6H^5 \cdot C^8H^7(BrCl)O^2$
Phenyl-lactic acid	$C^6H^5 \cdot C^8H^7(HOH)O^2$
Phenyl-chloropropionic acid	$C^6H^5 \cdot C^8H^7(HCl)O^2$
Phenyl-oxyacrylic (oxycinnamic) acid	$C^6H^5 \cdot C^8H^7(O)O^2$

Brominated and iodated compounds analogous to the chlorinated bodies in the above table are formed by precisely similar reactions, and the monobrominated and mono-iodated propionic acids are also converted by alkalis into oxycinnamic acid (Glaser, *Ann. Ch. Pharm.* cxlviii. 78; *Zeitschr. f. Chem.* [2] iii. 65; iv. 131; *Jahresb.* 1867, p. 418). For details respecting these acids, see LACTIC ACID and PROPIONIC ACID.

Bromocinnamic Acid. $C^6H^7BrO^2$ (Glaser, *Ann. Ch. Pharm.* cxliii. 325; *Jahresb.* 1866, p. 367).—When bromine acts at ordinary temperatures on hydrocinnamic acid, two brominated acids are formed by successive substitution, viz. $C^6H^7BrO^2$ and $C^6H^5Br^2O^2$, the latter of which is isomeric with the dibromide of cinnamic acid (or dibromo-hydrocinnamic acid), which Schmitt obtained by direct addition of bromine to cinnamic acid (p. 467). This dibrominated acid treated with alcoholic potash solution gives up HBr and yields two isomeric monobromocinnamic acids, $C^6H^7BrO^2$. To prepare these acids, the crude product of the action of bromine-vapour on cinnamic acid is dissolved in a small quantity of boiling alcohol, and an alcoholic solution of potash is added to it by portions in slight excess. It then deposits, first, white crystalline flocks of α -bromocinnamic acid, then an oily mixture, and ultimately nearly pure β -bromocinnamic acid; the complete separation of the two isomeric acids must be effected by fractional precipitation.

α -Bromocinnamic acid, $C^6H^7BrO^2$, separated from its ammonium salt, crystallises from boiling water in long shining four-sided needles, soluble in all proportions of alcohol, easily soluble also in alcoholic ether, less soluble in pure ether. It melts at 130° – 131° , crystallises in needles on cooling, and distils for the most part without decomposition. The ammonium salt $C^6H^7BrO^2 \cdot NH^4$ forms flat needles generally united in arborescent groups, moderately soluble in water and in alcohol. The potassium salt crystallises in needles easily soluble in water and in alcohol. The silver salt $C^6H^7BrO^2 \cdot Ag$ is sparingly soluble in water, and is resolved by heating with water to 150° into the free acid and a basic salt, without formation of silver bromide. The barium salt $(C^6H^7BrO^2)_2Ba$ crystallises in thin rhombic laminae, slightly soluble in cold water, insoluble in alcohol. The zinc salt forms laminae easily soluble in hot water; the cadmium salt large flat shining prisms; the lead salt crystallises from hot water in thin rhombic laminae.

α -Bromocinnamic acid is converted by contact with bromine into an acid richer in bromine, melting at 132° , and crystallising in needles. By sodium-amalgam it is converted into hydrocinnamic acid:

β -Bromocinnamic acid, $C^6H^7BrO^2$, purified by fractional precipitation as above mentioned, is a light snow-white powder composed of six-sided laminae. It is easily soluble in boiling water, and separates therefrom in large flat six-sided crystals, from ether in well-defined thick prisms. It melts at 120° , and is converted by distillation or by boiling with fuming hydriodic acid into α -bromocinnamic acid. Heated to 180° with weak soda-ley, it is resolved into carbon dioxide and a non-brominated oil boiling at about 160° . It is also converted by sodium-amalgam into hydrocinnamic acid. Its salts are totally different from those of the α -acid. The potassium salt $C^6H^7BrO^2 \cdot K$ forms slender very deliquescent needles easily soluble in alcohol. The silver salt $C^6H^7BrO^2 \cdot Ag$ is a white curly precipitate, which becomes crystalline on standing and is decomposed by boiling; at 120° it is resolved into the free β -acid and a basic salt; at 170° into α -bromocinnamic acid, carbon dioxide, silver bromide, and an aromatic oil.

β -Bromocinnamic acid exposed to the action of bromine-vapour is converted into a crystalline acid richer in bromine, which melts at 45° and 48° , and is decomposed by boiling water, with formation of a volatile oil having an odour different from that of the acid itself.

Hydrocinnamic Acid. $C^6H^5O^2$. *Homotoluic acid*, *Cumoylic acid*, *Phenylpropionic acid* (Erlenmeyer, *Zeitschr. Ch. Pharm.* 1862, p. 176; 1863, p. 307; *Zeitschr. f. Chem.* 1866, p. 206; *Ann. Ch. Pharm.* cxxvii. 327. A. Schmitt, *ibid.* cxxvii. 319. Popoff, *Bull. Soc. Chim.* [2] iv. 375. Fittig, *Zeitschr. f. Chem.* 1869,

p. 166).—This acid, isomeric with xylic, and homologous (in composition at least) with toluic acid, is produced: 1. By the action of sodium-amalgam on cinnamic acid. Pulverised cinnamic acid is agitated in a stoppered vessel with 20 to 24 times its weight of water and a quantity of sodium-amalgam containing 1 at. sodium to 1 mol. cinnamic acid, till the liquid becomes neutral or nearly so; a second and somewhat larger quantity of sodium-amalgam is then added; and the reaction is continued, with frequent agitation, till hydrogen gas is given off in regular bubbles. The resulting sodium salt is then neutralised with sulphuric acid; the solution is evaporated; the mother-liquor decanted from the crystallised sodium sulphate is supersaturated with sulphuric acid; and the hydrocinnamic acid which separates as an oil, but soon solidifies, is pulverised, washed with water, then distilled, and dissolved in boiling water, from which it separates at low temperatures in needles, or from a solution saturated at the boiling heat, as an oil which afterwards solidifies (Erlenmeyer).

2. By the action of sodium-amalgam on dibromohydrocinnamic acid, $C^9H^8Br^2O^2$, which is produced by direct addition of bromine to cinnamic acid (Schmitt).

3. By heating cinnamic acid with concentrated hydriodic acid: $C^9H^7O^2 + 2HI = C^9H^{10}O^2 + I^2$ (Popoff).

4. From ethyl-benzene, $C^8H^8 \cdot CH^2CH^3$, by passing chlorine into that compound at the boiling heat, whereby it is converted into phenyl-ethyl chloride, $C^8H^8 \cdot CH^2CH^2Cl$; converting this chloride into the corresponding cyanide by heating it with potassium cyanide and alcohol in a flask provided with an upright condensing tube; and heating the decanted alcoholic solution of phenyl-ethyl cyanide with solid caustic potash in a similar apparatus as long as ammonia is given off. On subsequently distilling off the alcohol, acidulating the remaining liquid with sulphuric acid, repeatedly agitating with ether, and distilling off the ether from the resulting solution, a yellow liquid acid is left, which solidifies after standing and repeated agitation with cold water. By converting this acid into a calcium salt, and decomposing the latter with hydrochloric acid, an acid is obtained identical in every respect with the hydrocinnamic acid obtained by the preceding methods. Its formation from phenyl-ethyl cyanide is represented by the equation:

This reaction is exactly similar to that by which ethyl cyanide is converted into propionic acid, and shows that hydrocinnamic acid has the constitution of phenyl-propionic acid (Fittig).

Hydrocinnamic acid melts at 47° (Erlenmeyer), at 46.5° (Fittig), and boils at 280° under a pressure of 754 mm. (Erlenmeyer). Its vapours condense to a liquid, which when at perfect rest may be cooled to 25° without solidifying; but when touched with a solid body immediately solidifies to a radiate mass of long needles, the temperature at the same time rising to 42° . It dissolves in 168 pts. water at 20° , much more easily in boiling water, and volatilises with vapour of water; it dissolves in alcohol, and separates therefrom in prisms apparently belonging to the monoclinic system; also in ether, chloroform, benzol, carbon bisulphide, and glacial acetic acid. Its salts are mostly crystallisable, and the solution of the potassium salt is not precipitated by salts of calcium, barium, magnesium, nickel, cobalt, or manganese; with silver nitrate, zinc sulphate, cupric nitrate, mercuric chloride, ferric chloride, and chromic chloride it gives flocculent precipitates; with lead acetate a glutinous precipitate. The silver salt $C^9H^7O^2Ag$ crystallises from water in nacreous laminae; the potassium, barium, calcium, and lead salts in needles; the copper salt is a pale green powder (Erlenmeyer). The calcium salt dried over sulphuric acid contains, according to Fittig, $2(C^9H^7O^2) \cdot Ca \cdot 3H^2O$.

Methyl hydrocinnamate, $C^9H^9O^2 \cdot CH^3$, is a liquid having a peculiar odour, a sp. gr. of 1.0455 at 0° , and 1.0180 at 49° , and boiling at 238° – 239° . The *ethyl ether* $C^9H^9O^2 \cdot C^2H^5$ smells like pine-apples, has a sp. gr. of 1.0343 at 0° , 0.9925 at 49° , and boils at 247° – 249° . The *amyl ether* $C^9H^9O^2 \cdot C^5H^{11}$ has a faint and stupefying odour, a sp. gr. of 0.9807 at 0° , 0.9520 at 49° , and boils at 291° – 293° .

Hydrocinnamic acid is oxidised by chromic acid mixture, giving off carbon dioxide

even at ordinary temperatures, and on distilling the liquid benzoic acid is given off, together with an oily body. Heated with soda-lime or potassium hydrate, it gives off first benzoic acid, and afterwards a yellow liquid containing hydrocarbons (toluene), and perhaps also ketones (Erlenmeyer).

Dibromohydrocinnamic or **Dibromo-phenylpropionic acid**, $C^6H^3Br^2O^2$, is formed by direct combination when bromine-vapour is passed over cinnamic acid at 100° ; liquid bromine is less readily absorbed. The brominated acid is insoluble in cold water, easily soluble in ether and in alcohol, crystallises from the latter in colourless rhombic laminae, has a bitter taste, and is not volatile without decomposition. Its **barium salt** $(C^6H^3Br^2O^2)_2Ba$, obtained by saturation, is easily decomposable, dissolves readily in water, alcohol, and ether, and crystallises in microscopic four-sided plates. The **sodium salt** $C^6H^3Br^2O^2Na$ is somewhat more stable; its solution gives precipitates with lead acetate, stannic chloride, and mercurous nitrate. The acid, $C^6H^3Br^2O^2$, boiled with water, gives off a neutral brominated oil having an odour of hyacinths, and the residual liquid deposits a crystalline body, difficult to purify, but probably consisting of $C^6H^3Br^2O^2$. The dibrominated acid is converted by sodium-amalgam into hydrocinnamic acid, together with a small quantity of another acid (not yet analysed), which is soluble in water and crystallises in large prisms (A. Schmitt, *loc. cit.*).

Oxycinnamic or **Phenyl-oxyacrylic acid**, $C^6H^3O^2 = C^6H^3 \cdot C^3H^2(O)O^2$ or $C^6H^3 \cdot C^3H^2(HO)O^2$, is produced by the action of alkalis on phenyl-chlorolactic or phenyl-bromolactic acid (p. 467). To prepare it, the alcoholic solution of the chlorinated or brominated acid is stirred up with an alcoholic solution of potash, soda, or ammonia, in sufficient quantity to render the liquid alkaline; the precipitate, consisting of metallic chloride or bromide, together with a salt of oxycinnamic acid, is collected on a filter after a few hours, washed with cold alcohol, and then digested with boiling alcohol, which dissolves out the oxycinnamate, and deposits it in the crystalline form on cooling. From the moderately dilute solution of this salt, the acid $C^6H^3O^2$ is precipitated by a stronger acid, as an oil which when cooled nearly to 0° solidifies in shining crystalline spangles. It is very unstable, changing soon after preparation into a resinous substance, with evolution of carbon dioxide, and being resolved by boiling with water into carbon dioxide and a volatile oil, probably oxycinnamene, C^6H^3O . It is resinised by heating with hydrochloric or hydrobromic acid.

Potassium oxycinnamate, $C^6H^3O^2K$, forms nacreous laminae easily soluble in hot water, but gradually decomposing in the aqueous solution into carbon dioxide and a colourless resin. The **sodium salt** $C^6H^3O^2Na$ crystallises in tufts of flat needles; the **ammonium salt** in small prisms. The **silver salt** $C^6H^3O^2Ag$ is sparingly soluble, and may be obtained by precipitation, or directly from phenyl-chlorolactic acid by slightly supersaturating with ammonia, and cautiously adding silver nitrate, so as first to decompose the ammonium chloride in the solution, and then precipitate the silver oxycinnamate from the filtrate. From a solution in boiling water, prepared in the dark and rapidly cooled, it is deposited as a crystalline powder consisting of six-sided laminae, easily altered by heat and light. The **barium salt** is obtained by double decomposition as a white precipitate which crystallises from boiling dilute alcohol in small needles. The **ethyl ether** $C^6H^3O^2 \cdot C^2H^5$, formed by the action of ethyl-iodide on the silver salt, is a liquid of agreeable fruity odour, and boiling at 279.5° (corr.), with partial decomposition. When boiled with baryta-water it is decomposed, with separation of barium carbonate.

Thiocinnamic Acid. C^6H^3OS .—Cinnamyl chloride, C^6H^3OCl , acts strongly on lead sulphethylate (mercaptide), forming lead-chloride, and an oil soluble in ether but insoluble in water, which boils with partial decomposition at 250° , and when boiled with alcoholic potassium sulphhydrate, gives off mercaptan, and yields crystalline nodules of potassium thiocinnamate, C^6H^3OSK (Engelhardt, Latschinoff a. Malyschew, *Zeitschr. f. Chem.* [2] iv. 359).

CINNAMIC ETHERS. **Ethyl Nitrocinnamate**, $C^6H^3(NO^2)O^2 \cdot C^2H^5$, is easily produced by dissolving ethyl cinnamate in very concentrated nitric acid. Treated with tin and hydrochloric acid, it yields colourless crystals consisting of a compound of stannous chloride with the hydrochloride of ethyl amido-cinnamate, $2[C^6H^3(NH^2)O^2 \cdot C^2H^5 \cdot HCl] \cdot SnCl^2 + 3aq.$, which, when freed from tin by hydrogen sulphide, yields colourless crystals of the *hydrochloride of ethyl amidocinnamate* (J. v. Rossum, *Jahresb.* 1866, p. 365).

Benzyl Cinnamate, $C^6H^3O^2 \cdot C^6H^5$. **Cinnamein** (i. 980).—This ether is obtained in the pure state by boiling a mixture of benzyl chloride, alcohol, and well-dried sodium cinnamate in a flask with upright condenser for several hours, till

no more sodium cinnamate separates out on cooling. On distilling off the alcohol, adding water, washing the pasty precipitate with an alkaline solution to remove free cinnamic acid, then agitating with ether, and evaporating the ethereal solution over the water-bath, an oily liquid remains, which when distilled in a vacuum yields at 100° a thin mobile liquid (benzyl alcohol and benzyl chloride), and between 225° and 235° benzyl cinnamate in the form of a thick oil, which gradually solidifies at 0° , and may be completely purified by dissolving it in alcohol at a temperature below 40° and cooling the solution to a low temperature. It is always partially decomposed during preparation into cinnamic acid and benzyl alcohol, the quantity thus decomposed being greater the longer the heating is continued.

Pure benzyl cinnamate forms short, shining white prisms having a pleasant aromatic odour; it melts at 39° , and may then remain liquid for several hours even at 0° . At about 350° it decomposes, with formation of cinnamic acid and oily substances. It dissolves easily in alcohol and ether, and is quickly decomposed by alcoholic potash, even in the cold. Frémy's metacinnaméin (i. 980) is probably pure benzyl cinnamate (Grimaux, *Zeitschr. f. Chem.* [2] v. 157).

According to Delafontaine (*ibid.* p. 156), the cinnaméin obtained from Peru balsam is a mixture of benzyl cinnamate and cinnyl cinnamate or styracén. When heated with alcoholic potash it yields potassium cinnamate, and an oil, which is resolved for the most part by fractional distillation into benzylic and cinnylic alcohols.

CINNAMIDE, $C^9H^9NO = C^9H^9O.NH^2$, is most conveniently prepared by treating cinnamyl chloride with concentrated aqueous ammonia, washing the resulting crystalline pulp with cold water, and recrystallising it from boiling water, from which it separates by slow cooling in dazzling white crystals; from alcohol it crystallises in needles; in ether it is but sparingly soluble. It is inodorous, has a faintly bitter taste, melts at 141.5° , and when boiled with hydrochloric acid appears to form an unstable hydrochloride. Boiled with mercuric oxide, it yields white pulverulent mercuric cinnamide, $(C^9H^9NO)_2Hg$ (J. v. Rossum, *Zeitschr. f. Chem.* [2] ii. 362).

Thiocinnamide, $C^9H^9NS = C^9H^9S.NH^2$, separates on treating an ammoniacal solution of cinnamoyl trile with hydrogen sulphide and evaporating, and crystallises from water in yellow laminar crystals (v. Rossum).

CINNAMONITRILE, C^9H^7N , is produced by heating cinnamide with an equivalent quantity of phosphorus pentachloride, distilling off the resulting phosphorus oxychloride, and heating the residue with potash. It crystallises at low temperatures, melts at 11° , boils at 254° – 255° , dissolves easily in alcohol, but is insoluble in water (v. Rossum).

CITRACETIC ACID. A tribasic acid formed, together with acconitic acid (p. 2), by the action of sodium on heated ethyl bromacetate. Its composition has not been determined, but appears not to differ much from that of acconitic acid. Its tribasic salt has a strong alkaline reaction; the silver and lead salts are amorphous precipitates soluble in water (Baeyer, *Zeitschr. Ch. Pharm.* 1864, p. 712).

CITRACONIC ACID. $C^9H^9O^4 = (C^9H^9O^3)(CO^2H)^2$.—This, like the isomeric compounds itaconic and mesaconic acids, is a bibasic acid, having two unsaturated units of affinity, and therefore capable of uniting directly with 2 at. hydrogen, chlorine, bromine, iodine, &c., or with 1 mol. HCl, HBr, HClO, &c., thereby producing saturated compounds. Treated with water and sodium-amalgam, it takes up 2 at. hydrogen and is converted into pyrotartaric acid, $C^9H^9O^4$. It unites at ordinary temperatures with 2 at. bromine, forming citradibromopyrotartaric acid, $C^9H^7Br^2O^4$, isomeric with itadibromopyrotartaric acid (Kekulé, *Jahresb.* 1862, p. 813). See PYROTARTARIC ACID, iv. 774; also in this volume. With hydrochloric acid it forms citramonochloropyrotartaric acid, $C^9H^7ClO^4$, which however is most readily formed by heating citraconic anhydride, $C^9H^5O^4$, with concentrated hydrochloric acid to 120° . The anhydride heated with fuming hydriodic acid is converted into pyrotartaric acid, but it is probable that a mono-iodopyrotartaric acid, $C^9H^7IO^4$, is formed as an intermediate product, though it has not been isolated (Swarts, *Jahresb.* 1866, p. 408). A dilute solution of citraconic acid neutralised with baryta and agitated with hypochlorous acid, is converted into the barium salt of chlorocitraconic acid, $C^9H^7ClO^4 = C^9H^5O^4 + HClO$ (Carius, *Ann. Ch. Pharm.* cxlvi. 195).

The difference of structure between the three isomeric acids, citraconic, itaconic, and mesaconic, has been explained in the article ACIDS, ORGANOIC, pp. 48, 49.

Citraconates.—The acid barium salt $(C^9H^9O^4)Ba$ crystallises in fine silky needles. The neutral barium salt $C^9H^9O^4Ba$ (at 100°) is deposited as a crystalline powder on cooling a solution of barium carbonate in citraconic acid. This acid calcium salt

$(C^2H^3O^4)^2Ca + 3aq.$ forms laminae permanent in the air, blackening and decomposing at 140° . The neutral salt is obtained as an amorphous powder on evaporating the acid saturated with lime-water; and on dissolving this powder in the exact quantity of water required, at ordinary temperatures, and leaving the solution to evaporate, the salt separates in step-shaped or radially grouped needle-shaped crystals having a nacreous lustre and consisting of $C^2H^3O^4Ca + 5aq.$ (Kämmerer, *Zeitschr. f. Chem.* [2] v. 262). The acid lead salt $(C^2H^3O^4)^2Pb$ (at 140°) separates in small yellowish crystals from a solution of the neutral salt in a large excess of citraconic acid. The neutral lead salt $C^2H^3O^4Pb$ is obtained on adding lead acetate to citraconic acid containing a little ammonia, as a white precipitate becoming crystalline on boiling. The crystals are anhydrous. The mother-liquor on cooling deposits a brown powder containing 1 mol. H^2O . The precipitate formed by neutral lead-acetate in a neutral solution of ammonium citraconate appears gummy when dried, and contains $2H^2O$; when boiled in the liquid it is converted into the anhydrous crystalline salt. On dropping a solution of an alkaline citraconate into a boiling solution of basic lead acetate, a crystalline pulverulent basic lead salt is precipitated, which is nearly insoluble in water, and contains $C^2H^3O^4Pb.PbO$ (Otto, *Jahresb.* 1863, p. 384). Acid strontium citraconate, $(C^2H^3O^4)^2Sr + 3aq.$, forms large colourless prisms, often truncated on the longitudinal edges. The neutral salt crystallises in a confused mass, and effloresces during the evaporation of its solution.

CITRIC ACID. $C^2H^3O^7 = (C^2H^3O^4)^2 \begin{Bmatrix} OH \\ (COOH) \end{Bmatrix}$.—To obtain an exportable material

for the manufacture of citric acid, Perret (*Bull. Soc. Chim.* [2] v. 42) treats clarified lemon-juice with excess of magnesia; washes the resulting insoluble granulo-crystalline magnesium salt with cold water; redissolves it in hot lemon-juice; and evaporates the solution rapidly, whereby a bibasic magnesium citrate, $C^2H^3O^4Mg^2$, is obtained in a form convenient for exportation to the manufactories. G. Schnitzer (*Chem. Centr.* 1868, p. 272) recommends that the warmed fresh lemon-juice be mixed with a quantity of lime or chalk not quite sufficient to neutralise the acid reaction, because an excess of lime likewise precipitates those constituents of the juice which excite fermentation and occasion loss of citric acid. The calcium citrate precipitated as above may, after once washing and rapid drying, be kept for a long time without decomposition. F. Rowe (*Chem. News*, xiii. 40) dilutes the concentrated lemon-juice imported from Sicily with water, to facilitate the clarification. He also removes the injurious excess of sulphuric acid which accumulates in the concentrated solutions of citric acid obtained by decomposition of the calcium salt, by renewed treatment with lime, whereby flocculent matters consisting of gypsum and phosphates, which interfere with the crystallisation, are likewise removed. A great improvement introduced by E. A. Pontifex in the manufacture of citric acid (also in that of tartaric acid) is the use of a vacuum-pan for the final evaporation of the solutions (see Richardson and Watts's *Chemical Technology*, pt. v. p. 142).

Decompositions.—Citric acid heated to 160° in a sealed tube for several days with 8 to 10 times its weight of water is slowly resolved into itaconic acid (perhaps with small quantities of mesaconic acid), carbon dioxide, and water; the decomposition is accelerated by the presence of sulphuric acid:

(Morkownikoff a. Purgold, *Zeitschr. f. Chem.* [2] iii. 264).

Robiquet showed that when strong sulphuric acid is poured upon dried citric acid, carbon monoxide is evolved, but that if the temperature be raised above 40° , acetone and carbon dioxide are given off (i. 996). If the liquid be freed from sulphuric acid by lead carbonate, and the filtrate partially saturated with barium carbonate, the resulting solution, evaporated below 40° , yields yellow crystals of a barium salt containing $(C^2H^3SO^4)^2Ba$. If the acetone be left out of consideration, the decomposition of citric acid by sulphuric acid may be represented by the equation:

The solution of the acid barium salt heated with baryta-water becomes turbid, from separation of barium carbonate, and the filtrate, freed from excess of baryta by carbonic acid and a second filtration, yields by evaporation white needles of another barium salt, $(C^2H^3SO^4)^2Ba$ (C. Wilde, *Ann. Ch. Pharm.* cxxvii. 170). A solution of citric acid in absolute alcohol treated with sodium is converted into the sodium salt of hydrocitric acid, $C^2H^3O^7$ (Kämmerer, *Zeitschr. f. Chem.* [2] ii. 709).

According to Chapman a. Smith (*Laboratory*, i. 39), a solution of a citrate boiled with strongly alkaline potassium permanganate reduces the latter only to manganate,

the liquid gradually acquiring a permanent green colour, whereas tartrates under similar circumstances reduce the permanganic acid to manganese dioxide, which is precipitated. According to Wimmel, on the other hand (*Zeitschr. f. Chem.* [2] v. 286), citrates effect the reduction to manganese dioxide as well as tartrates, only more slowly.

Constitution and Basicity.—Citric acid contains 4 atoms of replaceable hydrogen, of which three are easily replaced by metals, the fourth only by acid radicles, such as acetyl (p. 38): hence it is regarded as tetratomic and tribasic, and represented by the formula

A few quadrimetallic citrates are however known, and accordingly citric acid is by some chemists regarded as quadribasic. According to Schiff (*Jahresb.* 1862, p. 312),

a quadribasic cupric salt $\text{C}^3\text{H}^4\text{O}^7\text{Cu}^2$ [$\text{Cu}^2 = \text{H}^4$] is produced by drying the ordinary basic salt $(\text{C}^3\text{H}^3\text{O}^7)^2\text{Cu}^2$, $\text{CuH}^2\text{O}^2 + 2\text{aq.}$ (i. 998). The same chemist describes a ferric citrate, $\text{C}^3\text{H}^4\text{FeO}^8$, or perhaps $\text{C}^3\text{H}^4(\text{FeO})^{\text{H}}\text{O}^7$, obtained by desiccation of the pharmaceutical ammonio-citrate of iron. By dissolving ferric hydrate at 60° in citric acid, a brown liquid is obtained which dries up to the normal ferric salt $(\text{C}^3\text{H}^3\text{O}^7)^2(\text{Fe}^2)^{\text{H}} + 6\text{aq.}$

An amorphous *biplumbic salt* $\text{C}^3\text{H}^4\text{O}^7\text{Pb}^2 + \text{aq.}$ is obtained by dropping a neutralised or nearly neutralised solution of citric acid into excess of a boiling solution of basic lead acetate, boiling the solution for several hours, with addition of de-aerated water, and washing the precipitate by decantation: it gives off its water at 200° . A *basic salt* $(\text{C}^3\text{H}^3\text{O}^7)^2\text{Pb}^2 \cdot 2\text{PbO} + 3\text{aq.}$ (at 100°) is obtained by boiling ammonium citrate with basic lead acetate for several hours; it gives off its water at 150° (R. Otto, *Ann. Ch. Pharm.* cxxvii. 175).

Yttrium Citrates.—The *tri-yttric salt* $(\text{C}^3\text{H}^4\text{O}^7)^3\text{Y}^3 + 14\text{aq.}$ is obtained on mixing sodium citrate with yttrium acetate, as a bulky crystalline precipitate, soluble in excess of the sodium salt, more soluble in cold than in hot water, easily soluble in dilute acetic acid, mineral acids, ammonia, sal-ammoniac, cold potash-ley, and, when recently precipitated, also in warm aqueous citric acid. On heating the citric acid solution to boiling, a tri-yttric citrate separates out with 7 mol. water; and on evaporating the same solution at a temperature not above 30° , the *di-yttric salt* $\text{C}^3\text{H}^4\text{O}^7\text{Y}^2 + 4\text{aq.}$ crystallises out in small laminae.

An *ammonio-bismuth citrate*, used in medicine, is obtained by dissolving precipitated bismuth citrate in aqueous ammonia (not in excess) and leaving the solution to dry upon glass plates. It then forms translucent crusts, said to contain $(\text{C}^3\text{H}^4\text{O}^7)^{\text{H}}\text{Bi}^2\text{O}^2(\text{NH}^4)^2\text{O} + 5\text{aq.}$, or perhaps $(\text{C}^3\text{H}^3\text{O}^7)^2(\text{Bi}^2\text{O})^{\text{H}}(\text{NH}^4)^2 + 5\text{aq.}$ (N. G. Bartlett, *Chem. News*, xi. 28).

Observations on the composition and crystalline forms of several citrates have lately been published by H. Kämmerer (*Zeitschr. f. Chem.* [2] v. 234).

Ethylacetyl-citrate, $\text{C}^3\text{H}^4\text{O}^8 = (\text{C}^3\text{H}^4\text{O}^7)^{\text{H}} \left\{ \begin{array}{l} \text{OC}^2\text{H}^3\text{O} \\ (\text{COOC}^2\text{H}^3)^{\text{H}} \end{array} \right.$, is formed by heating 1 mol. ethyl citrate, $\text{C}^3\text{H}^4 \left\{ \begin{array}{l} \text{OH} \\ (\text{CO}^2\text{C}^2\text{H}^3)^{\text{H}} \end{array} \right.$, with 2 mol. acetyl chloride, $\text{C}^2\text{H}^3\text{OCl}$, and remains, after driving off the volatile products, as a yellowish oil, not miscible with water, but easily soluble in alcohol and ether. It does not solidify at -20° ; distils, for the most part unaltered, at 288° (corr.). By boiling with potash it is resolved into alcohol, acetic acid, and citric acid (Wislicenus, *Ann. Ch. Pharm.* cxxix. 175).

Hydrocitric Acid. $\text{C}^3\text{H}^4\text{O}^7$ (Kämmerer, *Zeitschr. f. Chem.* [2] ii. 709).—The sodium salt of this acid is produced by leaving a saturated solution of citric acid in absolute alcohol in contact with small pieces of sodium (3 mol. sodium to 1 mol. of the acid) for several days, or by the action of sodium on citric acid suspended in ether perfectly free from water and alcohol. On evaporating off the alcohol or ether, dissolving the sodium salt in water, precipitating with lead-acetate, decomposing the lead-salt with hydrogen sulphide, and evaporating the filtrate over sulphuric acid, hydrocitric acid gradually separates in a mass of small prisms gradually becoming

opaque and assuming the aspect of porcelain. It is insoluble in alcohol and ether, melts at 100° , crystallises again on exposure to the air, and then deliquesces. The solution gives with lead acetate a white amorphous precipitate, becoming crystalline when warmed, insoluble in water and in acetic acid. The neutralised acid gives white precipitates with the chlorides of calcium, barium, and zinc, pale green with cupric sulphate, light yellow with ferric chloride.

Hydrocitric acid is tribasic. Its sodium salt $2C^*H^*O^*Na^* + 5aq.$ crystallises in rhombic prisms; the barium salt contains $(C^*H^*O^*)^2Ba^* + 5aq.$, the calcium salt $(C^*H^*O^*)^2Ca^* \cdot 6aq.$, the lead salt $(C^*H^*O^*)^2Pb^*$ (at 100°). The silver salt $C^*H^*O^*Na^* + aq.$ (at 60°) is amorphous, easily reducible, and melts to a viscid mass when heated with water.

Hydrocitric acid yields by dry distillation a pyro-acid, forming a deliquescent potassium salt, which is precipitated by barium chloride, but not by calcium chloride; its lead-salt melts under boiling water to a viscid liquid.

COBALT. Atomic Weight.—Russell (*Chem. Soc. J.* [2] i. 51) has determined the atomic weight of this metal by reducing the monoxide CoO (prepared by strongly igniting cobaltoso-cobaltic oxide in a stream of carbon dioxide) to the metallic state in an atmosphere of hydrogen. The mean of a considerable number of experiments gave for the proportion of metal in the monoxide, 78.5926 p. c.; whence Co = 58.74. More recently (*ibid.* vii. 294), by dissolving metallic cobalt freed from oxide by strong ignition in a stream of hydrogen, in hydrochloric acid, measuring the quantity of hydrogen evolved, and reducing it to weight, Russell has found for the atomic weight of cobalt, Co = 58.76, a result which may be regarded as identical with the former. Sommaruga (*Pogg. Ann.* cxxx. 303; *Jahresb.* 1866, p. 244), by igniting cobaltous chloride in hydrogen, obtained the number 59.93, a result agreeing nearly with that which Schneider obtained (*Pogg. Ann.* ci. 387; *Jahresb.* 1857, p. 225) by determining the proportion of cobalt and carbon in pure cobaltous oxalate, viz. Co = 60.01. C. Winkler (*Zeitschr. anal. Chem.* vi. 18; *Jahresb.* 1867, p. 289) determines the atomic weight of cobalt by dissolving a known weight of the pure metal in excess of a neutral solution of auric chloride, and weighing the gold thereby separated; the reaction is expressed by the equation,

The mean of five experiments gave Co = 58.992. Hence Winkler concludes that the whole number 59 may be retained as the correct expression of the atomic weight of cobalt.

The following table exhibits all the values which have been given for the atomic weight of cobalt:

(1826) Rothoff	59.02	(1863) Russell	58.74
(1856) Marignac	$\left\{ \begin{array}{l} 58.64 \\ 59.02 \end{array} \right.$	(1867) Winkler	58.922
(1859) Dumas	59.08	(1869) Russell	58.78
(1857) Schneider	60.01	(1866) Sommaruga	59.93

Reactions of Cobalt Salts.—According to J. Bersch (*Zeitschr. f. Chem.* [2] iv. 308), the change of colour from red to blue which cobalt salts exhibit when heated, depends, not on difference of hydration, but on the formation of isomeric modifications. (See COBALT CHLORIDES, p. 476.)

1. A solution of a cobaltous salt mixed with 2 or 3 vol. strong hydrochloric acid acquires a blue colour of sufficient intensity to indicate the presence of $\frac{1}{10}$ milligrm. of cobalt in 1 c.c. of solution. Nickel and especially iron (but not manganese) interfere with the reaction, a small quantity of iron present in the cobalt solution changing the blue colour to emerald-green, while nickel changes the blue to green only when present in considerable quantity.

2. Cobalt nitrate mixed with a solution of acid sodium carbonate containing a small quantity of hypochlorite, forms a light green liquid of great colouring power, which, if not too concentrated, may be boiled for some hours without decomposition (*Field, Chem. Soc. Q. J.* xiv. 78). A solution of a cobaltous salt mixed with acetate and hypochlorite of soda, acquires a deep red colour, which on further addition of the hypochlorite, changes to a light yellow-brown. This mixture, even at ordinary temperatures, quickly becomes dark and almost black, but does not yield any precipitate, even when heated. On adding sodium carbonate and boiling, the whole of the cobalt is precipitated as peroxide, with deep brown colour. Any nickel that may be present also remains in solution until sodium carbonate is added (*Pogg. Ann. Ch. Pharm.* cxxxi. 363).

3. If a cobaltous solution diluted till it no longer appears red be shaken up with a few crystals of *sodium pyrophosphate* till the latter are dissolved, and *sodium hypochlorite* be then added, a deep brown solution of cobaltic phosphate is produced, almost black if the solution is moderately concentrated. Nickel under the same circumstances forms a colourless liquid. This reaction may therefore serve to detect cobalt in presence of nickel; but care must be taken not to warm the solution, as in that case both metals would be precipitated as black hydrated peroxides (C. D. Braun, *Zeitschr. f. anal. Chem.* 1868, p. 348). According to Liebig, the nickel may be immediately recognised in another portion of the solution by adding potassium cyanide and excess of alkali, which produces a black colour due to nickel alone (*Zeitschr. f. Chem.* [2] v. 309).

4. When a cobaltous solution is mixed, first with a strong solution of *potassium cyanide* till the resulting precipitate is redissolved, then with a concentrated neutral solution of *potassium nitrite* and a few drops of acetic acid, the liquid immediately assumes a deep orange-red to blood-red colour, or, if somewhat dilute, an orange-rose colour (peach-blossom-red in thin layers), apparently due to the formation of potassio-cobaltous nitrocyanide, and disappearing on adding ammonia or excess of acid. This reaction is not exhibited by potassium-nickel cyanide, and may therefore serve as an additional test between cobalt and nickel; but the presence of nickel in the cobalt solution renders it less certain; moreover it is not so delicate as the well-known blowpipe reaction (C. D. Braun, *J. pr. Chem.* xci. 107).

5. A solution of cobaltous chloride acidulated with acetic acid gives with excess of *ammonium nitrite*, a yellow precipitate consisting of microscopic cubes, similar in appearance and analogous in composition to potassio-cobaltous nitrite (i. 1058) (Erlmann, *Jahresh.* 1866, p. 247). See NITRITES.

6. A solution of a cobaltous salt in tartaric or citric acid mixed with excess of ammonia and then with *potassium ferricyanide*, assumes a red colour, perceptible even in very dilute liquids (W. Skey, *Chem. News*, xv. 111).

7. An alkaline solution of *potassio-cobaltous cyanide* shaken up with air, assumes a deep brown-red colour (probably forming cobaltic cyanide), and after standing for some time, deposits part of the cobalt as cobaltic hydrate (not, however, in very dilute solutions), while potassium cobalticyanide remains dissolved. A nickel solution, under similar circumstances, neither forms a precipitate nor undergoes any change of colour (C. D. Braun, *Zeitschr. anal. Chem.* iii. 465).

8. *Cobalt sulphide* precipitated from an ammoniacal solution by yellow ammonium sulphide, and freed from excess of ammonia by heat, is less soluble in *potassium cyanide*, in proportion as the ammoniacal solution, before the addition of ammonium sulphide, has been longer exposed to the air, and therefore more completely converted into roseo-cobaltic or purpureo-cobaltic salt. The reaction affords the means of detecting cobalt in presence of nickel. If the precipitate formed by adding ammonium sulphide to the ammoniacal solution after exposure to the air, till it no longer changes colour, consists wholly of nickel sulphide, it will dissolve completely in potassium cyanide; but cobalt will remain undissolved as sesquisulphide, Co_2S_3 ; any small quantity of cobaltous sulphide, CoS , that may be present will impart to the solution in potassium cyanide a deep brown-red colour (H. Fleck, *ibid.* v. 399).

Quantitative Estimation.—Winkler (*Zeitschr. anal. Chem.* iii. 265, 420; *Jahresh.* 1864, p. 716; 1865, p. 723) has given a volumetric method of estimating cobalt in presence of nickel, based on the fact that on adding potassium permanganate to a solution of cobaltous chloride mixed with mercuric oxide, the whole of the cobalt is precipitated as cobaltic hydrate:

The solution containing the cobalt and nickel (previously treated with barium chloride if it contains sulphuric acid) is mixed in the cold with precipitated and levigated mercuric oxide, and a normal solution of permanganate (titrated with pure cobalt solution) is gradually added, till the last drops give to the liquid a permanent amethyst colour. If the solution contains arsenic or phosphoric acid, these acids must be precipitated in the first instance by addition of ferric chloride. The excess of iron in the filtrate is then immediately precipitated as ferric oxide on adding the mercuric oxide, so that it does not interfere with the subsequent titration by the permanganate. The process gives exact results, provided the quantity of nickel present is not greater than twice that of the cobalt; in the contrary case it is best to precipitate the cobalt with potassium nitrite, mix the yellow precipitate with hydrochloric acid, evaporate to dryness, redissolve in water, and titrate the cobalt as above.

(*Zeitschr. f. Chem.* [2] iv. 529). Terroil (*Bull. Soc. Chim.* [2] v. 88; *Jahresb.* 1866, p. 806) separates nickel and cobalt by means of ammonia and potassium permanganate, with subsequent addition of hydrochloric acid to the boiling solution, whereby the cobalt is precipitated as roseo-cobaltic chloride. According to Fresenius (*Zeitschr. anal. Chem.* v. 114), this method is not exact, because a small portion of the cobalt always escapes the oxidising action of the permanganate, and moreover the roseo-cobaltic chloride is not quite insoluble in water containing hydrochloric acid.

Cobalt and nickel may be separated from iron by boiling the solution of the nitrates for four hours with litharge, whereby the iron is precipitated as ferric oxide. The filtrate is freed from lead by hydrogen sulphide, and the cobalt and nickel determined by the usual methods (Field, *Chem. Centr.* 1860, p. 383).

From manganese the same metals may be separated by mixing the solution with ammonia and sal-ammoniac, and adding phosphoric acid, which throws down the manganese as ammonio-manganous phosphate, while the cobalt and nickel remain in solution* (S. H. Henry, *Phil. Mag.* [4] xvi. 197).

Cobalt Chloride. CoCl_2 .—When a solution of this salt is concentrated till the boiling point rises to 111° , the remaining liquid, which solidifies on cooling to a red crystalline mass, has the composition $\text{CoCl}_2 \cdot 6\text{H}_2\text{O}$; when further heated to 116° it is converted into $\text{CoCl}_2 \cdot 4\text{H}_2\text{O}$. From this latter in the fused state blue crystals of the dihydrate $\text{CoCl}_2 \cdot 2\text{H}_2\text{O}$ separate as the temperature rises, and at 121° the entire mass is converted into this hydrate, which does not give up the whole of its water till heated above 140° . The anhydrous chloride has a pale blue colour like that of recently precipitated cupric hydrate. When exposed to the air, it turns red in a few minutes, from absorption of water, and is converted, after some time, into the hydrate $\text{CoCl}_2 \cdot 6\text{H}_2\text{O}$, without formation of the intermediate compounds; in contact with water, the same hydrate is quickly formed, and with considerable evolution of heat.

The dihydrate $\text{CoCl}_2 \cdot 2\text{H}_2\text{O}$, prepared by heating either of the higher hydrates, forms a fused, deep violet-coloured, crystalline mass; when prepared by dehydrating the compound $\text{CoCl}_2 \cdot 6\text{H}_2\text{O}$ over sulphuric acid, it forms a dark peach-blossom-coloured powder, which between 125° and 140° assumes the colour of sublimed chromic chloride. The dihydrate is extremely hygroscopic, and in contact with water is immediately converted into the hexhydrate.

The crystals of the tetrahydrate $\text{CoCl}_2 \cdot 4\text{H}_2\text{O}$ have a peach-blossom-red colour; do not give off any water over sulphuric acid (unlike the hexhydrate), and when heated above 116° decrepitate without fusion, leaving the hydrate $\text{CoCl}_2 \cdot 2\text{H}_2\text{O}$. When exposed to the air, they deliquesce to a solution from which the hexhydrate crystallises; in contact with water also they are converted into the same hydrate, with considerable increase of volume. It appears therefore that the dihydrate and tetrahydrate cannot exist in solution.

The current-red crystals of the hexhydrate, $\text{CoCl}_2 \cdot 6\text{H}_2\text{O}$, are permanent only in moist air; over sulphuric acid they quickly turn violet, and are ultimately converted into the dihydrate. On gently heating them, blue spots make their appearance at about 30° in the red crystalline mass, and continue to increase, till at 35° the entire mass has become blue without the slightest loss of weight; between 35° and 39° it swells up and splits into small spicular crystals which appear pale blue by reflected light, but are reconverted on cooling into the original red crystals. At 86° – 87° they melt to an indigo-blue liquid, from which the red crystals do not separate till it is cooled to 50° . In water the hexhydrate dissolves very easily and with considerable lowering of temperature.

The changes of colour in the several hydrates take place without any diminution of weight, and appear to be due merely to molecular action. It appears probable, therefore, that the chloride and other analogous compounds of cobalt (which exhibit similar changes of colour) are susceptible of two modifications, a red and a blue, and that the latter can exist in the tetra- and hex-hydrated chlorides only at comparatively high temperatures, but that in the dihydrate it can exist also at ordinary temperatures; moreover, all cobaltous compounds turn blue when heated, quite independently of any change in their amount of water (J. Bersch, *Wien. Akad. Ber.* lvi. [2] 724; *Jahresb.* 1867, p. 291).

Oxides. *Hydrated cobaltoso-cobaltic oxide.* $2\text{Co}^{\text{O}^+} \cdot \text{H}_2\text{O}$, is obtained by heating the commercial basic carbonate, $2\text{CoCO}_3 \cdot \text{Co}^{\text{H}^+}\text{O}^+ + 3\text{aq.}$, to 200° for twelve hours. [H. Rose (*Pogg. Ann.* lxxxiv. 653) regarded the product thus obtained as hydrated cobaltic oxide, $4\text{Co}^{\text{O}^+} \cdot \text{H}_2\text{O}$.] This hydrate exposed to the air gradually takes up water and is converted into the dihydrate $\text{Co}^{\text{O}^+} \cdot 2\text{H}_2\text{O}$. The latter dried at 100°

* According to Chancel, on the other hand, cobalt and nickel are completely precipitated by phosphoric acid from cold ammoniacal solutions (*Jahresb.* 1866, p. 805).

leaves the hydrate $4\text{Co}^{+}\text{O}^{4-}\cdot 5\text{H}_2\text{O}$, and at 110° , the hydrate $4\text{Co}^{+}\text{O}^{4-}\cdot 3\text{H}_2\text{O}$. Any oxide of cobalt ignited for about a quarter of an hour in a half-covered crucible over an ordinary gas-flame, and then quickly cooled, is converted into cobaltoso-cobaltic oxide, $\text{Co}^{+}\text{O}^{4-}$; but if the ignition be performed over a gas-flame urged by a blast, the residue consists chiefly of cobaltous oxide, CoO (C. D. Braun, *Zeitschr. anal. Chem.* vi, 76). According to Russell (*Chem. Soc. J.* [2] i, 51), cobaltoso-cobaltic oxide ignited over the gas blowpipe flame in an atmosphere of carbon dioxide, leaves pure cobaltous oxide.

Cobaltic Acid (?).—According to Winkler (*J. pr. Chem.* xci. 213; *Jahresh.* 1864, p. 267), finely divided (reduced) cobalt dissolves when boiled for a long time with its own weight of potassium hydrate and 3 pts. water, forming a deep blue liquid in which the cobalt exists as CoO^3 . The potassium-cobaltate has not been isolated in the solid state, and the solution itself decomposes spontaneously, losing its blue colour; chlorine passed into it gives rise to a rapid emission of oxygen. Winkler analysed it by determining the quantity of sulphuric acid formed by treating a known quantity with sulphurous acid. According to Schultze, however, Winkler's cobaltate is nothing but an alkaline solution of cobaltic hydrate (*Jahresh.* 1864, p. 269).

COBALT BASES, AMMONIACAL (i. 1051). The general formulae of the several ammonio-cobaltic compounds, according to the atomic weight of cobalt now admitted [Co = 59], are represented in the following table, in which X denotes an atom of chlorine or of an equivalent acid radicle such as NO₂, C₂H₃O₂, HSO₄, &c.:

Tetrammonio-cobaltic salts	$\text{Co}^2\text{X}^-\cdot 4\text{NH}^3$
Hexammonio-cobaltic salts	$\text{Co}^2\text{X}^-\cdot 6\text{NH}^3$
Oxy-octammonio-cobaltic (fusco-cobaltic) salts	$\text{Co}^2\text{OX}^-\cdot 8\text{NH}^3$
Decammonio-cobaltic (roseo- and purpureo-cobaltic) salts	$\text{Co}^2\text{X}^-\cdot 10\text{NH}^3$
Dinitro-decammonio-cobaltic (xantho-cobaltic) salts	$\text{Co}^2(\text{NO}_2)^-\text{X}^-\cdot 10\text{NH}^3$
Dodecammonio-cobaltic (luteo-cobaltic) salts	$\text{Co}^2\text{X}^-\cdot 12\text{NH}^3$
Oxy-cobaltic salts	$\text{CoOX}^-\cdot 5\text{NH}^3$

Many of these salts have been further examined by Braun (*Ann. Ch. Pharm.* cxxxii. 33; cxlii. 50; *Jahresb.* 1864, p. 270; 1867, p. 294).

Fusco-cobaltic salts are easily resolved under the influence of ammonia and of acids into roseo- and luteo-cobaltic salts; thus when fusco-cobaltic chloride is heated with concentrated hydrochloric acid, roseo-cobaltic chloride, which is the principal product, is always mixed with a certain quantity of luteo-cobaltic salt:

With dilute hydrochloric acid, on the other hand, the lutecobaltic chloride predominates: thus:

Roseo-cobaltic chloride may be prepared synthetically from fusco- and luteo-cobaltic chlorides. When these two chlorides are heated together with ammonia for several days in a sealed tube, placed in a sand-bath, there is obtained, together with undecomposed fusco-cobaltic salt and cobaltic hydrate, a red liquid from which roseo-cobaltic chloride gradually crystallises:

The separated cobaltic oxide arises from the decomposition of the free roseo-cobaltic oxide.

Roseo-cobaltic chloride is also produced by agitating a moderately concentrated solution of cobaltous nitrate with strong aqueous ammonia till it appears clear and of a dark brown colour, and then heating it for half an hour to an hour with pure indigo-blue; the liquid then assumes a deep violet-red colour, gradually changing to wine-red on exposure to the air, and on addition of strong hydrochloric acid deposits after a while, microscopic tetragonal crystals of roseo-cobaltic chloride. The reaction may be represented by the equation:

Roseo-cobaltic Sulphate. $\text{Co}^2(\text{SO}^4)^2 \cdot 10\text{NH}^3 + 5\text{aq.}$ (i. 1053).—According to Braun (*Ann. Ch. Pharm.* cxxxviii. 109), the oxidised ammoniacal solution of ammonio-cobaltous sulphate is not precipitated by sulphuric acid till after the addition of water or alcohol. The precipitated pulverulent salt gives off 5 mol. water at 100° , without losing its solubility, which is moderately great even in cold water. The salt decomposed with baryta-water yields roseo-cobaltic oxide, the strongly alkaline solution of which absorbs carbonic acid from the air.

Xantho-cobaltic Salts. $\text{CoOX}^4 \cdot 10\text{NH}^3 \cdot 2\text{NO} \cdot \text{H}^2\text{O}$ according to Gibbs u. Genth (i. 1054), $\text{Co}(\text{NO}^2)^2\text{X}^4 \cdot 10\text{NH}^3$ according to Braun.—These formulæ differ from one another only by H^2 , a difference not recognisable by analysis. Braun's formula is verified by the decomposition of the chloride with ferrous salts, the oxygen which it gives up to a titrated ferrous solution being estimated volumetrically. These salts digested in dilute solution for several days at a gentle heat with strong aqueous ammonia, are converted into roseo- and luteo-cobaltic salts, with separation of nitrous acid. When a small quantity of xantho-cobaltic nitrate is warmed with aqueous ammonia, a strong solution of sodium-pyrophosphate added, and the liquid again warmed, crystalline laminae of luteo-cobaltic pyrophosphate are quickly produced. A strong solution of xantho-cobaltic nitrate and an equal quantity of sal-ammoniac heated with strong hydrochloric acid, yield the chlorides of roseo- and luteo-cobaltic chlorides, according to the equation:

If dilute hydrochloric acid (sp. gr. 1.12) be used, and the temperature kept at about 60° , the chief product is luteo-cobaltic chloride. A mixture of the concentrated solutions of xantho-cobaltic nitrate and ammonium sulphate heated with hydrochloric acid, or of xantho-cobaltic nitrate and ammonium chloride heated with sulphuric acid, yields luteo-cobaltic sulphate and chloride, generally with a small quantity of roseo-cobaltic salt.

Luteo-cobaltic chloride may also be prepared by agitating a solution of cobaltous chloride or nitrate with strong aqueous ammonia and lumps of sal-ammoniac, adding lead dioxide to the dark brown liquid, and keeping the mixture in gentle ebullition for about half an hour. With sufficient oxidation and abundant addition of sal-ammoniac, the dark reddish-yellow liquid contains chiefly luteo-cobaltic chloride, together with a very small quantity of roseo-cobaltic chloride; with a smaller quantity of sal-ammoniac, the latter is more abundantly produced. Hydrochloric acid separates the luteo-cobaltic chloride from the concentrated liquid, as a yellow crystalline powder; from a dilute solution after a day or two, in needle-shaped crystals (Braun).

Mills (*Phil. Mag.* [4] xxxv. 245) prepares *luteo-cobaltic chloride* by heating cobaltous chloride with sal-ammoniac, aqueous ammonia, and a powerful oxidising agent under pressure (in a soda-water bottle closed with a caoutchouc stopper) to 70° for about twenty hours. Equal weights (16 grms.) of cobalt chloride, sal-ammoniac, and potassium permanganate heated in this manner with six times the weight of strong aqueous ammonia, form an orange-yellow liquid, together with nodular aggregations of luteo-cobaltic chloride and a copious precipitate of the higher oxides of manganese and cobalt. The liquid is poured into excess of hydrochloric acid; the crystals are dissolved in water acidulated with hydrochloric acid; these solutions are mixed; the resulting liquid, together with twice its volume of strong aqueous hydrochloric acid, is left to itself for 24 hours; and the yellow precipitate of luteo-cobaltic chloride thereby separated is washed on a filter with hydrochloric acid, and finally with alcohol: it amounts to 71 p. c. of the theoretical quantity. If the permanganate is replaced in the preparation by an equal weight of dichromate, the product amounts to nearly 80 p. c. Manganese dioxide, cobaltic oxide, iodine, or bromine may also be used as the oxidising agent. Cobaltic oxide treated as above with a large quantity of sal-ammoniac and strong ammonia is almost wholly converted into luteo-cobaltic chloride. Mixtures of cobaltous chloride and sal-ammoniac with ammonia and solid chloride of lime also yield a yellow precipitate after long standing in contact with hydrochloric acid. On the other hand, purpureo-cobaltic chloride boiled with aqueous ammonia yields but a very small quantity of luteo-cobaltic chloride. Purpureo-cobaltic chloride is not altered in weight when heated to 87° with ammonia; hence, and from certain weight-determinations, Mills concludes that the formation of luteo-cobaltic chloride from purpureo-cobaltic chloride does not depend upon a simple addition of

ammonia. Moreover, when purpureo-cobaltic chloride is heated with water and ethylamine, aniline, or pyridine (instead of ammonia), only ordinary luteo-cobaltic chloride is formed (besides the other products of decomposition): whence it appears that the luteo-cobaltic chloride is formed at the expense, not of the free ammonia, but of ammonia eliminated from the purpureo-cobaltic chloride.

To prepare *purpureo-cobaltic chloride*, 5 pts. of crystallised cobaltous chloride and 5 pts. sal-ammoniac are dissolved in 100 pts. of water; the cooled solution is mixed with 22 pts. strong aqueous ammonia and 2 pts. chloride of lime; and the mixture, after exposure to the air for 24 hours, is boiled with a large excess of hydrochloric acid, and left to crystallise.

Roseo-cobaltic chloride may be obtained quite pure by mixing an aqueous solution of 5 grms. crystallised cobaltous chloride diluted to 90 c.c. with 27.5 c.c. strong ammonia and 2.5 grms. potassium permanganate dissolved in 100 c.c. water, the temperature of the liquids before mixing not being allowed to rise above 18°. The solution after 24 hours' exposure to the air is filtered from the manganese precipitate; neutralised with dilute hydrochloric acid; precipitated with a cold mixture of 3 vol. hydrochloric acid and $\frac{1}{2}$ vol. alcohol; and the salt is washed first with the same mixture, then with alcohol alone. The product thus obtained has the composition $10\text{NH}^4 \cdot \text{Co}^2\text{Cl}^4 + \text{H}^2\text{O}$; it is quite free from purpureo-cobaltic chloride, but is immediately converted into that salt on heating its solution with a trace of hydrochloric acid. The solution of pure roseo-cobaltic chloride is not precipitated by potassium iodide or neutral potassium chromate; with the dichromate it forms a brick-red precipitate.

Luteo-cobaltic chloride heated with water to 70°-80° in sealed tubes is easily decomposed, forming a colourless solution of cobaltous chloride, ammonia, and sal-ammoniac, with a trace of nitric acid, and a black precipitate having nearly the composition of the oxide Co^2O^3 , mixed with silica arising from decomposition of the glass. Purpureo-cobaltic chloride is decomposed by water in a similar manner, but less quickly and completely, on account of its smaller solubility in ammoniacal sal-ammoniac. These decompositions appear to take place by two stages, part of the compound being first resolved into cobaltous chloride, free chlorine, and ammonia (which react with the water so as to form nitrogen, ammonium chloride, and a little nitric acid), and the cobaltous chloride exerts a further decomposing action on the remaining portion of the original compound:

For Purpureo-cobaltic chloride:

For Luteo-cobaltic chloride:

Both these cobalt-ammonium chlorides are in fact decomposed by heating with cobaltous chloride and water, forming precipitates which always contain less oxygen than Co^2O^3 , but (probably in consequence of subsequent oxidation) more than Co^2O^3 or Co^2O^2 . The conditions under which the liquid remains neutral are given for purpureo-cobaltic chloride by the equation II. a; for luteo-cobaltic chloride by the equation:

The strong corrosion of the glass which takes place when these chlorides are heated with ammonia and water is attributed by Mills to the transient formation of the hydrates $\text{Co}^2\text{Cl}^4 \cdot \frac{2}{3}(\text{HO})^3 \cdot 10\text{NH}^3$ and $\text{Co}^2\text{Cl}^4 \cdot \frac{2}{3}(\text{HO})^3 \cdot 12\text{NH}^3$. Aqueous ammonia does not act upon glass when heated in it either alone or with the precipitates; cobaltic oxide with sal-ammoniac solution (which produces cobaltous chloride) acts but slightly.

For the further development of Schiff's views on the constitution of the ammoniacal cobalt-compounds, see *Ann. Ch. Pharm.* cxxiii. 1; *Rép. Chim. pure*, iv. 380; *Jahrb.* 1862, p. 198. Respecting the salts which Geuther obtained by the action of ammonium sulphate on cobaltic hydrate, see *SULPHATES* (v. 644).

COCAINE (i. 1059). W. Lossen (*Ann. Ch. Pharm.* cxxiii. 351) purifies this base by dialysing the solution of the crude hydrochloride, precipitating the solution thus freed from colouring matter with sodium carbonate, and repeatedly crystallising the precipitated base from alcohol. Lossen assigns to cocaine the formula $\text{C}^7\text{H}^{11}\text{NO}$, which likewise agrees with Niemann's analyses. According to Tcherniak

(*Wien. Akad. Ber.* xlviii. [i] 34), the crystals of cocaine are monoclinic, exhibiting the combination $\sigma P. \infty P_{\infty} - P. - P_{\infty} . (P_{\infty})$, the inclined axes b, c forming an angle of $73^{\circ} 50'$, and the ratio of the axes $a : b : c$ being equal to $1.186 : 1 : 1.223$. Angle $\sigma P : - P_{\infty} = 119^{\circ} 20'$; $\sigma P : (P_{\infty}) = 135^{\circ} 16'$; $- P : \sigma P = 113^{\circ} 14'$. The crystals are prismatically elongated in the direction of the orthodiagonal, mostly hemimorphously developed in this direction, and imperfectly cleavable parallel to σP .

Cocaine dissolves easily in dilute acids, forming mostly crystallisable salts which are soluble in alcohol, but not in ether, have a bitter taste, and, like the free base, produce a transient numbing sensation on the tongue. The *hydrochloride* $C^{17}H^{21}NO^4.HCl$ crystallises from alcohol in short prisms, perpendicularly truncated at the ends; the *platinochloride* $2(C^{17}H^{21}NO^4.HCl).PtCl^4$ and the *aurochloride* $C^{17}H^{21}NO^4.HCl.AuCl^3$ are light yellow precipitates. The *sulphate* is gummy, and crystallises but slowly; the *neutral oxalate* crystallises quickly; an *acid oxalate*, $C^{17}H^{21}NO^4.C^2H^2O^4$, is deposited in feathery crystals on adding ether to an alcoholic solution of dehydrated oxalic acid and cocaine. The solution of cocaine in acetic acid leaves the pure base on evaporation (Lossen).

Cocaine heated with strong hydrochloric acid is resolved into ecgonine (*q.v.*), benzoic acid, and methyl alcohol (Lossen):

COCCININ. See CARMINIC ACID (p. 414).

COCHINEAL. The ash of silver-grey Honduras cochineal, amounting to 3.2 p. c., contains in 100 pts.: 18.63 K_2O , 13.40 Na_2O , 0.51 $NaCl$, 2.40 CaO , 16.44 MgO , 1.39 Al_2O_3 , 1.15 Fe_2O_3 , 47.25 P_2O_5 , and 7.92 SiO_2 (E. Dieterich, *Chem. Centr.* 1867, p. 287).

Cochineal-wax.—A species of cochineal (*Coccus Carica*, Fabr.; *Columnea testudiniformis*, Tozzetto) living on the fig-trees of Italy, contains a wax differing from beeswax only in the proportion of its constituents. Ether extracts from the insects about 65 p. c. of this wax, which is red-brown, melts at 51° to 52° , dissolves but partially in alcohol, and contains 51.3 p. c. cerolein, 12.7 cerotic acid, and 35.2 myricin, with very small quantities of butyric and valeric acids. The wax (about 59 p. c.) expressed from the cochineal under boiling water is grey after remelting, and melts at 57° ; when freed from the greater part of the cerolein by alcohol it melts at 62° to 63° , and when bleached resembles ordinary beeswax (F. Sestini, *Bull. Soc. Chim.* [2] vii. 482).

CODAMINE. $C^{17}H^{21}NO^4$.—A base recently obtained, together with others, by Hesse (*Ann. Ch. Pharm.* cliii. 47), from the aqueous extract of opium. When re-crystallised from ether, it forms large colourless six-sided prisms, mostly terminated by domes; soluble in alcohol, ether, and boiling water; very soluble in chloroform and benzol. All these solutions have an alkaline reaction, neutralise acids, and form salts which have a bitter taste and are mostly amorphous. The base melts at 121° , solidifies to an amorphous mass on cooling, decomposes at a higher temperature. It dissolves in strong nitric acid with dark green, in strong sulphuric acid with blue colour, changing to green, and afterwards to dark violet on warming the liquid. Ammonia and potash produce in solutions of the salts a white flocculent precipitate soluble in excess. The *platinochloride* $2(C^{17}H^{21}NO^4.HCl).PtCl^4$ is a yellow amorphous precipitate slightly soluble in water and in hydrochloric acid.

CODEINE. $C^{17}H^{21}NO^4$.—The action of hydrochloric acid on this base has recently been studied by Matthiessen & Wright (*Proc. Roy. Soc.* xvii. 460; xviii. 83). Codeine heated with excess of hydrochloric acid in sealed tubes splits up into methyl chloride, water, and apomorphine (see MORPHINE):

But when the reaction takes place under the ordinary atmospheric pressure, and at the temperature of the water-bath, a chlorinated base called chlorocodide is produced instead from codeine by substitution of Cl for HO ; thus:

To obtain this base in the pure state, codeine is heated under paraffin on the water-bath with 10 to 15 times its weight of strong hydrochloric acid for 12 to 15 hours; the resulting brownish liquid is evaporated to dryness; and the residue dissolved in water is mixed with sodium bicarbonate, whereby a bulky white precipitate is formed consisting chiefly of chlorocodide, with a trace of apomorphine. This precipitate, freed

from the apomorphine by washing with dilute ammonia, is dissolved in hydrochloric acid and fractionally precipitated with sodium bicarbonate; and the second fraction, which is pure white and free from codeine and apomorphine, is exhausted with ether, which dissolves nearly the whole. The clear ethereal solution is then shaken up with a few drops of hydrochloric acid, and the resulting solution of hydrochloride is fractionally precipitated with sodium bicarbonate, and the treatment with ether and hydrochloric acid is repeated. The product is a viscid colourless solution of the pure hydrochloride, which refuses to crystallise. By fractional precipitation with sodium bicarbonate it yields pure chlorocodide as a snow-white mass, scarcely affected by exposure to air, very soluble in alcohol and ether, but not crystallisable therefrom, owing to decomposition. Its physiological action is much less marked than that of apomorphine, doses of $\frac{1}{4}$ grain taken internally and $\frac{1}{10}$ gr. injected subcutaneously producing no appreciable effect. The hydrochloride contains $C^{18}H^{20}ClNO^2$. HCl; the platinocodide $2(C^{18}H^{20}ClNO^2, HCl) \cdot PtCl_4$ is a yellow precipitate permanent in the air, but decomposing in the moist state at 100° .

A solution of the hydrochloride of chlorocodide gives a pale amethyst coloration with ferric chloride; pale red with nitric acid; evanescent pale red with sulphuric acid and potassium dichromate; pale red with solution of bleaching powder and a drop of hydrochloric acid; a white precipitate with corrosive sublimate, decomposing with pale red colour on boiling; it reduces silver from the nitrate; gives with caustic potash, ammonia, and sodium carbonate, white precipitates slightly soluble in excess; white precipitates also with potassium iodide and sodium phosphate.*

When the hydrochloride is heated to 140° - 150° for three hours with 8 to 15 times its weight of strong hydrochloric acid, the base is resolved into methyl chloride and apomorphine:

The hydrochloride heated in a similar manner with 10 to 15 times its weight of water, splits up into hydrochloric acid and codeine hydrochloride without any evolution of gas:

This reaction is the inverse of that which takes place when codeine is heated on the water-bath with excess of hydrochloric acid.

Codeine heated with hydriodic acid is converted, in the first instance, into bromocodide, $C^{18}H^{20}BrNO^2$, analogous to chlorocodide; and this by further heating with codeine is converted into deoxycodine and bromotetra-codine:

(Wright, *Proc. Roy. Soc.* xix. 371.)

Codeine heated with hydriodic acid yields the hydriodide of a new base not yet examined (Matthiessen & Burnside).

Apocodine or Apocodina. $C^{17}H^{19}NO^2$ (Matthiessen & Burnside, *Proc. Roy. Soc.* xix. 71).—This base, containing the elements of 1 mol. H^2O less than codeine, is produced by heating codeine hydrochloride with a concentrated solution of zinc chloride to 170° - 180° for about fifteen minutes. On cooling, a yellowish-brown tarry mass separates from the liquid, which on further cooling may be drawn out into threads, and thus obtained almost free from zinc chloride. It consists of almost pure apocodine hydrochloride, and may be further purified by repeated solution in hot water and precipitation with hydrochloric acid. By dissolving this salt in water, precipitating with sodium carbonate, exhausting with ether, and evaporating, apocodine is obtained as an amorphous, gummy, reddish mass, soluble in alcohol, ether, and chloroform, insoluble in water, and uncrystallisable. It is much more stable than apomorphine, and therefore more easily prepared. Its reactions are nearly identical with those of apomorphine (see MORPHINE), the chief difference being that the blood-red colour which apocodine gives with nitric acid is much more permanent than that obtained with apomorphine. Hydrochloride of apocodine is amorphous, whereas the apomorphine salt is crystalline. The apocodine salt is a mild emetic, whereas apomorphine hydrochloride acts as a very violent emetic. The apocodine salt produces cutaneous abscesses at the point of injection, which the apomorphine salt does not.

Codeine heated with sulphuric acid (equal volumes of hydrogen sulphate and water) is converted, first into an amorphous base having the same composition; then, by abstraction of $\frac{1}{2}$ mol. water, into a base intermediate between codeine and apocodine: $2C^{18}H^{20}NO^2 - H^2O = C^{17}H^{19}N^2O^2$; then into apocodine, which lastly

* The behaviour of codeine to the above reagents is nearly the same as that of morphine (q.v.).

further change, apparently into apomorphine, by removal of CH^3 (Armstrong, *Chem. Soc. J.* [2] ix. 59).

CÆRULEIN. A blue colouring matter existing in certain volatile oils obtained from plants, chiefly of the composite order. (See *Oils*, iv. 185.)

COLCHICINE (i. 1080). This alkaloïd has been further examined by Hübner (*Chem. Centr.* 1865, p. 536; *Jahresb.* 1864, p. 450), who assigns to it the formula $\text{C}^{17}\text{H}^{19}\text{NO}^3$ and regards it as isomeric with colchicine. He prepares it by exhausting colchicum-seeds with boiling alcohol; diluting the filtered solution with at least 20 times its volume of water, which separates a fatty oil; treating the decanted watery liquid with basic lead acetate to remove colouring matters; and precipitating the excess of lead with sodium phosphate. The solution thus freed from foreign substances is fractionally precipitated with a solution of tannin, which throws down a compound of 3 mol. colchicine and 1 mol. tannic acid. The middle portion of this precipitate, which is the least coloured, is further purified by pressure and washing with a small quantity of water; then mixed with excess of levigated litharge and dried; the colchicine is extracted from the residue by alcohol; and the evaporated extract is again subjected to fractional precipitation with tannin and treatment with litharge, till the product exhibits a pure sulphur-yellow colour and dissolves completely in water and in alcohol.

Colchicine thus obtained is an amorphous substance having a faint aromatic odour and intensely bitter taste. It melts at 140° , is insoluble in ether, but easily soluble in water and in alcohol, neutral to litmus-paper; forms a yellow precipitate with auric chloride, white with mercuric chloride, and a curdy precipitate with tannic acid. Alkalies and strong mineral acids colour its solution deep yellow.

Colchicine, produced by the action of dilute sulphuric acid, alkalis, or baryta-water on colchicine, has, according to Hübner, the same composition as the latter. By repeated crystallisation from water, and finally from alcohol, it may be obtained in nodular groups of colourless needles which are much less bitter than colchicine, and are soluble in chloroform, less soluble in ether. It is completely abstracted from its aqueous solution by animal charcoal, being converted at the same time into a brown uncrystallisable substance, which is also easily formed from colchicine on exposure to the air. Colchicine has an acid reaction, dissolves easily in alkalis (in carbonates with evolution of carbon dioxide), forming amorphous salts whose solutions are precipitated by solutions of the alkaline earths and heavy metals; the copper-compound is crystallisable; the amorphous barium-compound has nearly the composition $(\text{C}^{17}\text{H}^{19}\text{NO}^3)_2\text{Ba}$.

COLLOIDAL ACIDS. See APPENDIX, v. 1088.

COLOPHONIN. $\text{C}^{10}\text{H}^{12}\text{O}^3$ (C. Tichborne, *Chem. News*, xx. 38).—When old *essence of resin* (obtained by distillation of colophony, i. 1087) is washed with water and the wash-water is evaporated, colophonin hydrate, $\text{C}^{10}\text{H}^{12}\text{O}^3 \cdot \text{H}_2\text{O}$, is obtained in large well-defined crystals having a sweet taste, destitute of odour, easily soluble in water, alcohol, ether, chloroform, and carbon bisulphide, less soluble in benzol and in essence of resin; from water it crystallises in fine colourless prisms. When heated it melts and sublimes, with partial loss of water. It also gives off water and effloresces when left over sulphuric acid. It may be completely dehydrated by prolonged fusion in a test-tube, the water which condenses in the upper part of the tube being continually removed by bibulous paper, and the sublimed crystals continually pushed back into the fused mass till no more water is given off. The compound thus dehydrated gave by analysis numbers agreeing with the formula $\text{C}^{10}\text{H}^{12}\text{O}^3$. Anhydrous colophonin and its hydrate differ from terpin and terpin hydrate respectively, by containing the elements of 1 mol. H_2O in addition. Bromine acts very strongly on colophonin hydrate, with formation of hydrobromic acid and separation of carbon. On the aqueous solution it acts less violently, forming an oil which appears to be a tetrabrominated substitution-product. The solution of the hydrate is optically inactive. When heated with acids (sulphuric, phosphoric, arsenic, citric, and tartaric), and then with alcohol, it exhibits a green colour; with most acids it is necessary to apply heat, but with sulphuric acid the reaction takes place in the cold. Under certain circumstances the green colour is also produced by hydrochloric acid; but when the hydrate is treated with strong hydrochloric acid, and the mass after half an hour is taken up with alcohol, a fine rose colour is developed. If the hydrochloric acid be allowed to act for a longer time, various shades of violet are produced, and ultimately a fine pure indigo-blue. None of these reactions are exhibited by terpin hydrate.

COLOPHONY. See *SILVIC ACID*.

COMBUSTION. 1. Temperature of Flame.—Experiments on the temperatures of the flames of carbon monoxide and hydrogen have been made by Bunsen (*Pogg. Ann.* cxxxi. 161; *Phil. Mag.* [4] xxxiv. 489; *Jahresb.* 1867, 39). When a combustible gas mixed with oxygen is set on fire, a rise of temperature takes place, which, supposing the combustion to be perfect, may be calculated from the heat of combustion of the gases and the specific heat of the products. If on the other hand the combustion is imperfect, the temperature may still be calculated, with the aid of Mariotte's and Gay-Lussac's laws, provided the pressure be known which is exerted by the gaseous mixture when exploded in a closed vessel. This pressure has been determined by Bunsen in the case of mixtures of hydrogen or carbon monoxide with oxygen, or with oxygen and nitrogen together, by means of an endiometer provided with a loaded safety valve. From this and the observed temperature of combustion, the quantity of the combustible gas (CO or H) which has been burnt at the moment when the flame attains its maximum temperature, and thence also the quantity which at this temperature has lost its power of combining, may be calculated.

The following table contains the results of the experiments, arranged according to the maxima of temperature, $t' - t$, which the several gaseous mixtures, calculated for volumes at 0°, attain by combustion in a closed vessel. Column III. gives the maximum temperatures for the mixtures in columns I. and II.; column IV. shows the fraction of the gas (CO or H) which has been burned:

I.	II.	III.	IV.	Mean	Deviation from the mean
$\frac{2}{3}$ vol. CO $\frac{1}{3}$ " O	0.0000 vol.	3172°	0.351	0.3316	+ 0.0194
$\frac{2}{3}$ " CO $\frac{1}{3}$ " O	0.0000 "	2893	0.319		- 0.0126
$\frac{2}{3}$ " H $\frac{1}{3}$ " O	0.0000 "	2854	0.338		+ 0.0064
$\frac{2}{3}$ " H $\frac{1}{3}$ " O	0.0000 "	2833	0.336		+ 0.0044
$\frac{2}{3}$ " CO $\frac{1}{3}$ " O	0.1079 " O	2558	0.314	0.5024	- 0.0176
$\frac{2}{3}$ " CO $\frac{1}{3}$ " O	0.6857 " CO	2471	0.460		- 0.0421
$\frac{2}{3}$ " CO $\frac{1}{3}$ " O	0.8854 " O	2325	0.478		- 0.0241
$\frac{2}{3}$ " CO $\frac{1}{3}$ " O	1.0861 " O	2117	0.490		- 0.0121
$\frac{2}{3}$ " CO $\frac{1}{3}$ " O	1.2563 " N	2084	0.515	0.5024	+ 0.0129
$\frac{2}{3}$ " H $\frac{1}{3}$ " O	1.2599 " N	2024	0.547		+ 0.0449
$\frac{2}{3}$ " CO $\frac{1}{3}$ " O	1.2563 " N	1909	0.470		- 0.0321
$\frac{2}{3}$ " CO $\frac{1}{3}$ " O	1.7145 " O	1726	0.520		+ 0.0179
$\frac{2}{3}$ " CO $\frac{1}{3}$ " O	2.1559 " O	1460	0.512	0.5024	+ 0.0099
$\frac{2}{3}$ " CO $\frac{1}{3}$ " O	3.1629 " CO	1146	0.527		+ 0.0249

These numbers show that in a mixture of carbon monoxide or hydrogen with the exact proportion of oxygen required for combination, and unmixed with any inert gas, only one-third of the carbon monoxide or hydrogen is burnt at the maximum temperature, whilst the other two-thirds, by being raised to the high temperatures of 2558°–3033°, have lost the power of combining; moreover, that when one of the same mixtures is diluted with 0.686 to 3.163 vol. of any gas that does not burn with it, and the temperature of the flame is thereby successively reduced from 2471° to 1146°, then, at all temperatures within this range, almost exactly half of the carbon monoxide

or hydrogen is burnt, whilst in the other half, the oxygen and carbon monoxide, or the oxygen and hydrogen, have lost the power of combining.

The combustion of gases appears therefore to take place in a manner very different from that which has been hitherto supposed. When a mixture of 2 vol. carbon monoxide and 1 vol. oxygen is set on fire, and its temperature thereby raised from 0° to 3033° , two-thirds of the carbon monoxide present remains in the unburnt and incombustible state; the temperature is then lowered, by radiation and conduction, from 3033° to 2558° without any combustion of this two-thirds of the carbon monoxide; but when the temperature falls somewhat lower, combustion recommences, restoring the heat lost by radiation and conduction, and raising the temperature again to 2558° , but not above that point. The gradual fall of temperature from 3033° is followed by a continuance of the temperature of 2558° till exactly half of the carbon monoxide is burnt, whereupon a third phase sets in, during which again no combustion takes place till the inflamed gaseous mixture has cooled down to at least 1146° . As, however, the gaseous mixture, after cooling, consists almost wholly of carbon dioxide, these alternate phases of constant and decreasing temperature must likewise be repeated below 1146° , till the last portion of gas is burnt. This discontinuous combustion of a uniform mixture of a combustible gas with oxygen is referred by Bunsen to a law of combination which he established some years ago. (See CHEMICAL AFFINITY, i. 860.)

In connection with this investigation, Bunsen has determined, by special experiments, the rate of propagation of the combustion in a pure detonating mixture of hydrogen and oxygen, and likewise of carbon monoxide and oxygen; in the former he finds the velocity of propagation to be 34 metres per second; in the latter less than 1 metre per second. When the explosive gaseous mixtures are gradually more and more diluted with a gas which does not take part in the combustion, the velocity of propagation is continually diminished, till at length, when the mixture has been brought to the very limit of inflammability, the progress of the combustion may be traced with the naked eye.

The temperature and composition of the flame of a mixture of carbon monoxide and oxygen have also been investigated by Deville (*Bull. Soc. Chim.* [2] v. 111). When a mixture of these gases in the combining proportions (2 vol. CO to 1 vol. O) issues under slight pressure from a jet having an area of 5 square millimetres, a flame 70 to 100 mm. high is formed, consisting of an inner and an outer cone. The outer cone, in which the combustion takes place, is deep blue at the base, yellowish or nearly colourless towards the apex; in the inner cone, which is only 10 mm. high, no combustion goes on, because the rapidity of displacement of the molecules is there superior to the very slow rate of propagation of heat in the mixture (*vid. sup.*). To collect the gases from the different parts of the flame, a silver tube pierced with a small aperture was placed across it in the part to be examined, and the gases were aspirated by passing a rapid stream of water through the tube. They are thus rapidly cooled, pass along the tube together with the water, and are finally collected by means of a bent delivery-tube in jars standing over a water-trough.

The temperatures and composition of the different parts of the flame are exhibited in the following table:

Height above the orifice	Corresponding Temperature	Composition of the gas		
		CO	O	N
67 mm.	Melting heat of silver, and above	0.2	21.3	78.5
64	Melting heat of gold	6.2	28.1	65.7
44	Commencing white heat of platinum	10.0	20.0	70.0
35	White heat of platinum	17.3	24.8	57.9
28	Strong white heat of platinum	19.4	26.5	54.1
18	Intense white heat of platinum	29.0	25.1	45.9
15	Incipient fusion of platinum	40.0	32.9	27.1
12	Melting heat of platinum	47.0	36.0	17.0
10*	Sparkling of the melted platinum	55.3	35.3	9.4
10†	Still higher temperature	55.1	36.5	8.4
0‡		64.4	33.3	2.3

* A little above the apex of the inner cone.

† Somewhat below the apex of the inner cone.

‡ Original mixture.

These numbers show that the highest temperature is at the apex of the inner cone or a little below it; that the temperature gradually diminishes towards the apex of the flame; and that the quantity of carbon dioxide increases in the same proportion from the apex of the inner cone, whereas at most two-thirds of the carbon monoxide and oxygen enter into combination, to the vertex of the flame itself, where carbon monoxide can no longer be detected. At the apex and edges of the inner cone, the carbon monoxide and oxygen unite almost instantaneously, but only partially, on account of the very high temperature there existing.

2. *Luminosity of Flame.*—It has generally been supposed that the light-giving power of a flame depends essentially on the presence of solid incandescent particles; and there is no doubt that the luminosity of a gaseous flame is very greatly increased by introducing into it a solid substance which can be raised by it to a very high temperature. Frankland has, however, shown that it is possible to produce very bright flames without the intervention of solid matter. Metallic arsenic burnt in a stream of oxygen produces an intense white flame, although both the metal itself and the product of its combustion (arsenious oxide) are gaseous at the temperature of the flame. The combustion of a mixture of nitrogen dioxide and carbon bisulphide also produces a dazzling white flame, without any separation of solid matter.

The conditions most essential to luminosity in a flame are a high temperature and the presence of gases or vapours of considerable density. The effect of high temperature is seen in the greater brightness of the flame of sulphur, phosphorus, and indeed all substances, when burnt in pure oxygen, as compared with that which results from their combustion in common air. The relation between the luminosity of a flame and the vapour-densities of its constituents may be seen from the following table, in which the vapour-densities are referred to that of hydrogen as unity:

Relative densities of gases and vapours.

Hydrogen	1	Arsenious chloride	92
Water	9	Phosphoric oxide	71, or 142
Hydrochloric acid	18½	Metallic arsenic	150
Carbon dioxide	22	Arsenious oxide	108
Sulphur dioxide	32		

A comparison of these numbers shows that the brightest flames are those which contain the densest vapours. Hydrogen burning in chlorine produces a vapour more than twice as heavy as that resulting from its combustion in oxygen, and accordingly the light produced in the former case is stronger than in the latter; carbon and sulphur burning in oxygen produce vapours of still greater density, namely, carbon dioxide and sulphur dioxide, and their combustion gives a still brighter light; lastly, phosphorus, which has a very dense vapour, and likewise yields a product of great vapour-density, burns in oxygen with a brilliancy which the eye can scarcely endure. Moreover, the luminosity of a flame is increased by condensing the surrounding gaseous atmosphere, and diminished by rarefying it. The flame of arsenic burning in oxygen may be rendered quite feeble by rarefying the oxygen; and on the contrary the faint flame of any ordinary spirit lamp becomes very bright when placed under the receiver of a condensing pump. Frankland has also found that candles give much less light when burning on the top of Mont Blanc than in the valley below, although the rate of combustion in the two cases is nearly the same (i. 1100). The effect of condensation in increasing the brightness of a flame is also strikingly seen in the combustion of a mixture of oxygen and hydrogen, which gives but a feeble light when burnt under the ordinary atmospheric pressure, as in the oxy-hydrogen blowpipe, but a very bright flash when exploded in the Cavendish eudiometer, in which the water vapour produced by the combination is prevented from expanding.

Under a pressure of ten atmospheres, the flame of hydrogen, and still more that of carbon-monoxide burning in oxygen, gives a bright light and a continuous spectrum. The electric spark is more luminous in proportion as the gas or vapour through which it passes has a greater density. The feeble light produced by the combustion of phosphorus in chlorine, which yields a very dense product, (PCl_3), appears to be due to the low temperature of the flame. Strongly heated phosphorus-vapour burns in hot chlorine with a dazzling white light.

The brightness of ordinary lamp, candle, and gas flames is due, not, as commonly supposed, to the separation of solid particles of carbon, but to that of very dense hydrocarbons, which produce the same effect as the vapours of arsenic and phosphorus in their respective flames. That such is the case is shown, first by the perfect transparency of the flame, which is quite inconsistent with the presence of solid particles;

secondly by the nature of the soot or lampblack deposited from it, which is well known not to consist of pure carbon, but to contain considerable quantities of hydrogen (Frankland, *Journal of Gas-lighting*, July 1867, p. 291; *Proc. Roy. Soc.* xvi. 419).

3. *Conditions of Explosion* (Abel, *Phil. Trans.* 1869; *Chem. Soc. J.* [2] viii. 41; abstr. *Proc. Roy. Soc.* xvi. 395).—The degree of rapidity with which an explosive substance undergoes metamorphosis, as also the nature and results of such change, are in the greater number of instances susceptible of several modifications, by variation of the circumstances under which the conditions essential to chemical change are fulfilled. Excellent illustrations of the modes by which such modifications may be brought about are furnished by gun-cotton, which may be made to burn very slowly and almost without flame, to inflame with great rapidity but without development of great explosive force, or to exercise a violent destructive action, according as the mode of applying heat, the circumstances attending its application, and the mechanical conditions of the explosive agent are modified. In general, the explosion is more violent and the combustion more complete in proportion to the amount of resistance offered at the commencement of the combustion to the escape of the gases—in other words, in proportion as the strength of the receptacle enclosing the gun-cotton, and the consequent initial pressure developed by the explosion, is increased. (See PYROXYLIN, iv. 779.)

Other explosive compounds and mixtures are similarly influenced by the circumstances attending their metamorphosis. A charge of *gunpowder* in a cylindrical tin case, fired by a fuse inserted near the bottom, explodes much more violently than the same charge ignited by a fuse placed just beneath the surface; in the first instance the main body of the charge acts at the moment of ignition as tamping does in a blast-hole, by presenting a resistance to the escape of the gases generated, and thus for a moment establishing the pressure essential to the violent and perfect explosion of the powder first inflamed, whereupon the same character of explosion extends throughout the charge. In like manner *mercuric fulminate* (50 grains) inflamed by bringing an incandescent platinum wire just in contact with the surface or edge of the heap, explodes with a dull report, and produces no effect on a flat plate of copper sheet on which it rests; but a much smaller quantity ($15\frac{1}{2}$ grains) of the same fulminate heaped up over the platinum wire produces a sharp and violent explosion, the force of which deeply indents and bends up the support of sheet copper.

The volume of the explosion of a small quantity of *silver fulminate* confined in a case of stout sheet metal is very decidedly greater than if a corresponding quantity be enclosed in metal foil, or freely exposed to air and inflamed in the same manner. The violence of explosion of *iodide of nitrogen* is very decidedly increased by enclosing it in an envelope or shell of plaster of Paris, or, better still, in a case of sheet metal, while the *chloride of nitrogen* explodes with but comparatively little violence, unless it is confined. The reputation which this substance has enjoyed of being the most violent explosive body known, appears to be due to the fact that experiments on its explosion have always been conducted with a covering of water upon the material. Three or four drops (about 0.14 grm. = 2 grains) placed in a watch-glass covered only with a thin layer of water, explode with a sharp report when touched with turpentine, and almost pulverise the glass; but similar quantities, of which the upper surfaces were exposed to air, have been repeatedly exploded in watch-glasses without breaking them. Two grms. of the chloride, contained in a watch-glass, and covered with a thin layer of water, were placed upon a small solid cylinder of hard *papier mâché* which rested upon paving. A violent explosion was produced by touching the chloride with turpentine, the watch-glass was pulverised and dispersed, and the cylinder was greatly shattered, fragments being projected in all directions. Four grms. of the chloride, with the upper surface exposed to air and placed upon a similar cylinder of *papier mâché*, produced a comparatively very feeble explosion; the watch-glass was broken, but the cylinder was not in the slightest degree affected, and remained undisturbed in its original position. A repetition of the experiment with 4 grms. of the chloride, enclosed by a thin layer of water, produced complete disintegration of the cylinder. It appears from these results that, in the case of the chloride of nitrogen, the decomposition of which is of an instantaneous character, the resistance offered at the moment by the layer of water acts as effectually in intensifying the force of explosion as a thin sheet-metal case does with the mercuric fulminate, or as a strong iron shell with gun-cotton or gunpowder.

Nitroglycerin or *Glonoïn*, which bears some resemblance to chloride of nitrogen in the suddenness of its explosion, requires the fulfilment of special conditions for the full development of its explosive force. Its explosion by the simple action of heat

can be accomplished only when the source of heat is applied for a considerable time in such a way that chemical decomposition is established in some portion of the mass, and is favoured by the continued application of heat to that part. Under these circumstances the chemical change proceeds with very rapidly accelerating violence, and eventually brings about a sudden transformation of the heated portion into gaseous products, which transformation is instantly communicated throughout the mass of nitroglycerin, so that confinement of the substance is not necessary to develop its full explosive force. This result can be obtained more expeditiously, and with greater certainty, by exposing the substance to the concussive action of a detonation produced by the ignition of a small quantity of fulminating powder, closely confined and placed in contact with or near to the nitroglycerin.

The development of the violent explosive action of nitroglycerin freely exposed to air through the agency of a detonation was regarded until recently as a peculiarity of that substance; but Abel's experiments have shown that gun-cotton and other explosive compounds and mixtures do not necessarily require confinement for the full development of their explosive force, this result being obtained (and very readily in some instances, especially in that of gun-cotton) by means similar to those applied in the case of nitroglycerin, viz. by the percussive action of a detonation.

The action of a detonation in determining the violent explosion of gun-cotton, nitroglycerin, &c., cannot be ascribed to the direct operation of the heat developed by the chemical changes of the charge of detonating compound used as the exploding agent. An experimental comparison of the mechanical force exerted by different explosive compounds, and by the same compound employed in different ways, has shown that the remarkable power exhibited by the explosion of small quantities of certain bodies (the mercuric and argentic fulminates) to accomplish the detonation of gun-cotton, while comparatively large quantities of other highly explosive agents are incapable of producing this result, is generally accounted for in a satisfactory manner by the difference in the amount of force suddenly brought to bear in the different instances upon some portion of the mass operated upon. Most generally, therefore, the degree of facility with which the detonation of a substance will develop similar change in a neighbouring explosive substance may be regarded as proportionate to the amount of force developed within the shortest space of time by that detonation, the latter being, in fact, analogous in its operation to that of a blow from a hammer or of the impact of a projectile.

Several remarkable results of an exceptional character have, however, been obtained, which indicate that the development of explosive force under the circumstances referred to is not always simply ascribable to the sudden operation of mechanical force. Thus silver fulminate, which explodes much more suddenly and with much more powerful local force than mercuric fulminate, nevertheless, when applied under the same conditions, does not induce the explosion of gun-cotton so readily as mercuric fulminate. 5 grains of mercuric fulminate enclosed in a case of stout sheet metal and exploded in close contact with compressed gun-cotton, caused the detonation of the latter; but 5 grains of silver fulminate enclosed in tin-foil, though it appeared to produce quite as sharp a detonation as the same quantity of the mercury salt enclosed in the stout case, did not explode gun-cotton with which it was surrounded, but merely scattered the mass; when enclosed in the stout sheet-metal case, however, the 5 grains of silver fulminate accomplished the detonation of the gun-cotton. Iodide and chloride of nitrogen are much more susceptible of sudden explosion even than silver fulminate; nevertheless the iodide does not appear to be capable of causing the explosion of compressed gun-cotton; and the chloride of nitrogen shows but little capability of producing the same effect, 50 grains being the smallest quantity that will answer the purpose. Lastly, it is found that nitroglycerin when exploded by a charge of mercuric fulminate will not bring about the explosion of compressed gun-cotton placed in contact with it, though under precisely similar circumstances the explosion of gun-cotton or of nitroglycerin will induce the explosion of a larger mass of its own kind.

These results point to the conclusion that the effect of the detonation of one substance in causing the explosion of another depends not only on the force, but also on the nature of the vibrations developed in the former, the most probable explanation of the observed results being that the vibrations attendant upon a particular explosion, if synchronous with those which would result from the explosion of a neighbouring substance in a state of high chemical tension, will, by their tendency to develop those vibrations, either determine the explosion of that substance, or, at least, greatly aid the disturbing effect of mechanical force suddenly applied, while, in the instance of another explosion, which develops vibratory impulses of a different character, the mechanical force applied through its agency has to operate with little or no aid, so

that greater force or a more powerful detonation is required in the latter case to accomplish the same result.

Instances of the apparently simultaneous explosion of numerous distinct and even somewhat widely separated masses of explosive substances (such as simultaneous explosions in several distinct buildings at powder-mills) occur not unfrequently, in which the generation of a disruptive impulse by the first or initiative explosion, which is communicated with extreme rapidity to contiguous masses of the same nature, appears much more likely to be the operating cause, than that the simultaneous explosion should be brought about by the direct operation of heat and mechanical force developed by the starting explosion.

The explosion of gun-cotton and gunpowder by the agency of detonation is much more sudden and violent than when the same substances are exploded, even in confined spaces, by the simple agency of heat. This has been abundantly proved, in the case of gun-cotton, by blasting operations in various descriptions of rock, and by measurement of the comparative destructive effect of charges exploded under water. Charges of gun-cotton contained in blast-holes, and having a detonating fuse inserted in or placed immediately over them, have produced much greater rending and shattering effects in hard rock and in wood (although the blast-holes were left entirely open, or only filled with loose sand, earth, or powdered rock) than corresponding charges applied in similar positions, but fired with ordinary fuses, although in the latter instances the gun-cotton was confined by 'tamping,' or firmly closing the blast-hole to a considerable depth. A series of systematic experiments has been carried on at Chatham by the Government Committee on Floating Obstructions, with the view of comparing the destructive power of gunpowder and gun-cotton, in which charges of these materials were exploded in proximity to submerged targets, with systematic variations of the strength of the cases containing the charges, the depth of their immersion beneath the surface, and their distances from the targets. The results of these experiments warranted the conclusion that gun-cotton, when confined in cases of sufficient strength to develop its full explosive action, exerts a destructive effect equal to about five times that of gunpowder. A few experiments to compare with these have been recently instituted with charges of gun-cotton enclosed in thin sheet-metal cases and exploded by means of detonating fuses, and in these the destructive action upon vertical targets, placed at very considerable distances from the charges, was from ten to twelve times greater than that of gunpowder. The concussion imparted through the water to considerable distances, by the explosion of small charges (2 to 3 lb.) of gun-cotton in the new manner, very greatly exceeded in their effects the results produced by the explosion of submerged charges by the ordinary method.

An examination of the decomposition-products of gun-cotton exploded by detonation has shown that they do not differ in any important respect from those obtained by the complete metamorphosis of the substance when exploded in strong shells under ordinary conditions (iv. 779). The increased destructive effect developed by the explosion through the agency of detonation must therefore be ascribed to the greater rapidity of the explosion under these conditions. The ordinary explosion of gun-cotton is attended by a considerable body of flame, due to the ignition of the generated carbonic oxide; but the detonation of gun-cotton is attended only by a sudden flash, which it is very difficult to observe in daylight if only small quantities are exploded. The transformation of the solid into gas appears, in fact, to be too sudden for the generated combustible gas to become inflamed.

CONHYDRINE. $C^8H^{10}NO = \left. \begin{matrix} (C^8H^{10}O) \\ H \end{matrix} \right\} N$ (ii. 1).—Wertheim (*Wien. Akad.*

Ber. xlv. [2] 299) obtained from 333 kilograms of fresh hemlock-seeds 700 grms. of pure conine, and rather more than 40 grms. of pure conhydrine, the greater part of the latter being obtained by fractional distillation of the crude conine, a smaller portion from the residues in the still. These residues, after neutralisation with sulphuric acid and filtration from the separated gypsum, were evaporated to dryness, exhausted with strong alcohol, and the extract again evaporated was agitated with strong potash-ley and other; the conhydrine which remained after spontaneous evaporation was obtained pure by one recrystallisation from ether.

Conhydrine melts at $120^{\circ}0'$, and boils at $225^{\circ}45'$ (bar. at $719^{\circ}8$ mm.). It is not acted upon by nitrous acid, but by phosphoric anhydride or by sodium it is converted into conine. With mercuric oxide it resinises without giving off gas. *Conhydrine sulphate*, which is easily soluble in water and in alcohol, crystallises in flat, rather

hard prisms; the *nitrate* is somewhat less soluble, and gradually solidifies to a crystalline mass. The *hydrochloride* and *acetate* are uncrystallisable.

Ethyl-conhydrides.—When conhydride is heated with ethyl iodide, a brisk reaction takes place, and ethyl-conhydride hydriodide, $C^2H^4(C^2H^5)NO.HI$, is obtained, as an easily soluble crystalline mass; and this, when decomposed by potash-ley, yields ethyl-conhydride as an oil which also solidifies in the crystalline form. It distils without decomposition, and is more soluble in ether than conhydride. Heated with ethyl iodide, it solidifies to a mass consisting of diethyl-conhydride hydriodide, $C^2H^4(C^2H^5)^2NO.HI$, which gradually separates from its almost syrupy aqueous solution, in small hard crystals, having an almost adamantine lustre, and consisting, according to measurements by Zepharovich (*Wien. Akad. Ber.* xlvii. [1] 275), of rhombic sphenoido-hemihedral combinations of $\frac{P}{2} - \frac{P}{2}, \infty P, \frac{P}{2}\infty$, the face $\frac{P}{2}$ generally occurring alone. Axes $a : b : c = 0.8823 :$

$1 : 1.05$. This salt decomposed with silver oxide yields a caustic bitter syrup which rapidly absorbs carbonic acid. The *hydrochloride* of this ammonium-base is very soluble in water and crystallises slowly in thin needles; the *platinochloride*, $[C^2H^4(C^2H^5)^2NO.CH^3].PtCl_4$, is a light wine-yellow precipitate which separates from hot water in beautiful orange-red crystals consisting, according to Zepharovich, of quadratic combinations $P.2P.9P.\infty P$. For P , the ratio of the secondary axes to the principal axis is $1 : 0.8679$. Angle $P : P$ (terminal) $= 113^\circ 31'$; $P : P$ (basal) $= 78^\circ 21'$; $2P : 2P$ (terminal) $= 98^\circ 11'$; $2P : 2P$ (basal) $= 135^\circ 40'$; $9P : 9P$ (terminal) $= 90^\circ 28'$; $9P : 9P$ (basal) $= 169^\circ 39'$.

Azoconhydride. $C^2H^4N^2O$.—The near agreement of the vapour-density, 5.39, calculated from this formula with that found by experiment (in three experiments, 5.437, 5.691, and 5.410) shows that the formula $C^2H^4N^2O$ originally given to this substance (ii. 964) was too high. *Nascent hydrogen* (zinc and hydrochloric acid) converts azoconhydride into conine:

When azoconhydride is heated to 160° with metallic *sodium* broken into small pieces by agitation while in the melted state, it gives off a large quantity of gas ($11\frac{1}{2}$ p.c. hydrogen to 88 nitrogen), and leaves a residue containing a large quantity of conine, together with unaltered azoconhydride; perhaps thus:

and

Azoconhydride dissolves abundantly in concentrated acetic or formic acid, and absorbs large quantities of anhydrous hydrocyanic acid, but the resulting compounds are decomposed by water and by heating to 100° (Wertheim, *Wien. Akad. Ber.* xlvii. [2] 491).

CONIFERIN. $C^2H^4O^{12}$ (Kubel, *J. pr. Chem.* xvii. 243; *Jahresh.* 1866, p. 676).—A glucoside occurring in the cambium of coniferous woods (*Abies excelsa*, *A. pectinata*, *Pinus Strobus*, *P. Cembra*, *Larix europea*). It forms needle-shaped crystals containing $C^2H^4O^{12}.3H^1O$, which effloresce in dry air and give off all their water at 100° ; melts at 185° , and carbonises at a higher temperature, giving off the odour of caramel; dissolves easily in hot water, sparingly in cold water and in alcohol, and is insoluble in ether. The aqueous solution tastes faintly bitter, and turns the plane of polarisation to the left. Boiled with dilute acids it gives off an odour of vanilla, and deposits a resinous body insoluble in alkalis, while the filtrate contains a dextrorotatory sugar. Strong sulphuric acid in contact with coniferin or the resinous body just mentioned acquires a characteristic dark violet colour, and on adding water a precipitate is formed which gives to the liquid an indigo-blue colour. By this reaction coniferin may be detected in coniferous woods, namely, by moistening a fresh section with strong sulphuric acid; the young wood and the bast exhibit a violet colour.

CONINE. C^2H^5N .—Schiff (*Ann. Ch. Pharm.* clvii. 352) has obtained this base synthetically by heating normal butyric aldehyde, C^4H^7O , with alcoholic ammonia, whereby a base, *dibutyraldine*, $C^4H^9NO = 2C^2H^5O + NH^3 - H^1O$, is obtained, and subjecting this base to dry distillation: $C^4H^9NO - H^1O = C^2H^5N$.

CONYLENE. C^2H^4 (ii. 964).—This hydrocarbon, produced by the action of phosphoric anhydride on azoconhydride, is mixed with a less volatile body not yet examined. It does not appear to be poisonous.

When 9 pts. (1 mol.) conylene-bromide, $C^2H^4Br^2$, are heated to 120° – 140° , with

11 pts. (2 mol.) silver acetate and a small quantity of glacial acetic acid, conylene diacetate, $(C^6H^{11})_2(C^2H^3O^2)_2$, is formed, having an acid reaction, an odour of peppermint, a sp. gr. of 0.988 at 18.2°, and boiling at 225°. This acetate, distilled with pulverised potassium hydrate at a temperature above 230°, gives off, first a pale yellow oily liquid, and then a smaller quantity of a very viscid distillate. The latter is lighter than water, insoluble therein, but soluble in alcohol and ether, and has the composition of conylene alcohol, $(C^6H^{11})(HO)^2$. The more volatile distillate has the composition of dicynylene alcohol, $C^6H^8O^2$ or $(C^6H^{11})_2H^2O^2$, but the lower boiling point renders this view of its constitution somewhat improbable (Wortheim, *loc. cit.*).

COOKEITE. A silicate occurring, together with red tourmaline and lepidolite, in the granite formation of Hebron and Paris in the State of Maine. It is white, sometimes yellowish-green, with a nacreous lustre; hardness = 2.5; sp. gr. = 2.70. Its analysis gave 34.93 p. c. SiO_2 , 44.91 Al_2O_3 , 2.57 K_2O , 2.82 Li_2O , 0.47 SiF_4 , 13.41 H_2O , and 0.38 hygroscopic water, a composition nearly the same as that of euphyllite and margarite (G. J. Brush, *Sill. Am. J.* [2] xli. 246).

COPAIBA BALSAM. According to Roussin (*J. Pharm.* [4] i. 221), the hardening of this balsam by lime or magnesia depends upon the presence of a certain quantity of water (about $\frac{1}{20}$ of the balsam), the lime or magnesia being thereby converted into a hydrate which unites with the balsam.

The variety of copaiba balsam from Maracaibo in Columbia has been examined by Strauss (*Ann. Ch. Pharm.* cxlviii. 148; *Zeitschr. f. Chem.* [2] v. 301). It has a wine-yellow colour, syrupy consistence, and sp. gr. = 0.900 at 15°; dissolves in all proportions in alcohol, ether, and benzol. With ammonia it forms a clear solution, which becomes turbid on addition of a large quantity of water, and with magnesia a plastic soapy mass; it is coloured brown-red by strong sulphuric acid; does not smell like turpentine when heated.

On boiling this balsam with weak soda-ley, the greater part of the volatile oil separates on the surface. This oil, when dehydrated over calcium chloride and rectified, is limpid, has a pleasant aromatic odour and burning bitter taste. Sp. gr. 0.921 at 10°. Boiling point 250°–260°. It dissolves in ether, benzol, and chloroform, in about 3 pts. of cold absolute alcohol, more readily in hot alcohol, and separates from this solution on cooling. It is coloured yellow by dilute nitric acid, deep red by nitric acid of sp. gr. 1.41, the latter after a few minutes oxidising it violently, and forming a resinous mass which dissolves at the heat of the water-bath in the supernatant liquid, the solution when evaporated leaving a resinous residue soluble with red colour in potash-ley; hydrochloric acid added to the potash solution throws down an amorphous substance soluble in alcohol. The vapour-density of the oil, which is nearly 9.5, shows that its molecular formula is $C^{20}H^{32}$.

Metacopaivic Acid. $C^{22}H^{40}O^4$.—When the alkaline resin-solution decanted from the volatile oil is mixed with sal-ammoniac, the resin-soaps rise to the surface together with the volatile oil still dissolved in the liquid; and on adding hydrochloric acid to the ammoniacal solution filtered through moistened paper, metacopaivic acid rises to the surface in the form of a flocculent substance which may be dried in the air, and purified by repeated crystallisation from boiling alcohol. It crystallises in laminae, dissolves in alcohol and ether, in petroleum only when heated; is insoluble in water; melts at 205°–206°; has an acid reaction; and decomposes carbonates. Its neutral solution in ammonia forms white precipitates with calcium, barium, and lead salts. The silver salt $C^{22}H^{32}O^4Ag^2 + H_2O$ is sparingly soluble in water, easily soluble in ammonia, and becomes anhydrous at 150°. The cupric salt $C^{22}H^{32}O^4Cu.H_2O$ is a bluish-green precipitate. The sodium salt forms very hygroscopic crystals.

The quantity of metacopaivic acid in the balsam is very small. Strauss regards it as probably identical with Werner's gurgunic acid obtained by treating wood-oil or gurgun balsam (i. 495) with potash-ley, although the melting point of the latter, as given by Werner (*Jahresh.* 1862, p. 462), is 14° or 15° higher.

According to Flückiger (*J. pr. Chem.* ci. 235), Maracaibo balsam is optically dextrogyrate, Maranha balsam levogyrate, and a mixture of the two in certain proportions is optically inactive.

COPPER. Atomic Weight 63.4. Equivalent 31.7.—Field & Abel (*Chem. Soc. J.* [2] i. 89) have examined the impurities in native copper from several localities. In thick plates of copper from Chile (the so-called *Chargui copper*) covered on both sides with talc and chlorite, they found only traces of bismuth and silver. Two specimens of Minnesota copper from Lake Superior contained 0.56 p. c. silver without any other admixture; a third consisted, to about $\frac{1}{3}$ of its entire mass, of native silver,

occurring in thick veins and containing a trace of lead. A specimen of Siberian copper, occurring with green altered arragonite and superficially converted into red copper ore, was found to be very impure, containing 1.28 p. c. arsenic, together with small quantities of silver, bismuth, and lead. Native copper from Algodon Bay in Bolivia was found by v. Bibra (*J. pr. Chem.* xvi. 193) to contain, on the average, 97.6 p. c. copper, 2.0 iron, 0.3 silicon, and a trace of antimony.

Copper is contained to the amount of 5.9 p. c. in *turacin*, the red pigment of the wing-feathers of the Turaco (*Church, Chem. News*, xix. 265).

Metallurgy.—A method of extracting copper from poor ores containing lime or dolomite is described by G. Bischof (*Lond. Journal of Arts*, 1862, p. 277; *Dingl. pol. J.* clxv. 31; *Jahresb.* 1862, p. 649). It consists essentially in igniting the ores (in a lime-kiln) at a moderate heat, partly removing the lime and magnesia by washing, and fusing the residue with iron pyrites (5 pts. to 1 pt. of copper) to obtain *coarse metal* (ii. 23). The latter is finely pulverised, and roasted in mud-furnaces for a long time at a low red heat, and the roasted product is lixiviated, whereby it is resolved into a solution of cupric sulphate and a residue from which the cupric oxide is extracted by dilute sulphuric acid. The copper is then precipitated from the sulphate solution by metallic iron, washed with liquids containing copper, freed from arsenic and antimony by roasting, and finally melted. A method of extracting copper from poor sulphurous ores, practised at Foldal in Norway, is described by C. Woltz (*Dingl. pol. J.* clxiv. 289; *Jahresb.* 1862, p. 648). See also H. Wagner (*Dingl. clxxxiii.* 338; *Jahresb.* 1867, p. 889); Aubel (*Dingl. clxxxiv.* 137; *Jahresb. ibid.*). Chindo (*Dingl. clxxx.* 860) describes a process for obtaining refined copper at one operation from sulphuretted ores. It consists essentially in smelting the roasted ore with charcoal in a furnace so constructed that the coarse copper, as it is formed, may run off into a reverberatory furnace, where it is converted into refined copper by the united action of air and over-heated steam.

An examination of the products of the Mannsfeld process (i. 31) in its several stages has been made by G. Steinbeck (*Inaugural Dissertation*, Halle, 1862; *Jahresb.* 1862, p. 643).

Many kinds of pyrites which are burnt for the preparation of sulphuric acid contain sufficient copper to render its extraction from the residues remunerative. Haeflilly (*Lond. Journal of Arts*, May 1862, p. 278; *Rép. Chim. app.* iv. 384) roasts these residues a second time, lixiviates the product with an acid solution of manganous chloride (residues of chlorine manufacture), and precipitates the copper from the resulting solution (which must contain free acids) by means of the basic calcium sulphide of the soda manufacture. The precipitated sulphide is then treated by the ordinary methods. For other methods of treating these cupriferous pyrites residues, see Richardson and Watts's *Chemical Technology*, pt. iii. p. 73, and pt. v. p. 206.

For the electrolytic precipitation of copper from poor cementation-waters (ii. 86), Patena (*Dingl. clxxxiv.* 134) passes the solutions slowly through an apparatus in which the positive pole is formed of iron plates immersed in a porous cell containing hydrochloric acid or solution of common salt, and the negative pole of granulated copper or coke connected with the iron by a copper wire.

Impurities in Commercial Copper.—The quantities of different non-metallic impurities, especially oxygen, in several kinds of refined copper have been determined by Abel (*Chem. Soc. J.* [2] ii. 164). Ingots of Kapunda copper (which is remarkably free from metallic impurities) having depressions on their upper surface were found to contain a larger proportion of cuprous oxide (1.704 to 2.631 p. c.) than those with even surface (0.856 to 1.409 p. c.); the latter also exhibited a regular decrease in the proportion of cuprous oxide from the surface to the middle of the bar. Copper fused in a crucible lined with charcoal and left to solidify without access of air, did not contain a trace of cuprous oxide if the fusion had been long continued; in the contrary case it was found to contain a small quantity (0.13 to 0.19 p. c.). When the copper fused in the charcoaled crucible was cooled in contact with the air, spitting took place shortly before complete solidification, and the metal then contained oxygen. Several varieties of copper from the Haford works gave the following percentages of cuprous oxide:

	Cuprous oxide in 100 parts
Overpoled copper	0.228 to 0.357
Tough-pitch copper	0.223 „ 0.321
Half-poled copper	1.616 „ 1.873
Dry copper, inner portion	3.750 „ 3.782
„ „ outer portion	4.631 „ 4.663

Carbon was not detected with certainty in Alten and Kapunda copper remelted with charcoal; but Alten copper and a specimen from North America were found to contain a trace (at most 0.003 p. c.) of **selenium**; copper from Copiapo, Manila, and Hungary was found to be free from that element. The amount of **sulphur** found in various kinds of copper, by four hours' ignition in a stream of hydrogen, was about 0.005 p. c.; phosphorus and nitrogen could not be detected.

Detection and Estimation.—A borax bead containing only a small quantity of copper remains transparent and colourless when heated in the reducing flame, and then left to cool, especially if the bead itself is not very large and the heating has been long continued. If gently heated again it becomes ruby-coloured and transparent, but the colour disappears if the heat is too strong (Gerland, *Bull. Soc. Chim.* [2] i. 271).

For quantitative estimation copper may be precipitated:

a. In the metallic state, by electrolysis. The solution of the sulphate is poured into a small platinum dish serving as the negative pole of a battery of one or two elements, the positive pole being formed by a thick platinum wire dipping into the solution. The copper, which is deposited in the dish in a few hours in the form of a shining film, is washed with distilled water, dried over sulphuric acid in a vacuum, and weighed in the dish (W. Gibbs, *Sill. Am. J.* [2] xxxix. 58). See also Luckow (*Jahresh.* 1865, p. 685). Ullgren (*Zeitschr. f. Chem.* [2] v. 307) uses for this purpose a glass tube half an inch wide, closed at the bottom with a piece of bladder, and loosely at the top with a cork, through which a strip of zinc may be moved up and down. The tube filled to $\frac{2}{3}$ with solution of common salt is immersed to a small depth into the copper solution acidulated with sulphuric acid; and the strip of zinc dipping into the salt-solution is connected with a piece of platinum foil, on which is placed the platinum dish containing the copper solution. The rate of deposition of the copper may be regulated by immersing the zinc more or less deeply in the salt-solution; the more slowly it takes place the more compact is the deposit.

β. Copper may be estimated as cuprous sulphide, Cu_2S (containing 79.85 p. c. copper), by precipitating it as cupric sulphide from the solution of the sulphate or chloride with hydrogen sulphide, and strongly igniting the washed and dried precipitate in a porcelain crucible through which a stream of hydrogen is directed by a tube passing through the perforated platinum lid (H. Rose, *Pogg. Ann.* cx. 120). In precipitating copper with hydrogen sulphide, it is best to keep the solution at the boiling heat; the precipitate is then compact and does not oxidise in washing. The copper may also be at once precipitated as cuprous sulphide by addition of sodium hyposulphite to the solution of the sulphate, previously freed from hydrochloric and nitric acids by evaporation to dryness with sulphuric acid (Flajolot, *Ann. Ch. Phys.* [3] xxxix. 460). The precipitate is ignited, as above, in an atmosphere of hydrogen, to expel any excess of sulphur that it may contain.

γ. Gibbs (*Zeitschr. anal. Chem.* vii. 255, 422) precipitates the copper as cuprous hydride, Cu_2H_2 , by adding magnesium hypophosphite in excess to a moderately dilute solution of cupric sulphate containing a slight excess of sulphuric acid, but free from nitric or hydrochloric acid (in presence of nitric acid the precipitation is incomplete; hydrochloric acid interferes with it by forming cuprous chloride). The solution is gradually heated to 80° or 90° to ensure the complete precipitation of the cuprous hydride; and the latter, after washing and drying, is ignited in a stream of hydrogen, whereby it is resolved into hydrogen gas and metallic copper, which is weighed. The process may be applied to the valuation of copper ores, the ore being first roasted in the finely divided state, then heated to low redness with a mixture of equivalent quantities of nitrate and acid sulphate of potassium, and the fused mass heated with a quantity of strong sulphuric acid, sufficient to convert the whole of the potassium into acid sulphate. The filtered aqueous solution is then to be treated as above.

δ. As Cuprous Iodide, Cu_2I_2 . The copper solution, not containing excess of nitric acid, is mixed with excess of sulphurous acid, and then gradually with a solution of iodine in sulphurous acid. The precipitate, after standing for twelve hours, and washing, is converted into cupric oxide by suspending it in water, treating it with chlorine, and precipitating with potash (Flajolot, *loc. cit.*). Pisani (*Compt. rend.* xlvii. 294) collects the precipitated cuprous iodide on a weighed filter, dries it at 100° – 120° , and weighs it; but this method appears to be troublesome. Pisani also recommends potassium iodide as a precipitant; but, according to Flajolot, the cuprous iodide is slightly soluble in excess of this reagent.

ε. As Cuprous Sulphocyanate, $\text{Cu}_2(\text{CNS})_2$. The cupric solution free from nitric acid is reduced by sulphurous acid, and precipitated by potassium sulphocyanate,

and the precipitated cuprous sulphocyanate is dried and weighed: it contains 52.5 p. c. copper. Or the precipitate may be converted into cuprous sulphide by fusion with sulphur in a covered crucible (Rivot, *Compt. rend.* xxxviii. 868). This method is recommended by Wolffskron (*Chem. Centr.* 1866, p. 265) for separating copper from palladium.

The precipitation of copper as cuprous iodide or sulphocyanate is better adapted than the ordinary mode of precipitation with hydrogen sulphide for effecting the complete separation of copper from zinc, nickel, cobalt, and manganese.

For estimating the quantity of cuprous oxide (or oxygen) present in refined copper, Abel (*Chem. Soc. J.* [2] ii. 164) recommends the following process, based upon the fact that neutral silver nitrate is decomposed by cuprous oxide, with separation of metallic silver, and formation of a basic cupric salt, which requires for conversion into neutral salt a quantity of acid equivalent to the cuprous oxide (or oxygen) present in the copper:

A known weight of the copper under examination is digested for about three hours with a cold neutral solution of silver nitrate; and the portion unacted upon is picked out, thoroughly washed, and weighed, the difference between its weight and the original weight representing the quantity of copper acted upon by the silver nitrate. The mixture of precipitated silver and basic cupric nitrate is then collected, washed, and digested for half an hour with a known quantity of normal sulphuric acid (containing 1 pt. SO^4H^2 to 100 pts. water), after which the solution is filtered from the metallic silver, and the free acid in the filtrate is determined by alkalimetry. The quantity of acid neutralised by the cupric oxide is equivalent to the oxygen or the cuprous oxide in the metallic copper.*

The proportion of cuprous oxide in red copper ore may be estimated by digesting the finely pulverised mineral with dilute sulphuric acid and silver sulphate. Metallic silver is then separated in the proportion of 2 at. silver to 1 mol. cuprous oxide: $\text{Cu}_2\text{O} + \text{SO}^4\text{H}^2 = \text{Cu} + \text{SO}^4\text{Cu} + \text{H}_2\text{O}$, and $\text{Cu} + \text{SO}^4\text{Ag}^2 = \text{SO}^4\text{Cu} + \text{Ag}_2$ (Abel, *Zeitschr. anal. Chem.* vi. 459). There must of course be no metallic copper present.

On the volumetric estimation of copper, see Galetto (*Zeitschr. anal. Chem.* 1869, 135; *Zeitschr. f. Chem.* [2] vi. 91).

Compounds of Copper with Non-metallic Elements.

Copper is a diatomic or bivalent metal, forming two series of compounds designated as *cupric* and *cuprous*. The compounds of both these series contain in their molecule 2 at. of a univalent, or 1 at. of a bivalent radicle, associated in the cupric compounds with 1 at. of copper. In the cuprous compounds with 2 at. of copper linked together by one of their units of affinity; in fact, the group —Cu—Cu— , composed of two diatomic atoms, is itself diatomic; e. g.,

Cuprous Chloride, Cu^2Cl^2 , may be obtained in the crystalline state by passing sulphurous acid gas into a solution of cupric sulphate mixed with an equivalent quantity of sodium chloride. The precipitated crystalline powder, consisting of small tetrahedrons, must be washed by decantation with aqueous sulphurous acid; if washed with pure water, it turns yellow, light brown, and violet, and in boiling water assumes a bright brick-red colour. It is so sensitive to light that the crystals, immersed in aqueous sulphurous acid and exposed to direct sunshine for only five minutes, acquire a complete copper colour and metallic lustre. This copper-coloured body is probably a cuprous oxychloride formed together with hydrochloric acid; when exposed to the air it oxidises, as quickly as the colourless crystals, to green cupric oxychloride (Wöhler, *Ann. Ch. Pharm.* cxxx. 373). Metallic copper dipped into solution of cupric chloride, ferric chloride, dilute nitromuriatic acid, or a solution of potassium chromate or chlorate mixed with hydrochloric acid, becomes covered with a whitish-gray film of cuprous chloride, which when exposed to light gradually becomes black, with copper reflex; this property may be made available for photography. In its original, as well as in its altered state, it is not perceptibly soluble in dilute nitric or sulphuric acid, but dissolves in sodium hyposulphite, potassium cyanide, iodine, potassium iodide, hydrochloric acid, and ammonium sulphate (Renault, *Compt. rend.* lix. 319; *Jahresb.* 1864, p. 278).

* Abel has shown that the estimation of the oxygen by igniting the copper in hydrogen gas, as practised by Dick (*Phil. Mag.* [4] xi. 109), does not give exact results.

Cuprous Bromide, Cu^2Br^2 , is formed in like manner by dipping a plate of copper into aqueous solution of cupric or ferric bromide, or into a solution of bromine in potassium bromide. It becomes distinctly blue in sunshine, much more slowly in diffused daylight, and then dissolves, though much less easily than the unaltered bromide, in hyposulphite or chloride of sodium (Renault).

Cuprous Iodide, Cu^2I^2 .—A plate of copper exposed to the action of *iodine-vapour* or solution of iodine becomes covered with white crystalline cuprous iodide, which is much less sensitive to light than the chloride or the bromide. Both in its original and in its altered state this iodide is insoluble in sodium chloride and sulphite, potassium bromide and nitrate, and sal-ammoniac, but soluble in ammonia, sodium hyposulphite, and potassium cyanide, and in dilute hydrochloric, sulphuric, or nitric acid. An iodised copper plate exposed for a long time to light, and then immersed in a very weak solution of mercuric nitrate, becomes brick-red on the insulated parts, greenish on the unaltered parts (Renault).

A copper plate dipped into *cupric fluoride* and then exposed to light, becomes black and afterwards violet like the chlorinated plate (p. 493), though much more slowly; and the film is then much less soluble in hyposulphite or chloride of sodium than the original whitish-grey film (Renault).

Oxides.—**Cuprous oxide** of a fine red colour is easily obtained by heating 1 pt. cupric sulphate with $\frac{1}{2}$ pt. sodio-potassic tartrate, 2 pts. cane-sugar, and 12 pts. water, then adding $1\frac{1}{2}$ pt. sodium hydrate, and boiling for an hour (Böttger, *J. pr. Chem.* xc. 163).

Precipitated cuprous oxide dissolves in a concentrated aqueous solution of magnesium chloride, slowly at ordinary temperatures, more quickly at 100° , forming magnesium hydrate and cuprous chloride:

When cuprous oxide is dissolved to saturation in a warm solution of magnesium chloride, and the solution is left to cool without separating the magnesium hydrate, an orange-red precipitate of cuprous hydrate, or perhaps of cuprous oxychloride, is deposited, which dissolves when heated and reappears on cooling. When solid cuprous chloride is digested with magnesia and water, cuprous hydrate and magnesium chloride are produced. Nevertheless the double chloride of copper and magnesium is permanent in presence of magnesium hydrate, provided a considerable excess of magnesium chloride is also present. A filtered solution of cuprous oxide in magnesium chloride yields on dilution a precipitate of cuprous chloride coloured orange-yellow by adhering cuprous oxide. A mixed solution of magnesium sulphate and sodium chloride may also be used as a solvent of cuprous oxide (T. S. Hunt, *Compt. rend.* lxxix. 1366; *Zeitschr. f. Chem.* [2] vi. 152).

Cuprous oxide and ferrous chloride yield ferric oxide, with partial reduction of the cuprous oxide to metal. This reduction may be effected by adding recently precipitated and still suspended ferrous hydrate to a solution of cuprous chloride in common salt, and gently warming the liquid. A similar result is obtained on adding a soluble ferrous salt to a non-filtered solution of cuprous oxide in magnesium chloride. Ferrous oxide also reduces cupric to cuprous chloride, and if present in sufficient quantity precipitates all the copper as metal. Cupric oxide, even after ignition, acts on a solution of ferrous chloride in the cold according to the equation: $3\text{CuO} + 2\text{FeCl}_2 = \text{Cu}_2\text{Cl}_2 + \text{CuCl}_2 + \text{Fe}_2\text{O}_3$. The reaction is greatly retarded by the insolubility of the cuprous chloride, but in presence of common salt, or when aided by heat, it goes on quickly and completely. When a solution of ferrous chloride and sodium chloride is digested with a large excess of cupric oxide, the latter unites with the cupric chloride produced, forming an insoluble oxychloride (Hunt, *loc. cit.*).

The mutual action of cupric and ferrous salts, resulting in the formation of cuprous oxide and a basic ferric salt, first studied by Levol (ii. 68), has also been investigated by Braun and Weith (*Zeitschr. f. Chem.* [2] iii. 568, 623; *Bull. Soc. Chim.* [2] viii. 409; ix. 214; *Jahresb.* 1867, p. 301).

Tetracupric oxide, $(\text{Cu}^4)^2\text{O}$, Rose's *quadrantoxide of copper*, is prepared by treating a cooled solution of cupric sulphate with an alkaline solution of stannous chloride not in excess, whereby a blue precipitate of cupric hydrate is first formed, which after a while changes into yellow cuprous hydrate, and ultimately into olive-green tetracupric oxide: it must be washed, first with pure water, then with ammoniacal water in an atmosphere of hydrogen. This oxide, when exposed to the air, is quickly resolved into a mixture of cupric and cuprous oxide, and must therefore be kept under water. It has not yet been obtained quite free from stannous oxide. Dilute hydrochloric acid quickly converts it into a darker coloured substance, probably the corresponding

chloride, which is rapidly resolved into metallic copper and cuprous chloride. With hydrogen sulphide it forms a black substance, probably tetracupric sulphide, which when left in the liquid is gradually converted into a higher sulphide, with disengagement of hydrogen. With hydrocyanic acid it yields a black cyanide, which is converted by silver nitrate into silver cyanide, metallic copper, and cupric nitrate (H. Rose, *Pogg. Ann.* txx. 1; *Jahresb.* 1863, p. 271).

Oxychlorides.—By boiling cupric chloride with a small quantity of potassium or sodium hypochlorite, the oxychloride $\text{CuCl}^2 \cdot 3\text{CuO}$ is precipitated in combination with 4 or 6 mol. H^2O , according to the duration of the boiling. The composition of atacamite from Cobija, as determined by Berthier, agrees nearly with the formula $\text{CuCl}^2 \cdot 3\text{CuO} + 6\text{H}^2\text{O}$ (*Field, Phil. Mag.* [4] xxiv. 123). The same oxychloride is precipitated with $3\frac{1}{2}$ mol. water, or as $2(\text{CuCl}^2 \cdot 3\text{CuO}) + 7\text{H}^2\text{O}$, on mixing a hot dilute solution of cupric chloride with a soluble salt of formic, acetic, propionic, or valeric acid: e.g. with sodium acetate:

also by mixing a soluble chloride with cupric acetate; with boiling solutions the precipitation takes place immediately; with cold solutions after 24 hours. This hydrated oxychloride is very sparingly soluble; a solution containing only $\frac{1}{25000}$ pt. of anhydrous sodium acetate produces a perceptible turbidity in a solution of cupric chloride. It is of greenish colour, and at first of flocculent consistence; afterwards however it becomes more finely divided and requires the addition of sodium sulphate to separate it from the liquid. It appears to be gradually decomposed by water; when boiled with water it quickly assumes the colour of cupric hydrate (Casselmann, *Zeitschr. anal. Chem.* iv. 34; *Jahresb.* 1865, p. 275).

Basic sulphates and nitrates of copper of analogous composition are obtained in like manner, e.g. the sulphate $2(\text{SO}^4\text{Cu} \cdot 3\text{CuO}) \cdot 7\text{H}^2\text{O}$ by mixing a hot dilute solution of cupric sulphate with the soluble salt of a fatty acid, or the copper salt of one of these acids with a soluble sulphate (Casselmann).

A cupric oxychloride having nearly the composition of atacamite, $2(\text{CuCl}^2 \cdot 3\text{CuO}) + 9\text{H}^2\text{O}$, is obtained by boiling precipitated cupric oxide with ammonium chloride. The same oxide boiled for some time with ammonium sulphate yields an apple-green powder consisting of a basic sulphate having nearly the composition of brochantite; with ammonium carbonate, a green carbonate nearly allied to malachite; with ammonium nitrate, a basic cupric nitrate having nearly the composition $2(6\text{CuO} \cdot \text{N}^2\text{O}^2) + 15\text{H}^2\text{O}$ (Tuttschew, *Zeitschr. f. Chem.* [2] vi. 109).

Phosphides (Abel, *Chem. Soc. J.* [2] iii. 249).—Dicupric phosphide, Cu^2P^2 , is converted into hexcupric phosphide, Cu^6P^2 , by ignition, either alone or in hydrogen gas—in the latter case with evolution of phosphorus vapour and hydrogen phosphide. The hexcupric phosphide, which contains 14 p. c. phosphorus, is the highest phosphide of copper that can exist at a red heat. Phosphorus vapour passed over copper heated to low redness forms, with incandescence, a fused mass which becomes steel-grey and partly crystalline on cooling, contains 12.2 to 13.5 p. c. phosphorus, and does not give off any of it when heated in a tube. By adding phosphorus to fused copper and stirring the mass till it is nearly cold, a product is obtained consisting of three layers, the uppermost being white, very hard, and brittle, with shining crystalline fracture, and containing from 7 to 12 p. c. phosphorus; the middle layer, which forms the principal portion of the mass, being grey, with granular fracture, and containing 4 to 6 p. c. phosphorus; while the lowest, which is insignificant in quantity, consists of nearly pure copper containing only 0.5 p. c. phosphorus.

By adding phosphorus to copper melted at such a temperature that part of it still remains solid, a compound is formed containing from 2 to 4.7 p. c. phosphorus, which by casting in iron moulds may be obtained in homogeneous hard masses having a fine-grained fracture, like that of bell-metal, but quickly tarnishing. By fusing this compound with pure copper, other compounds containing smaller proportions of phosphorus were obtained, which exhibited greater tenacity than ordinary gun-metal: thus the tenacity of the compound containing 2.6 p. c. phosphorus was represented by a breaking power of 47,908 lb. to the square inch, that of gun-metal being from 24,991 to 26,424 lb. The mode of casting has however considerable influence on the physical properties of these phosphoretted coppers: thus copper containing 1 p. c. phosphorus, when cast in an iron mould, exhibited a tenacity of 36,893 lb. to the square inch, whereas when cast in a sand mould, its tenacity was only 12,958 lb. to the square inch. Altogether phosphoretted copper is not adapted for casting, as it contracts very much in solidifying, and when it is cast in moulds of sand or loam, the casting is also porous. By fusing the phosphoretted copper with iron, the greater part

of the phosphorus is removed, with formation of iron phosphide, which separates as a distinct layer, while the copper becomes alloyed with iron.

COPPER BASES, AMMONIACAL (i. 79). The ammoniacal cupric compounds consist of a cupric salt, CuR^2 or CuR^2 , united with the elements of 1, 2, 3, 4, 5, or 6 molecules of ammonia, NH^3 . There are also cuprous salts of similar constitution whose formulæ may be derived from the preceding by substitution of $(\text{Cu}^2)^*$ for Cu^2 . To explain the constitution of these salts, it must be observed: (1) That NH^3 being a bivalent radicle, any number of such groups united together will also form bivalent radicles; thus:

(2) The polyammoniacal compounds, when heated, readily give off part of their ammonia, leaving a compound containing 2NH^3 or 1NH^3 to one atom of copper, the last atom, NH^3 , being moreover retained much more forcibly than any of the rest. Thus the sulphate $5\text{NH}^3 \cdot \text{SO}^4\text{Cu}$ heated not quite to 149° gives off 3NH^3 , leaving the compound $2\text{NH}^3 \cdot \text{SO}^4\text{Cu}$; and at a little above this temperature it leaves $\text{NH}^3 \cdot \text{SO}^4\text{Cu}$, which again at a still higher temperature suffers complete decomposition, giving off nitrogen and other volatile products and leaving metallic copper. The last molecule of ammonia may be supposed to be united with the copper in such a manner as to form the bivalent radicle cuprammonium:

which again may unite with other molecules of ammonia, forming other bivalent radicles, $(\text{NH}^3\text{—NH}^3\text{Cu})^*$, $(\text{NH}^3\text{—NH}^3\text{—NH}^3\text{Cu})^*$ or $(2\text{NH}^3, \text{Cu})^*$, $(3\text{NH}^3, \text{Cu})^*$, &c. Thus we have the following ammonio-cupric chlorides:

also the ammonio-cuprous chlorides:

All these ammoniacal copper salts are capable of taking up a quantity of oxacid or hyacid sufficient to saturate the ammonia contained in them: thus $\text{NH}^3 \cdot \text{CuCl}^2$ can take up HCl ; $4\text{NH}^3 \cdot \text{CuCl}^2$ can take up 4HCl , &c.; but the compounds thus formed are not ammonio-compounds like those above formulated, but true double salts, identical in properties with those formed by the direct union of an ordinary ammonium salt with a cupric salt; thus

Under certain circumstances the ammonio-copper compounds can dissolve in water without decomposition, especially at low temperatures or in presence of free ammonia: thus the compound $5\text{NH}^3 \cdot \text{CuBr}^2$ dissolves completely in a small quantity of water and may be crystallised therefrom; but on adding more water, the liquid becomes turbid and deposits cupric hydrate (ii. 52).

CORIAMYTETIN. $\text{C}^{30}\text{H}^{56}\text{O}^{18}$.—The active principle of *Coriaria myrtifolia*. (See Additions, vol. v. p. 1090.)

CORK. This substance has been examined by Siewert (*Zeitschr. f. Chem.* [2] iv. 383) with the following results: 12 pounds of rasped cork were twice boiled in portions of 100 grams each with 4 litres of alcohol of 95° Tr., whereby 10 p. c. of the cork was dissolved. The residue yielded scarcely perceptible traces of substance to alcohol, ether, chloroform, or benzol.

The alcoholic extract first deposited from 1.62 to 1.75 p. c. of Chevreul's cerin (i. 830), as a white, crystalline, neutral substance, together with white masses of an acid compound.—1. Cerin, $\text{C}^{17}\text{H}^{20}\text{O}$, is regarded by Siewert as a homologue of phenol, and designated as phellyl alcohol. It melts at 100° , dissolves in 500 pts. of boiling and 5,000 pts. of cold absolute alcohol.—2. The amorphous acid, called decacrylic acid, has the composition $\text{C}^{18}\text{H}^{16}\text{O}^2$. It has an acid reaction; dissolves in 1,200 pts. of cold and 52 pts. of boiling alcohol; melts at 86° ; dissolves slowly in aqueous or alcoholic potash at the boiling heat; and separates therefrom as a yellow precipitate on cooling.—3. After the separation of those two substances, the

alcoholic extract yielded, on further evaporation, 2·5 p. c. of a fatty substance, eulysin, $(C^{21}H^{32}O^2)$, soluble in 10 pts. of cold alcohol, and melting without decomposition at 150° .—4. The remainder of the alcoholic solution evaporated to dryness left a mass which when repeatedly boiled with water, yielded to that liquid a tannic acid, separating from the aqueous solution in dark red flocks (0·5 p. c.). Its solution forms with gelatin a yellow, with tartar-emetic a brown precipitate, and reduces an ammoniacal silver solution in the cold. Potash and ammonia colour its solution red; baryta-water forms a dark-coloured precipitate. The calcium salt of this acid contains $(C^{17}H^{21}O^{17})^{12}Ca + 8H_2O$.—5. The aqueous extract when further evaporated deposited a brown-red precipitate, $C^{12}H^{16}O^2$, called by Siewert corticic acid.—6. The portion insoluble in water of the residue obtained by evaporating the original alcoholic extract, had nearly the appearance of the original cork-substance, dissolved easily and almost completely in boiling alcohol, and partly separated on cooling as a jelly (2·5 p. c.). Its alcoholic solution evaporated on paper penetrates the paper like fat.

CORPUS LUTEUM. The yellow particles occurring in the ovary of the cow at a certain stage of development have been examined by Holm (*J. pr. Chem.* v. 142; *Jahresh.* 1867, p. 779) and by Piccolo a. Lieben (*Zeitschr. f. Chem.* [2] iv. 645). The latter evaporated the yellow ethereal extract of these bodies and boiled the residue with potash to saponify the fats. On adding an excess of water, a turbid liquid was obtained, holding in suspension small shining dichroic crystals. The liquid filtered from these crystals was found to contain cholesterol, together with smaller quantities of one or more amorphous bodies, insoluble in water, but soluble in alcohol, ether, and carbon bisulphide.

The dichroic crystals are insoluble in water and in alcohol, not attacked by strong potash-ley even at the boiling heat, soluble with yellow colour in ether and in benzol, dissolving very easily in carbon bisulphide with deep red colour, and in chloroform with deep yellow colour. From all these solutions they may be repeatedly recrystallised. Treated with strong sulphuric acid under the microscope, they are seen to turn blue and dissolve. With nitric or hydrochloric acid, they acquire a dark colour soon changing to light yellow. Hydriodic acid turns them brown. They are not altered by sulphurous acid, solution of stannous chloride, or tincture of iodine. Glacial acetic acid does not act on them at ordinary temperatures, but decomposes them when heated. When exposed to the air they gradually lose their deep red colour, more quickly in the light than in the dark. When protected from the air, they remained unaltered for more than a year.

Holm regards these dichroic crystals as identical with hæmatoidin; but according to Piccolo a. Lieben, they constitute a distinct substance, which these chemists designate as leuco-hæmatoidin or hæmolutein.

CORUNDOPHILITE. This mineral, occurring at Chester, Massachusetts, has been shown to be identical with clinoclase (*Jahresh.* 1866, p. 893; 1866, p. 936; 1867, p. 993).

CORYDALINE. $C^{11}H^{16}NO^4$.—This base, occurring in the roots of *Corydalis bulbosa*, *C. fabacea*, and *Bulbocarpus cava* (rad. *Aristolochie cava*), has been further examined by H. Wicke (*Ann. Ch. Pharm.* cxxxvii. 274). To prepare it, the chopped roots of the last-mentioned plant were repeatedly exhausted at 50° with 6 pts. of water containing sulphuric acid; the expressed liquids were precipitated with basic lead acetate; and the filtrate, freed from lead by sulphuric acid, was mixed with metatungstate or phosphotungstate of sodium, in such proportion as to leave the liquid acid. The resulting yellowish-white precipitate was pressed, mixed with levigated chalk, and dried, and the dry mass was exhausted with hot alcohol. On distilling off the alcohol, the corydaline crystallised from the viscid residue in stellate groups of prisms, which were freed from adhering resin by washing with alcohol containing ether, pressing, and recrystallisation from ether-alcohol.

Corydaline crystallises from strong solutions in short prisms, from dilute solutions in slender needles; it is soluble in alcohol, ether, chloroform, amyl alcohol, carbon bisulphide, benzol, and oil of turpentine, but not in water. The alcoholic solution, if free from resin, remains colourless when heated; it has a bitter taste and strong alkaline reaction, and on addition of water deposits the base in microscopic needles. Corydaline melts at 130° , without loss of weight, to a brown-red amorphous mass which solidifies again in the crystalline form after long standing. The alcoholic solution yields a flocculent precipitate with tannic acid; the solution in acids forms precipitates with caustic and carbonated alkalis (soluble in excess of caustic alkali), also with potassium sulphocyanate, mercuric chloride, potassium-mercuric iodide, iodine,

Sup.

K K

sodium picrate, potassium chromate, sodium metatungstate, auric chloride, and platinum chloride.

Corydaline dissolves in *nitric acid*, leaving a brown-red resin. The *hydrochloride* $C^{10}H^{12}NO^4.HCl + 5H^2O$, formed by agitating a solution of corydaline in carbon bisulphide with weak hydrochloric acid, crystallises in tufts of needles which give off all their water over sulphuric acid; from warm dilute hydrochloric acid, the salt separates in the crystalline state. The *platinochloride* $(C^{10}H^{12}NO^4)^2.2HCl.PtCl^4$ is a yellow crystalline precipitate. The *acid sulphate* $C^{10}H^{12}NO^4.H^2SO^4$ forms needle-shaped crystals which dissolve but slowly in water.

Ethyl-corydaline hydriodide, $C^{10}H^{12}(C^2H^5)NO^4.HI$, is formed by heating corydaline to 100° with ethyl iodide, and separates from the yellow solution in reddish-yellow crystals sparingly soluble in water. With moist silver oxide it yields an alkaline solution from which the base cannot be obtained pure. The *platinochloride* $2C^{10}H^{12}(C^2H^5)NO^4.Cl.PtCl^4$ is a dingy yellow amorphous precipitate.

COUMARILIC ACID, $C^9H^6O^2$ (Perkin, *Chem. Soc. J.* [2] ix. 45).—The potassium salt of this acid is produced by boiling α -bromocoumarin (p. 499) with potash; and this salt decomposed by hydrochloric acid, yields the acid as a snow-white crystalline precipitate, melting at 192° – 193° , subliming when gently heated, and decomposing partially when distilled. The acid is extremely soluble in alcohol, sparingly in chloroform and carbon bisulphide, moderately soluble in boiling water, from which it crystallises in long needles. Not decomposed by heating with potassium hydrate to 180° . It is monobasic, forming easily soluble crystalline salts with ammonia and the alkali metals. The barium, calcium, silver, lead, mercurous, and ferric salts are obtained by precipitation.

Bromocoumarilic acid, $C^9H^5BrO^2$, is formed by decomposing α -dibromocoumarin with potash, and crystallises from weak spirit in needles melting at 250° , having a bitter taste, very soluble in alcohol, sparingly in water. Heated to 180° with potassium hydrate it decomposes and turns brown, with formation of potassium bromide. It is monobasic; the ammonium, potassium, and sodium salts are soluble and crystalline; the barium, silver, and lead salts are white precipitates.

COUMARIN, $C^9H^6O^2$, and **COUMARIC ACID**, $C^9H^5O^3$ (Perkin, *Chem. Soc. J.* [2] vi. 53).—The intimate relation of these bodies to the salicylic series, shown by the conversion of coumaric acid into salicylic and acetic acids by fusion with potash (ii. 93), is further demonstrated by the following mode of formation of coumarin from salicyl. Sodium-salicyl, $C^7H^5NaO^2$ (salicylite of sodium, v. 169), dissolves in acetic anhydride with considerable evolution of heat; and on boiling the solution for a few minutes, and then pouring it into water, an oily body separates, while sodium acetate passes into solution. On distilling this oil, acetic anhydride first passes over, then salicyl, and finally at 290° , a body which crystallises in the receiver, and after repeated crystallisation from alcohol, exhibits the composition and all the properties of coumarin from Tonka beans, melting at 67° to 67.5° , and boiling at 290.5° to 291° .* Its formation may be represented by the following equations:

and

According to this view, coumarin is a mixed acid radicle composed of acetyl and diptyl, C^7H^5O , a radicle belonging to the cinnamyl series; and in its formation from acetosalicyl, an atom of hydrogen is taken from the benzene residue, C^6H^5 , and an atom of oxygen from the group OC^2H^3O .

But the formation of coumarin in this reaction cannot be attributed to the dehydration of acetyl-salicyl by acetic anhydride; for these two bodies when heated together to 150° unite and form a definite compound, $C^7H^5O^2.C^2H^3O^2$, which is resolved by distillation into its original components. Moreover, acetic anhydride and acetosalicyl may be distilled together at higher temperatures without yielding a trace of coumarin. The formation of coumarin in the action of acetic anhydride on sodium-salicyl, as above described, depends indeed on the simultaneous formation of sodium acetate; for when a mixture of acetyl-salicyl, acetic anhydride, and

* Perkin finds that the melting and boiling points of natural coumarin are about 20° higher than those hitherto assigned to it.

sodium acetate is heated to the boiling point, a considerable quantity of coumarin is produced. Perkin attributes the influence of the sodium acetate in this reaction to the formation of a compound of that salt with acetic anhydride, like the anhydrodiacetate of potassium (i. 18); but it is by no means obvious why such a compound should exert a stronger dehydrating action than acetic anhydride itself (Perkin, *Chem. Soc. J.* [2] vi. 181).

According to Fittig, on the other hand (*Zeitschr. f. Chem.* [2] iv. 595), the product of the reaction of acetic anhydride on sodium-salicylöl at high temperatures is not acetyl-salicylöl, but its isomeride, coumaric acid, the reaction being analogous to that by which cinnamic acid is formed from acetyl chloride and benzoic aldehyde (i. 983); in fact, coumaric acid bears to cinnamic acid the same relation as salicylöl to benzoic aldehyde; thus:

The coumaric acid, at the high temperature at which it is formed, is then resolved into coumarin and water.

According to these views, coumarin is the anhydride of coumaric acid. But it does not appear to be producible from coumaric acid by the action of any of the ordinary dehydrating agents; moreover, as pointed out by Perkin, it is formed in plants in presence of water, and may be repeatedly crystallised from water without alteration. When boiled with strong potash-ley it yields a saline compound, from which it is separated by acids still as coumarin, and to convert it into coumaric acid it requires to be boiled with a supersaturated solution of caustic alkali. Again, coumarin does not form an amide with ammonia as true anhydrides do (Perkin, *Chem. Soc. J.* [2] vii. 192). See further Biesecke (*Zeitschr. f. Chem.* [2] iv. 585).

When sodium-amalgam is added by small portions to a solution of coumarin in water containing a little alcohol, at 40°-60°, the coumarin is first converted, by assumption of water, into coumaric acid, and this, by addition of hydrogen, is transformed into melilotic or hydrocoumaric acid, $\text{C}^9\text{H}^{10}\text{O}^3$ (Zwenger, *Jahresh.* 1865, p. 343; 1867, p. 443).

The coumarin of *Melilotus officinalis* is in combination with melilotic acid. When the evaporated aqueous decoction of the plant is treated with ether, as long as the ether acquires an acid reaction, and the green mass remaining after evaporation of the ether is repeatedly boiled with a large quantity of water, a solution is obtained, which on cooling deposits large well-defined crystals of the compound of coumarin with melilotic acid, while free melilotic acid remains in solution. The crystals, after repeated crystallisation from alcohol, with addition of animal charcoal, are colourless, apparently rhomboidal plates, or silky needles. They have an aromatic bitter taste, smell like coumarin when heated, dissolve sparingly in cold, more easily in boiling water, very easily in alcohol and ether. Ammonia decomposes them in the cold, dissolving the melilotic acid, and separating coumarin identical in every respect with that obtained from Tonka beans (Zwenger u. Bodenbender, *Ann. Ch. Pharm.* cxvii. 257; *Jahresh.* 1863, p. 552).

COUMARIN DIBROMIDE, $\text{C}^9\text{H}^7\text{O}^2\text{Br}^2$, isomeric with dibromomelilotic anhydride, is formed by adding about 7 pts. of powdered coumarin to 8 pts. of bromine, both dissolved in carbon bisulphide. On leaving the solution to itself for about twelve hours, and then evaporating the solvent, a crystalline mass is obtained, which may be freed from secondary products by washing with a little cold alcohol and recrystallisation from the same solvent, with the aid of but little heat. The dibromide crystallises in transparent oblique prisms, melting at about 100°, with partial decomposition, and giving off bromine at a higher temperature. It dissolves easily in alcohol, and decomposes quickly when boiled with alcohol or when its alcoholic solution is exposed to light, the bromine apparently acting on the solvent, and leaving coumarin in solution (Perkin, *Chem. Soc. J.* [2] viii. 368; ix. 37).

BROMOCOUMARINS.—Mono- and di-bromocoumarin have been obtained, each in two modifications. *a*-*Mono-bromocoumarin*, $\text{C}^9\text{H}^6\text{BrO}^2$, is most easily prepared by decomposing the dibromide of coumarin with alcoholic potash. It crystallises from

alcohol in transparent needles about half an inch long, melting at 110° . Heated to 200° in a sealed tube for five or six hours, it decomposes slightly, with formation of hydrobromic acid. Cold alcoholic ammonia decomposes it, with formation of ammonium bromide and a glutinous substance soluble in water. Heated with potassium hydrate, it yields bromide and coumarilate of potassium.— *β -Monobromocoumarin* is formed by the action of acetic anhydride on sodium bromosalicyl. On boiling the product for ten or fifteen minutes and pouring it into water, the *β -bromocoumarin* separates as a heavy oil which, when purified by rectification, boils at 160° . When boiled with alcoholic or aqueous potash, it does not decompose, but simply dissolves like ordinary coumarin (Perkin, *loc. cit.*).

α -Dibromocoumarin, $C^{10}H^7Br^2O^2$, is prepared by heating a mixture of 1 pt. coumarin, 2 pts. bromine, and 4 or 5 pts. carbon bisulphide, with addition of iodine, in a bath of salt and water for four or five hours. The product is freed from carbon bisulphide by evaporation, from iodine by means of potassium iodide, and finally purified by two or three crystallisations from alcohol. It crystallises in small needles melting at about 183° ; is easily decomposed by alcoholic potash, yielding potassium bromide and the potassium salt of a new acid; and by alcoholic ammonia, with formation of ammonium bromide and a crystalline product.— *β -Dibromocoumarin*, $C^{10}H^7Br^2O^2$, obtained by the action of acetic anhydride on sodium-dibromosalicyl, crystallises in hard needles melting at 176° and not decomposed by alcoholic potash (Perkin).

COUMARIN DICHLORIDE, $C^{10}H^6Cl^2O^2$, is produced by direct combination when chlorine is passed into a solution of coumarin in chloroform, and remains on leaving the solution to evaporate, as a syrupy product having the appearance of new honey. It is converted by distillation into chlorocoumarin, and is decomposed by alcoholic potash, like the dibromide (Perkin, *Chem. Soc. J.* [2] ix. 43).

CHLOROCOUMARINS.— *α -Chlorocoumarin*, $C^{10}H^7ClO^2$, is produced by heating a mixture of 1 pt. coumarin and 3 pts. phosphorus pentachloride to about 200° , or more easily by treating the dichloride with alcoholic potash. It crystallises in flat needles, moderately soluble in alcohol, slightly in hot water, melting at 122° – 123° , emitting an aromatic odour when heated, and resolved by boiling with alcoholic potash into hydrobromic and coumarilic acids (Perkin).

β -Chlorocoumarin, $C^{10}H^7ClO^2$, is obtained by the action of acetic anhydride on sodium-chlorosalicyl. It crystallises in needles, melting at 162° , subliming even below that temperature, nearly insoluble in cold, perceptibly soluble in boiling water, slightly soluble in cold alcohol and ether, very soluble in benzol and carbon bisulphide. Potash at a gentle heat dissolves it without alteration, but by prolonged boiling with strong potash-ley it is converted into chlorocoumaric acid, and by fusion with potassium hydrate into chlorosalicylic acid (Bäsecke, *Ann. Ch. Pharm.* cliv. 84; *Zeitschr. f. Chem.* vi. 583).

Tetrachlorocoumarin, $C^{10}H^6Cl^4O^2$, is formed by passing chlorine into a solution of coumarin and iodine in carbon tetrachloride. It crystallises from alcohol in small white needles melting at 144° – 145° , and is decomposed by heating with alcoholic potash into hydrobromic acid and a new acid not yet examined (Perkin).

Homologues of Coumarin and Coumaric Acid (Perkin, *Chem. Soc. J.* [2] vi. 53, 472).—Compounds homologous with coumarin are obtained by the action of butyric and valeric anhydrides on sodium-salicyl, the mode of action being exactly similar to that by which coumarin itself (acetic coumarin) is formed.

BUTYRIC COUMARIN. $C^{11}H^{10}O^2 = C^{10}H^7 \begin{pmatrix} CO'' \\ C^9H^3O \end{pmatrix}$ or $C^{10}H^7 \begin{pmatrix} CO'' \\ C^9H^3O'' \end{pmatrix}$. — Pro-

duced by heating sodium-salicyl with butyric anhydride, boiling the product for a few minutes, then pouring it into water, distilling the oil which separates, and collecting the portion which passes above 290° . It melts at 70° – 71° , solidifies to a crystalline mass on cooling, and distils, with slight decomposition, at 296° – 297° . It dissolves sparingly in boiling water, easily in alcohol and ether. The aqueous solution becomes turbid on cooling, and deposits a few needle-shaped crystals; from alcohol the compound crystallises in large translucent prisms. It smells like ordinary coumarin, and at the same time like fresh honey. It is nearly insoluble in strong aqueous potash at ordinary temperatures, but when heated with it, forms a pale yellow solution, which on evaporation deposits a deliquescent potassic compound of butyric coumarin (*infra*). By fusion with potash, butyric coumarin yields salicylic acid, phenol, and apparently also butyric acid. With bromine it reacts like ordinary coumarin, becoming liquid, and yielding on subsequent distillation a resinous mass, which when heated with alcoholic potash, forms an acid separable by hydrochloric acid.

pared by adding sodium-salicylöl by small portions to boiling valeric anhydride, distilling the oil separated by water, collecting the portion which distils above 290° , dissolving it in strong boiling potash-ley, agitating the diluted solution with ether to remove oily products, and decomposing the clear aqueous solution with hydrochloric acid. The compound thereby separated is dissolved in ether; the ethereal solution, after agitation with sodium carbonate, is evaporated; and the residual oil, which solidifies to a crystalline mass, is pressed between bibulous paper and several times recrystallised from alcohol. The product thus obtained is pure valeric coumarin; it melts at 54° , boils with slight decomposition at 301° , smells like coumarin, but less strongly than the preceding compound, is nearly insoluble in cold water, and crystallises from alcohol in transparent prisms nearly $\frac{1}{4}$ inch long. With potash-ley and solid potassium hydrate it reacts like butyric coumarin.

BUTYRO-COUMARIC ACID. $C^{11}H^{10}O^3 = C^6H^3 \begin{Bmatrix} C^2H^2O \\ COOH \end{Bmatrix}$. This acid is formed from butyric coumarin in the same manner as coumaric acid from coumarin. Butyric coumarin dissolves in boiling aqueous potash, and on evaporating the solution, an oily layer separates, which solidifies on cooling to a hard mass consisting of a compound of 1 mol. butyric coumarin with 1 mol. potassium hydrate. This compound when heated melts, boils up, becomes pasty and frothy, and is converted into a soft mass perfectly soluble in water; and on adding hydrochloric acid to this solution, butyro-coumaric acid separates as a white crystalline mass, which may be purified by solution in ammonia and reprecipitation with hydrochloric acid, and finally by digestion with chloroform, which removes traces of unaltered butyric coumarin. Butyro-coumaric acid crystallises in flat shining prisms, melting with slight decomposition at 174° . It is extremely soluble in alcohol and ether, sparingly soluble in water and in chloroform, and does not exhibit any coloured reaction with iron salts. Its sodium salt is crystalline and very soluble. The solution of the ammonium salt leaves the acid when evaporated. The silver salt $C^{11}H^{10}O^3Ag$ is a light yellow precipitate, becoming white and crystalline after a short time; it is somewhat soluble in water and blackens at 100° (Perkin).

CREATINE. $C^4H^7N^2O^2$.—From the decomposition of creatine by baryta-water into urea and sarcosine (methyl-glycine) Strecker inferred that it is a compound of cyanamide (urea minus water) with methyl-glycine (ii. 98):

In corroboration of this view, Vollhard (*Zeitschr. f. Chem.* [2] v. 319) has lately produced creatine by direct union of cyanamide and sarcosine. The combination may be effected by heating the two bodies together in alcoholic solution to 100° for some hours, or by mixing them in aqueous solution, and either evaporating or leaving the liquid to itself for some time. In either case creatine crystallises out mixed with more or less creatinine formed from it by the action of heat. Strecker some years ago obtained glyocyamine, $C^3H^5N^2O^2$, the lower homologue of creatine, by combining cyanamide with glycine (ii. 906).

The following method of estimating the amount of creatine in muscular flesh is given by Neubauer (*Zeitschr. anal. Chem.* ii. 22). From 200 to 250 grms. of finely chopped meat is heated to 55° – 60° with an equal weight of water for ten or fifteen minutes, with constant stirring, till the albumin begins to coagulate. The liquid is thoroughly expressed, the residue being twice stirred up with 60 to 80 c.c. water; heated over the open fire till the albumin is completely coagulated; filtered when cold; precipitated with basic lead acetate, carefully avoiding an excess; and the solution, freed from lead by hydrogen sulphide, is finally evaporated over the water-bath to a thin syrup. The colourless creatine which is deposited after a few days is separated from the mother-liquor; the latter is mixed with 2 to 3 vol. strong alcohol; and the entire crystalline mass (after washing with alcohol of 88 p. c. and finally with absolute alcohol) is collected on a small weighed filter, dried at 100° , and weighed. As creatine gives off 12.17 p. c. water at 100° , this water must be taken into account in estimating the amount of crystallised creatine. By this method, Neubauer has

CREATININE.

found the amount of creatine in 100 pts. of the flesh of various animals to be as follows:

	Ox			Pig		Calf	Horse	
	1	2	3	1	2		1	2
Creatine dried at 100°	0.150	0.204	0.193	0.117	0.184	0.160	0.157	0.166
" crystallised	0.170	0.232	0.220	0.133	0.209	0.182	0.179	0.189

No creatinine was found either in the creatine thus prepared, or in the mother-liquor from which it had crystallised. Hence, and from the fact that creatine is converted into creatinine by prolonged heating, Neubauer concludes that creatinine is altogether absent from normal muscular flesh, that consequently in the metamorphosis of tissue creatine is the primary product; and that this substance in its passage through the blood is converted by the action of heat into creatinine, which is eliminated in the urine.

Nawrocki also (*Zeitschr. anal. Chem.* iv. 330) concludes from experiments on frogs, that the muscles (whether at rest or tetanised) contain no creatinine, and that the quantity of creatine in frogs' muscles (0.221 to 0.388 p. c.) does not diminish during muscular activity.

Creatine may be conveniently prepared from Liebig's extract of meat, in which it occurs crystallised, together with a small quantity of creatinine. To obtain it, 40 pts. by weight of the extract are dissolved in 800 pts. of water; the solution is precipitated with a slight excess of basic lead acetate, filtered, and freed from lead by hydrogen sulphide; the liquid again filtered is evaporated down to 40 pts. (the original weight); and the creatine deposited from this concentrated liquid is collected on a filter and washed. The mother-liquor, after standing for a week, deposits an additional quantity (Mulder & Mouthaan, *Zeitschr. f. Chem.* [2] v. 341).

A concentrated aqueous solution of cadmium chloride saturated at 50° with creatine, deposits, first unaltered creatine, then by evaporation over sulphuric acid, a compound of creatine with cadmium chloride, $C^4H^8N^2O^2 \cdot CdCl_2 \cdot 2H^2O$, in large colourless crystals, which give off their water at 100° and are resolved by hot water into creatine and cadmium chloride. In the same manner may be obtained a compound of creatine with zinc chloride, $C^4H^8N^2O^2 \cdot ZnCl_2$, in small anhydrous crystals, which are likewise decomposed by hot water. Creatine forms similar compounds with cupric chloride and mercuric nitrate (Neubauer, *Ann. Ch. Pharm.* cxxxvii. 298).

CREATININE. $C^4H^8N^2O$.—The whey of milk after putrefaction contains creatinine, evidently produced from the creatine in the fresh whey (Commaille, *Zeitschr. f. Chem.* [2] vi. 93).

Creatinine heated with concentrated baryta-water is resolved into ammonia and methyl-hydantoin (Neubauer, *Ann. Ch. Pharm.* cxxxvii. 288); see HYDANTOIN:

Action of Nitrous Acid.—Dessaignes, by passing nitrous acid vapour into a solution of creatinine, obtained, with evolution of carbon dioxide, a base to which he assigned the formula $C^4H^8N^2O^3$ (ii. 102). This reaction has been further examined by Märcker (*Ann. Ch. Pharm.* cxxxiii. 305; *Jahresb.* 1865, p. 406), who finds that nitrogen is evolved as well as carbon dioxide, and assigns to the base discovered by Dessaignes the formula $C^4H^8N^2O^2$; he has also shown that a second base isomeric with the first is produced at the same time.

When the nitrous gas evolved from a mixture of arsenious oxide and nitric acid is passed into a concentrated aqueous solution of creatinine, a brisk evolution of carbon dioxide and nitrogen takes place, and the brown liquid deposits well-defined crystals of the nitrate of a base α , which by repeated precipitation with ammonia is obtained as a white powder formed of microscopic needles, and having the composition $C^4H^8N^2O^2$. It is but slightly soluble in cold water or alcohol, and quite insoluble in ether. Its hydrochloride, $C^4H^8N^2O^2 \cdot HCl \cdot H^2O$, crystallises in laminae or prisms easily soluble in hot water, slightly soluble in strong alcohol, insoluble in ether. The platinum and gold salts of this base cannot be prepared, inasmuch as they are very easily decomposed, with reduction of the metal. The nitrate $C^4H^8N^2O^2 \cdot HNO^3$ forms large rhombic tables soluble in water, insoluble in alcohol and ether.

The mother-liquor from which the preceding base has been separated by ammonia contains, together with a large quantity of ammonium nitrate, a second base, β , isomeric with the first, the nitrate of which separates out on evaporation. This base crystallises from water in spherical nodules, and dissolves easily in water and dilute alcohol, but is insoluble in ether. The hydrochloride is likewise easily soluble in water.

~~water and crystallises in white laminae. The~~ *platinochloride* $2(C^2H^3N^3O^2 \cdot HCl) \cdot PtCl_4$ is insoluble in ether-alcohol, soluble in water and in alcohol, and crystallises in yellow tables.

The formation of both these bases is represented by the equation :

The base α , insoluble in water, melts at 210° , with evolution of gas, and leaves a residue which is resolved by hydrochloric acid into an insoluble brown substance, and the soluble hydrochloride of a base, $C^2H^3N^3O^2$ (?), precipitated by ammonia in gelatinous flocks. The base β melts at 195° , and carbonises with slight evolution of gas at 220° .

By carefully mixing the base α under water with bromine, a non-basic body, $C^2H^3BrN^3O^2$, is formed, easily soluble in water, and crystallising therefrom in yellowish needles; with excess of bromine a brominated resin is produced.

The base α heated to 160° with *ethyl iodide* is converted into a brown syrup which contains a large quantity of free iodine, and is decomposed by boiling with silver oxide, with evolution of ethylamine, and formation of a base, $C^2H^3N^3O^4$ (?), which crystallises in needles melting at 152° .

Constitution of Creatine and Creatinine.—Allusion has already been made to Strecker's view of the constitution of creatine, according to which it is regarded as a hydramine containing the elements of cyanamido and methyl-glycoccine, and represented by the formula

$$\left(\begin{array}{c} CN \\ C^2H^2O \\ CH^2 \\ H^2 \end{array} \right) N^2 \cdot O.$$
 By a slight alteration the formula may be

converted into that of a diamine containing hydroxyl-glycollyl, $C^2H^2O \cdot OH$, a monatomic radicle, which may be supposed to exist in glycollic acid, $C^2H^2O^2 \left\{ \begin{array}{l} OH \\ OH \end{array} \right.$; and creatinine, which is derived from creatine by abstraction of the elements of water, may be represented as a diamine containing the bivalent radicle glycollyl, C^2H^2O ; thus :

These two bodies, both of which yield methyl-guanidine (methylluramine) by oxidation, may also be represented as triamines derived from methyl-guanidine: creatine by substitution of hydroxyl-glycollyl for 1 at. hydrogen, creatinine by substitution of glycollyl for 2 at. hydrogen :

CREOSOL. See the next article.

CREOSOTE (ii. 104). From further experiments by Gorup-Besanez (*Ann. Ch. Pharm.* cxliii. 129; *Jahresb.* 1867, p. 683), it appears that the several varieties of wood-tar creosote are mixtures of compound ethers of guajacol, $C^8H^8O^2$, and creosol, $C^8H^{10}O^2$, the former predominating in Rhenish beech-tar creosote, the latter in Moravian and English creosote. Rhenish creosote has a sp. gr. of 1.0831 at 17.5° , and begins to boil at 130° , but the greater part distils between 199° and 208° , a smaller portion between 208° and 216° , leaving a dark-coloured residue. The portion distilling between 199° and 208° has a sp. gr. of 1.077 at 14° , does not solidify at -11.3° , and when repeatedly distilled does not exhibit any constant boiling point. This distillate dissolves completely in acetic acid of sp. gr. 1.046, also in dilute potash-ley and in excess of aqueous ammonia. Its alcoholic solution mixed with an alcoholic solution of ferric chloride acquires a fine emerald-green colour. This character serves to distinguish wood-creosote from phenol, the alcoholic solution of which forms a brown mixture with alcoholic ferric chloride. According to Ruot (*Bull. Soc. Chim.* [2] viii. 375), a solution of ferric chloride mixed with ammonia till the precipitate just becomes permanent, is coloured blue or violet by phenol, green and afterwards brown by beech-tar creosote. Another distinctive test is afforded by collodion, 16 pts.

phenol and 10 pts. collodion forming a gelatinous mass, whereas creosote forms with collodion a transparent liquid.

When potassium chlorate is added by small portions to a warmed mixture of beech-tar creosote and hydrochloric acid, till green chlorine-vapours begin to escape (for which 18 to 24 hours' treatment is necessary), and the pasty yellow mass obtained on cooling is washed with water and with alcohol, golden-yellow scales are obtained, which when sublimed and treated with cold chloroform are separated into insoluble tetrachloroguaiacone, $C^4H^2Cl^4O^2$, and soluble tetrachlorocreosone, $C^8H^{10}Cl^4O^2$, bodies homologous with a compound having the composition of tetrachloroquinone. Gorup-Besanez supposes them to be formed in the manner represented by the equations:

For another view of their formation see p. 506. Tetrachloroguaiacone and tetrachlorocreosone are lemon-yellow crystalline bodies nearly insoluble in cold water and alcohol, slowly soluble in cold ether, easily soluble in boiling alcohol and chloroform. The former sublimes, at 180° , the latter at 160° – 170° . Dilute potash-ley colours tetrachloroguaiacone blackish-grey or black, tetrachlorocreosone grass-green; warm potash-ley dissolves both with black-brown colour. The bodies formerly described as hexachloroxylin and pentachloroxylin (ii. 105) agree in all their properties, excepting solubility in ether, with tetrachloroguaiacone and tetrachlorocreosone, and are regarded by Gorup-Besanez as mixtures of the two with trichlorocreosone, $C^6H^4Cl^3O^2$.

When creosote saturated with water is treated with phosphorus and iodine, the latter being added by small portions and the phosphorus kept in slight excess, methyl-iodide distils over and a viscid residue is left containing pyrocatechin, together with amorphous phosphorus, and an oil having an intolerable odour. By lixiviating this residue with water, neutralising with barium carbonate, precipitating the filtrate with lead acetate, decomposing the washed precipitate with hydrogen sulphide, evaporating the solution, pressing the crystals thereby obtained, and subliming them, pyrocatechin is obtained with all its characteristic qualities. It is formed from guaiaacol as represented by the equation:

(Gorup-Besanez). H. Müller (*Zeitschr. Ch. Pharm.* 1864, p. 40) obtained from English creosote by the same process a syrupy uncrystallisable liquid, $C^4H^2O^2$, which is a homologue of pyrocatechin, and is formed in like manner from creosol, the chief constituent of English wool creosote:

Gorup-Besanez has lately obtained the same compound, homopyrocatechin, together with a small quantity of pyrocatechin, from a sample of Rhenish beech-tar creosote consisting chiefly of creosol (*Zeitschr. f. Chem.* [2] iv. 393). The same kind of creosote distilled with manganese dioxide and dilute sulphuric acid, yielded phlorol or phloryl alcohol, $C^8H^{10}O$ (Gorup-Besanez and v. Rad, *ibid.* 560).

Lastly, the composition of Rhenish beech-tar creosote has been examined by Marasse (*Deut. chem. Gesellsch.* Berlin, 1868, p. 99; 1869, p. 71; *Zeitschr. f. Chem.* [2] iv. 502; v. 348), who finds that it may be resolved by repeated fractional distillation into three portions, boiling at constant temperatures, the first passing over at 184° , the second between 200° and 203° , the third between 217° and 220° . The portion boiling at 184° solidifies on cooling and consists of phenol. The distillate obtained between 200° and 203° is a mixture of guaiaacol (boiling at 200°) and creosol, $C^8H^{10}O$ (boiling at 203°). The third portion, boiling between 217° and 220° (that in which Hlasiwetz, Müller, and Gorup-Besanez had found creosol), was converted, by heating to 160° in a sealed tube with hydriodic acid, into methyl iodide, homopyrocatechin, and phlorol, $C^8H^{10}O$.

Marasse finds that pure guaiaacol treated with potassium chlorate and hydrochloric acid does not yield a trace of chlorinated quinones; but the portion of beech-tar creosote boiling between 200° and 203° treated in this manner yields the tetrachloroguaiacone, $C^4H^2Cl^4O^2$, described by Gorup-Besanez (p. 503), its formation being due

to the cresol contained in that portion of the distillate. The occurrence of phlorol in the least volatile portion of the cresote accounts in like manner for the production of tetrachlorocresone, $C^6H^3Cl^4O^2$, by the action of hydrochloric acid and potassium chlorate, and of phlorone, $C^6H^3O^2$, by that of manganese dioxide and sulphuric acid. The same compound was obtained by Rommier a. Boulhon (*Jahresb.* 1862, p. 322) by the action of manganese dioxide and sulphuric acid on the portion of acid coal-tar oil distilling between 195° and 220° .

From these results it appears that Rhenish beech-tar cresote is a mixture of the following compounds:

Phenol series.

$C^6H^5.OH$ (B.P. 184°)

$C^6H^4(CH^3).OH$ (B.P. 203°)

$C^6H^3(CH^3)^2.OH$ (B.P. 220°)

Guajacol series.

$C^8H^4.OCH^3.OH$ (B.P. 200°)

$C^8H^3.CH^3.OCH^3.OH$ (B.P. 217°)

The existence of phenol in this cresote is confirmed by the experiments of Frisch *et. pr.* *Chem. v.* 223; *Jahresb.* 1867, p. 689, who obtained phenylsulphuric acid by treating it with strong sulphuric acid; dinitrophenic and trinitrophenic (picric) acids by subjecting it to the action of strong nitric acid; and several chlorinated quinones and hydroquinones by the action of potassium chlorate and hydrochloric acid.

Cresol. $C^6H^5O^2$ (ii. 105).—When rectified cresote is heated for several hours to 60° , with an equal weight of strong sulphuric acid, *cresol-sulphuric* or *sulphocresolic acid*, $C^6H^5SO^3 = C^6H^5O^2.SO^2H$, is formed as a deep red mass which dissolves with violet colour in water. The pure acid separated from its lead salt is obtained by evaporation as a light yellow syrup, which on exposure to the air quickly turns brown and absorbs water. Its salts are crystallisable, easily soluble in water and alcohol. The *potassium salt* $(C^6H^5SO^3)K$ forms nodular groups of slender needles; the *lead salt* $(C^6H^5SO^3)_2Pb$ dries up in a vacuum to a light yellow mass of slender needles.

Cresyl chloride, C^6H^5OCl , produced by the action of phosphorus pentachloride on rectified cresote, is a limpid, strongly refracting, mobile, oily liquid, having a faint acid reaction, a slightly pungent not unpleasant odour, a very sharp taste, and a sp. gr. of 1.028; it turns brown in the air, dissolves sparingly in water, easily in alcohol and ether. With silver nitrate it forms silver chloride; with ferric chloride it exhibits a fine green, with ammonia a dark brown colour; alkalis abstract the chlorine (Bichele, *Ann. Ch. Pharm.* cli. 104).

When $\frac{1}{2}$ pt. cresote is heated to 140° – 150° with 1 pt. oxalic acid and 2 pts. strong sulphuric acid, carbon dioxide, carbon monoxide, and water are given off, the mass acquires a dark brown-red colour, and after boiling with water, which dissolves a large quantity of phenylsulphuric acid, solidifies to a black-brown brittle resin. This substance is insoluble in water, soluble in glacial acetic acid, sparingly soluble in cold, more easily in boiling alcohol, soluble with splendid purple-red colour in ammonia and potash-ley, and separates therefrom on neutralisation in orange-coloured flocks, which become resinous again when warmed. The compound when dried has a splendid orange-red colour, like that of precipitated alizarin. It melts at 80° , giving off phenol. It becomes colourless when treated with iron-filings and acetic acid, or with sodium-amalgam, but is not affected by alkalis. Its percentage composition is represented by the formula C^6H^5O (Kolbe a. Schmitt, *Ann. Ch. Pharm.* exix. 169). Wanklyn (*Chem. News*, x. 171) suggests that it may have the constitution $\begin{matrix} \text{C}^6\text{H}^5\text{O} \\ \text{OH} \end{matrix}$, formed on the ethylene type.

CRESOL. $C^6H^5O = C^6H^4(OH).CH^3$. *Cresyl Alcohol.* *Cresylic Phenol.*—This body was first obtained in an impure state from urine by Städeler (1850), who called it *taurylic acid* (v. 701). Williamson and Fairlie (1854) prepared it by fractional distillation from coal-tar cresote, in the form of a liquid boiling constantly at 203° , and Duclos (1859) obtained it from the cresote of fir-wood tar (ii. 106). More recently it has been produced by definite reactions, viz.: 1. By the action of water on nitrate of diazotoluene (Griess, *Jahresb.* 1866, p. 458):

2. By fusing potassium toluene-sulphate with potassium hydrate (Wurtz, *ibid.* 1867, p. 612):

3. By heating thymol with phosphoric anhydride, whereby the thymol is resolved into cresol and propylene (Engelhardt a. Latschinoff):

Now there are two isomeric modifications of toluene-sulphuric acid, α and β , distinguished by the different degrees of solubility of their potassium salts (p. 286), and these when fused with potash yield two isomeric cresols, α and β , one of which (α) is identical with the cresol of coal-tar and wood-tar. The cresol obtained from thymol constitutes a third modification, γ (E. and L.). These three modifications are doubtless the ortho-, meta-, and para-cresols, resulting from the different relative positions of the radicles OH and CH³; thus:

PARA-CRESOL is prepared: 1. By fusing the potassium salt of α -toluene-sulphuric acid with 3 pts. potassium hydrate, dissolving the fused mass in water, neutralising with hydrochloric acid, dissolving out the separated cresol with ether, dehydrating the ethereal solution with calcium chloride, evaporating the ether, and distilling the residue in a stream of carbon dioxide.—2. By converting the sulphate of α -toluidine (ordinary crystallised toluidine) into the corresponding salt of diazo-toluene (v. 867) by treatment with nitrous acid, and decomposing this salt with boiling water. Cresol obtained by either of these processes has exactly the same properties, and may be completely purified by treating it with benzoyl chloride, recrystallising the resulting benzoyl-cresol from ether, and decomposing it with potash at 100°.

Paracresol thus prepared is a transparent colourless liquid, having a disagreeable phenolic odour like that of putrid urine. It solidifies in a freezing mixture to a lamino-crystalline mass which does not melt again at ordinary temperatures. Boils at 198°–200° (Engelhardt a. Latschinoff). A. v. Rad (*Zeitschr. f. Chem.* [2] v. 715) by treating commercial coal-tar creosote by the process applied by Duclos to wood creosote (ii. 106) finds that the portion of the product boiling at 198° has the composition of cresol, C⁷H⁸O, whereas the portion boiling at 203° (the boiling point found by Williamson a. Fairlie and by Duclos) contains about 2 p. c. carbon more than the quantity required by the formula of that body. When the cresol thus obtained is very gently heated with potassium chlorate and hydrochloric acid, it is converted, according to v. Rad, into trichlorocresol, which crystallises from hot alcohol in yellow laminae. Other chemists, however, have obtained by this reaction chlorinated homologues of quinone (p. 503).

Methyl-paracresol or **Methyl-cresylic ether**, C⁷H⁹O·CH³ or C⁷H⁸(OCH³).CH³, is obtained by the action of methyl-iodide on potassium-cresol. Cresol is heated with pulverised potassium hydrate till the latter is dissolved, and the solution is introduced, together with excess of methyl-iodide and a small quantity of methyl alcohol, into a flask connected with an inverted condenser, the violent action which first sets in being moderated by immersing the flask in cold water, and the subsequent action being assisted by a gentle heat. The product washed with water and potash-ley, then dried and rectified, yields methyl-cresol as a colourless liquid lighter than water, having an aromatic odour like that of anise-oil, and boiling without decomposition at 171°. By oxidation with chromic acid mixture it is converted into methyl-para-oxybenzoic or aniseic acid (Körner, *Bull. Acad. Belg.* [2] xxiv. 154; *Jahrb.* 1867, p. 326).

Ethyl-paracresol, C⁷H⁹O·C²H⁵, produced by heating paracresol with potassium hydrate, ethyl iodide, and alcohol, is an aromatic liquid insoluble in water and boiling at 186°–188° (Engelhardt a. Latschinoff).

Benzoyl-paracresol, C⁷H⁹O·C⁷H⁵O, prepared by treating paracresol with benzoyl chloride, is insoluble in water, soluble in a mixture of alcohol and ether, and crystallises by slow evaporation in large six-sided tables melting at 70°. Heated with potash-ley, it is resolved into benzoic acid and paracresol (Engelhardt a. Latschinoff).

Paracresol-sulphuric acid, C⁷H⁸SO³ = C⁷H⁴(SO³H)(OH), exhibits exactly the same properties whether prepared by the action of sulphuric acid on paracresol, or by treating paratoluidine-sulphuric acid with nitrous acid, whereby it is converted into diazo-toluene-sulphuric acid, and decomposing this compound with boiling water. Its potassium salt C⁷H⁷SO³K + 2H²O = C⁷H⁴(SO³K)OH + 2H²O crystallises from boiling water in large flat six-sided prisms; from boiling alcohol in needles. The normal barium salt (C⁷H⁷SO³)₂Ba or C⁷H¹²(S²O³Ba)₂O·H² is much less soluble in boiling water than the potassium salt, and crystallises on cooling from the saturated solution in a mass of laminae, which, however, on leaving the crystallising vessel in a warm place, are converted into large plates of the anhydrous salt. A basic barium salt C⁷H¹¹(S²O³Ba)₂O·Ba + 4H²O or C⁷H⁸SO³Ba + 2H²O separates on adding baryta-water to a solution of the preceding salt, or to a solution of the potassium salt mixed with barium chloride, as a white precipitate consisting of slender needles. It is but very

slightly soluble in water, even at the boiling heat, and crystallises on cooling from the boiling solution in needles. The normal lead salt forms very soluble nodules. The paracresolsulphates form with basic lead acetate a basic paracresolsulphate of lead. With ferric chloride they form a solution of a fine violet colour.

Paracresoldisulphates.—The potassium salt $C^6H^4(SO^4K)^2OH + 3H^2O$ is obtained by heating potassium paracresolsulphate on the water-bath with Nordhausen sulphuric acid holding sulphuric anhydride in solution; dissolving the product in water; saturating with barium carbonate; and decomposing the filtered solution with potassium sulphate. It is very soluble in water and forms large transparent efflorescent crystals. The barium salt $C^6H^4(SO^4Ba)^2OH + 2\frac{1}{2}H^2O$ separates in long needles on mixing the solution of the potassium salt with barium chloride (Engelhardt a. Latschinoff).

Gräbe a. Borgmann (*Zeitschr. f. Chem.* [2] iv. 118) by treating paracresol with potassium chlorate have obtained two chlorinated homologues of quinone:

ORTHO-CRESOL.—This modification has not been obtained quite free from paracresol. It is prepared by fusing the more soluble β -toluene-sulphate of potassium (p. 286) with potassium hydrate, or by decomposing orthotoluidine (liquid toluidine, β -toluidine, Rosenstiehl's pseudotoluidine) with nitrous acid. It is a transparent colourless or yellowish liquid which does not solidify in a freezing mixture, and boils at about 189° (Engelhardt a. Latschinoff).

Methyl-ortho-cresol is obtained by treating a cooled mixture of methyl-mono-bromophenol, methyl-iodide, and anhydrous ether with excess of sodium:

It is a liquid boiling at 175° , and smelling like rotten apples. By oxidation with chromic acid mixture it is converted into methyl-oxybenzoic acid. Hydriodic acid converts it into a cresol probably identical with the orthocresol above mentioned; but its properties have not been examined (Körner, *Zeitschr. f. Chem.* [2] iv. 327). **Benzoyl-ortho-cresol** is a thick yellow oil insoluble in water, easily soluble in ether (Engelhardt a. Latschinoff).

Orthocresol-sulphuric acid was obtained by the action of sulphuric acid on orthocresol (containing paracresol). The acid solution was saturated with barium carbonate, and the filtered boiling solution was mixed with baryta-water, which threw down the sparingly soluble barium salt of paracresol-sulphuric acid. The filtrate from the latter yielded, after evaporation and cooling, small nodules consisting of the basic barium salt of the ortho-acid $C^6H^4(SO^4Ba)O^2H^2 + 4H^2O$. The normal barium salt $C^6H^4(SO^4Ba)O^2H^2 + 2H^2O$ is uncrystallisable, very soluble in water, soluble in boiling alcohol, from which it separates as a white powder on cooling. The potassium salt is easily soluble in water and uncrystallisable (Engelhardt a. Latschinoff).

METACRESOL (γ -cresol) is produced by decomposition of thymol (propyl- or isopropyl-phenol). When 100 grms. of thymol are heated in a flask with 35 grms. phosphoric anhydride, propylene gas is given off, and metacresol-phosphoric acid remains in the form of a yellowish liquid; and by fusing this product with potash, dissolving in water, agitating with ether, decomposing the ethereal solution with hydrochloric acid, again dissolving in ether, evaporating, and distilling in a stream of carbon dioxide, metacresol is obtained, together with an oil which has not been further examined. Metacresol is a transparent liquid, which does not solidify in a freezing mixture, boils at 195° – 200° , and has a phenolic odour, but without the peculiar character of that of paracresol. **Ethyl-metacresol** is an aromatic oil boiling at 188° – 191° . **Benzoyl-metacresol** is a white crystalline mass melting at 38° , and distilling between 290° and 300° .

Metacresolsulphates.—The potassium salt $C^6H^4(SO^4K)OH + 2\frac{1}{2}H^2O$ is very soluble in water, and crystallises in needles or short prisms, soluble also in alcohol. The normal barium salt $C^6H^4(SO^4Ba)O^2H^2 + 2H^2O$ is easily soluble in water and crystallises in hard nodules. The basic barium salt $C^6H^4(SO^4Ba)O^2Ba + 4H^2O$ forms spherical groups of needles very slightly soluble in cold water. The salts of metacresol-sulphuric acid form with basic lead acetate a white precipitate of basic lead metacresolsulphate. Solution of ferric chloride colours them violet (Engelhardt a. Latschinoff).

L. Henry (*Zeitschr. f. Chem.* [2] v. 371), by treating salicylol, $C^6H^4(OH)_2.CHO$, with phosphorus pentachloride in the cold, has obtained the compound, $C^6H^4(OH)_2.CHCl_2$, which he designates as dichlorocresol (if really a cresol derivative, it must from its origin be dichloro-metacresol). It crystallises in prisms melting at

82°, is coloured dark red in alcoholic solution by ferric chloride, and when heated with phosphorus pentachloride is converted into *chlorobenzylene dichloride*, $C^6H^4Cl_2.CHCl_2$.

Dinitrocresols. $C^6H^4(NO_2)_2O$.—A body having this composition is formed, together with other products, by the action of nitrous acid on nitrate of para-amidotoluic acid (see TORULIC ACID): it forms yellow crystals melting at 85° (Boilestein a. Kreusler, *Jahrsb.* 1866, p. 360). The same compound (melting at 84°) is produced by the action of nitrous acid on ordinary toluidine. Its silver salt $C^6H^3(NO_2)_2OAg$ crystallises in dark orange-coloured slender needles having an iridescent aspect. The red powder known in commerce as *Victoria-yellow* or *Aniline-orange* is a nearly pure salt of dinitrocresol; but the dinitrocresol separated from it is isomeric, not identical, with that just mentioned, as it forms scarcely yellowish crystals melting at 109°–110°, and its silver salt crystallises in thicker needles of a lighter orange-yellow colour. This dinitrocresol dissolves easily in alcohol, ether, and chloroform, producing deep yellow solutions (Martius a. Wichelhaus, *Zeitschr. f. Chem.* [2] v. 440).

CRESOTIC ACID. $C^6H^4O^3 = C^6H^3OH \left\{ \begin{smallmatrix} CH^3 \\ COOH \end{smallmatrix} \right.$ —Kolbe and Lautemann obtained the sodium salt of this acid, together with that of its isomeric, carboecresylic acid, by passing carbon dioxide into cresol holding sodium in solution (ii. 106). The acid thus prepared was paracresotic acid. It melts at 153° (Kolbe a. Lautemann at 147°–150°) (Engelhardt a. Latschinoff), and is coloured violet by ferric chloride.

The same acid has lately been obtained by G. Vogt (*Zeitschr. f. Chem.* [2] v. 577) from xylene as follows: Chloroxylenes, $C^6H^4Cl \left\{ \begin{smallmatrix} CH^3 \\ CH_3 \end{smallmatrix} \right.$, is heated with fuming sulphuric acid, whereby it is converted into the chlorinated sulpho-acid $C^6H^3Cl \left\{ \begin{smallmatrix} CH^3 \\ CH_2SO^3H \end{smallmatrix} \right.$; by fusing the potassium salt of this acid with excess of potassium hydrate, the chlorine and the residue SO^3H are replaced by OH , forming the compound $C^6H^3OH \left\{ \begin{smallmatrix} CH^3 \\ CH^3OH \end{smallmatrix} \right.$ which, by the oxidising action of the potash, is immediately converted, with evolution of hydrogen, into the potassium-salt of cresotic acid:

The cresotic acid separated from this salt by hydrochloric acid crystallises in long prisms melting at 148°.

Orthocresotic acid is produced (together with the preceding) by similar treatment of orthocresol containing paracresol; it is formed much more easily than paracresotic acid. When the mixture of the two acids separated from their sodium salts by hydrochloric acid is fractionally boiled with small portions of water, the last fractions yield paracresotic acid melting at 147°–150°, while the first portions deposit orthocresotic acid in long needles melting at 114°, and likewise coloured violet by ferric chloride. The barium salt of this acid is very soluble in water and in alcohol. **Metacresotic acid**, obtained in like manner from metacresol, is soluble in boiling water and crystallises in needles, melting at 168°–173°, and coloured violet by ferric chloride. Its barium salt is very soluble in water and crystallises in stellate groups of needles (Engelhardt a. Latschinoff).

CRITHMUM. The seeds of samphire (*Cr. maritimum*), an umbelliferous plant growing on rocks on the sea-coast, yield by distillation with water a volatile oil boiling at 175°–178°, and having a sp. gr. of 0.980 at 13°. It oxidises in the air, and is converted by dilute nitric acid into crithmic acid, an acid resembling benzoic acid. The seeds also contain a less volatile oil and a drying fatty oil (Hérouard, *J. Pharm.* [4] iii. 324).

CROCIN. This term, originally applied to the yellow colouring matter of the pods of *Gardenia grandiflora* (ii. 108), has lately also been given to a red substance obtained by decomposition of the natural colouring matter of saffron. (See **SAFFRON**, in this volume.)

CROOKESITE. A native selenide of copper, silver, and thallium, from the copper-mine of Skrikerum in Norway, exhibiting the following composition:

Cu	Ag	Fe	Tl	Se
46.11	1.44	0.63	18.55	—
46.55	5.04	0.36	16.27	30.86 = 99.08
44.21	5.09	1.28	16.89	32.10 = 99.57

It forms lead-grey compact masses having the hardness of copper-glance, and a sp. gr. of 6.9 (A. E. Nordenskjöld, *Ann. Ch. Pharm.* cxlv. 127).

CROTONIC ACIDS. $C^4H^4O^2$.—This formula represents three isomeric acids, viz.,

The first of these is the liquid acid, originally called crotonic acid, described by Schlippe as a product of the saponification of eroton oil (ii. 112). According to Geuther, however, the saponification of this oil does not yield any acid having the composition $C^4H^4O^2$, the liquid volatile acids obtained by that process being acetic, butyric, and valerianic, with a small quantity of a higher homologue, probably ceananthylic acid, and some of the higher members of the oleic series.

Liquid crotonic acid is obtained by the following processes: 1. By the action of chloroethylidene and metallic silver on monochloroacetic acid (Stacewicz, *Zeitschr. f. Chem.* [2] v. 321):

2. By the action of nascent hydrogen on the modification of monochlorocrotonic acid which melts at 59.5° (Fröhlich, p. 511).

Crotonic acid prepared by either of these processes is an oily liquid which does not solidify at -15° ; it has an aromatic somewhat pungent odour and blisters the skin. The acid prepared from chlorocrotonic acid boils at 171.9° (Geuther, *Zeitschr. f. Chem.* [2] v. 270); the boiling point of the acid obtained by the second process is said to be 127° (perhaps a misprint for 172°).

ALPHA-CROTONIC ACID (Will a. Körner, *Ann. Ch. Pharm.* cxxv. 257; *Jahresb.* 1863, p. 500; Bulk, *Ann. Ch. Pharm.* cxxxix. 62; *Jahresb.* 1866, p. 315; Claus, *Ann. Ch. Pharm.* cxxxi. 52; *Jahresb.* 1864, p. 336).—This acid is produced: 1. By heating allyl cyanide with caustic potash:

Now as allyl alcohol is converted by oxidation into acrylic acid, $CH(CH^3).COOH$, its constitution is probably $CH(CH^3)^2.CH^2OH$; and consequently that of allyl cyanide will be $CH(CH^3)^2.CH^2CN$, and that of the acid formed by treating it with alkali $CH(CH^3)^2.CH^2CO^2H$:

2. By heating citramonochloropyrotartaric acid with an alkali (Swarts, *Jahresb.* 1866, p. 406):

The acid thus produced (which has not been particularly described) is commonly said to be crotonic acid; but it is more probably alpha-crotonic acid, as shown by the following formulae, in the first of which the atoms of chlorine and hydrogen eliminated as hydrochloric acid are connected by a bracket:

3. By the dry distillation of β -oxybutyric acid: $C^4H^4O^3 - H^2O = C^4H^4O^2$ (Wislicenus, *Zeitschr. f. Chem.* [2] v. 325).

4. By oxidation of crotonic aldehyde, C^4H^4O (Kekulé, *ibid.* 572). Now this aldehyde, formed by dehydration of acetic aldehyde, $[2C^2H^4O - H^2O = C^4H^4O]$, appears to have the constitution $CH^2=CH-CH^2-COOH$ (p. 512); the acid formed from it is therefore constituted according to the formula $CH^2=CH-CH^2-COOH$.

5. By the action of sodium-amalgam on the less volatile of the two chlorocrotonic acids to be presently described (Geuther a. Fröhlich, p. 511).

Alpha-crotonic acid crystallises by cooling from concentrated solutions in needles; by slow evaporation over oil of vitriol, in well-defined monoclinic combinations $oP. - P\infty. + P\infty. - P. + mP$, tabular by predominance of the basal end-face; cleaving distinctly parallel to oP and $+mP$ (Knop). It melts at $72^\circ-73^\circ$, solidifies at 70.5° , and boils at 183.8° (corr. 187°) without sensible decomposition; volatilises even at ordinary temperatures, diffusing a peculiar odour, distantly resembling that of butyric acid; dissolves in 12 pts. water at 15° . Its salts, with the exception of the silver salt, are easily soluble in water. The sodium salt $C^4H^3O^2Na$ crystallises in deliquescent tables; the potassium salt is also deliquescent and crystalline. The barium salt forms radiate groups of crystals; the lead salt $(C^4H^3O^2)^2Pb$, stellate groups of needles, which separate from the evaporated solution after the deposition of prismatic laminae of a basic salt. The silver salt $C^4H^3O^2Ag$ is a white curly precipitate quickly blackened by light; from a hot-saturated solution this salt separates in dendritic crystals which are decomposed at the boiling heat, with separation of metallic silver.

Nascent hydrogen evolved either by zinc and sulphuric acid, or by water and sodium-amalgam, converts alpha-crotonic acid into an optically inactive acid, $C^4H^4O^2$, identical with ordinary butyric acid (Bulk); according to Körner, however (*Jahresh.* 1866, p. 318), alpha-crotonic acid is not converted into butyric acid by the action of sodium-amalgam.

Aqueous alpha-crotonic acid mixed with bromine forms a colourless solution, which when evaporated leaves a mixture of a syrupy liquid with a solid acid, which gives out hydrobromic acid; by the action of bromine vapour on crystallised alpha-crotonic acid, only the solid brominated acid is produced. The latter forms monoclinic crystals melting at 78° , solidifying at 75.5° , and moderately soluble in water. It contains 65.72 p. c. bromine, agreeing with the formula of dibromocrotonic acid, $C^4H^2Br^2O^2$, rather than with that of dibromobutyric acid, $C^4H^2Br^2O^2$. The syrupy acid contains a smaller proportion of bromine, and perhaps consists mainly of monobromocrotonic acid, $C^4H^3BrO^2$ (Bulk). According to Körner, on the other hand, bromine forms with alpha-crotonic acid a crystalline acid, agreeing with the formula $C^4H^3Br^2O^2$, melting at 90° , more soluble in water than crotonic acid, and yielding, when treated with alkalis, either monobromocrotonic acid, or by further decomposition, carbon dioxide and a brominated oil having the composition C^3H^3Br .

METHACRYLIC ACID (Frankland a. Duppa, *Chem. Soc. J.* [2] iii. 133).—The ethylic ether of this acid is produced by treating ethyl dimethoxalate with phosphorus trichloride (p. 42):

This ether, which has a very powerful odour of decayed fungi, is resolved by heating with alcoholic potash into alcohol and methacrylic acid, $C(CH^3)^2(CH^2)^2.COOH$, which by distilling its potassium salt with sulphuric acid, is obtained as a colourless oil, smelling slightly like pyrogallic acid, and not solidifying at 0° . It has a strong acid reaction, and its salts exhibit the same tendency as those of the other members of the acrylic series to give off their acid when their solutions are evaporated. The silver salt $C^4H^3O^2Ag$ is a white precipitate not much affected by light; the barium salt is gummy and very soluble in water; the cupric salt is also moderately soluble. The acid heated with potassium hydrate to the temperature of boiling oil is resolved into propionic and formic acids:

Nomenclature of the Acids $C^4H^5O^2$.—As the saponification of croton-oil does not yield any acid of this composition, Geuther proposes to discard altogether the name 'crotonic acid,' and to designate the liquid acid commonly called by this name (p. 508) as *quartenylic acid*, the corresponding chlorinated acid $C^4H^3ClO^2$ melting at 59.5° and boiling at 194.8° , being called *monochloroquartenylic acid*. The solid acid $C^4H^5O^2$, hitherto called α -crotonic acid, Geuther designates as *tetracrylic acid*, and the chlorinated acid $C^4H^3ClO^2$ melting at 94° and boiling at $206.2-211^\circ$ (p. 511), from which it is formed by the action of sodium-amalgam, as *monochlorotetracrylic acid*.

Bromocrotonic Acids (Kekulé, *Ann. Ch. Pharm. Suppl.* ii. 85; *Jahresb.* 1862, p. 341. Cahours, *Ann. Ch. Phys.* [3] lxxvii. 129; *Jahresb.* 1862, p. 316. Bulk, *Ann. Ch. Pharm.* cxxxix. 62; *Jahresb.* 1866, p. 315. Körner, *Ann. Ch. Pharm.* cxxxvii. 233; *Jahresb.* 1866, p. 317).

Monobromocrotonic acid, $C^4H^4BrO^2$, is produced: 1. By treating α -crotonic acid successively with bromine and with an alkali. The crotonic acid then takes up 2 at. bromine, forming an acid isomeric with dibromobutyric acid, $C^4H^4Br^2O^2$; and this, under the influence of the alkali, gives up HBr, and is converted into bromocrotonic acid (Körner).—2. By the action of alkalis on citradibromopyrotartaric acid, the reaction taking place by two stages, carbon dioxide being first removed, and then hydrobromic acid (Kekulé; Cahours). The mode of transformation is exactly similar to that by which crotonic acid is formed from citramonobromopyrotartaric acid, and shows that the bromocrotonic acid thus formed has the structure of a derivative of α -crotonic acid. The mode of preparation adopted by Kekulé is as follows: Calcium citradibromopyrotartrate is prepared by saturating the acid with ammonia, then adding a concentrated solution of calcium chloride, and precipitating with alcohol. The calcium salt, which when once precipitated is but slightly soluble in water, is collected, suspended in water, and the water is boiled. Carbon dioxide is then evolved, and the solution on cooling yields colourless nodules of calcium bromocrotonate. The concentrated solution of this salt mixed with hydrochloric acid yields crystals of bromocrotonic acid, the remainder of which may be extracted from the solution by agitating with ether and evaporating.

Bromocrotonic acid crystallises in long flat needles like benzoic acid. It melts at 65° (Kekulé); 60° (Cahours); and boils, with very slight decomposition, at $228^\circ-230^\circ$. It is sparingly soluble in cold, moderately soluble in boiling water; heated with a quantity of water not sufficient to dissolve it completely, it melts below 60° . The aqueous solution saturated at the boiling heat deposits the acid at about 60° in the form of an oil which slowly crystallises. It has a peculiar odour, resembling that of butyric acid.

By *sodium-amalgam and water*, bromocrotonic acid is converted into butyric acid, $C^4H^7BrO^2 + 2H^2 = HBr + C^4H^7O^2$. Heated with *bromine* to 100° in sealed tubes, it takes up Br^2 , and forms an acid isomeric with tribromobutyric acid, which crystallises in very hard colourless prisms.

The metallic bromocrotonates are all soluble in water, especially in hot water. The *calcium salt* $(C^4H^4BrO^2)_2Ca$ crystallises in nodular groups of small needles. The *silver salt* $C^4H^4BrO^2Ag$ also crystallises in needles.

Ethyl Bromocrotonate, $C^4H^5BrO^2.C^2H^5$, prepared by passing a rapid current of hydrochloric acid gas into a concentrated alcoholic solution of the acid heated nearly to boiling, then separated by water and purified in the usual way, is a colourless aromatic liquid boiling at $192^\circ-193^\circ$ (Cahours).

Dibromocrotonic acid, $C^4H^3Br^2O^2$ (Cahours, *loc. cit.*).—When the acid $C^4H^4BrO^2$, produced by the action of bromine on monobromocrotonic acid, is dissolved in an alkali and heated, it gives up a molecule of hydrogen bromide, and is converted into dibromocrotonic acid. The liquid saturated with hydrochloric acid and left to cool deposits the dibromocrotonic acid as a crystalline precipitate, which may be purified by washing with water and solution in alcohol. By evaporating the alcoholic solution the acid is obtained in long silky needles resembling caffeine. It dissolves readily in ether, and separates in fine crystals by spontaneous evaporation, melts at a gentle heat, and distils at a higher temperature without perceptible alteration.

The metallic dibromocrotonates are mostly crystallisable, and less soluble in boiling water than the monobromocrotonates. The *ethylic ether* is obtained by the action of hydrochloric acid gas on a nearly boiling alcoholic solution of the acid.

Tribromocrotonic acid, $C^4H^2Br^3O^2$.—When dibromocrotonic acid is heated to $120^\circ-125^\circ$ in sealed tubes with 2 at. bromine, an acid, $C^4H^2Br^3O^2$, isomeric with tetrabromobutyric acid, is formed, which when boiled with alkalis gives up HBr, and is converted into tribromocrotonic acid. This acid, separated from the alkaline solution by hydrochloric acid, dissolves very easily in alcohol and ether, sparingly in

cold water, more freely in boiling water, and separates on cooling in slender silky needles very much like those of the dibrominated acid (Cahours).

Chlorocrotonic Acid. $C^4H^5ClO^2$ (O. Fröhlich, *Zeitschr. f. Chem.* [2] v. 270).—When ethyl-di-acetic acid, $C^4H^7O^3$ (Wanklyn's hydrogen-triacetyl, p. 16), is treated with phosphorus pentachloride, and the product is poured into water, two crystallisable chlorinated acids are obtained having the composition $C^4H^5ClO^2$, together with an oil which appears to consist of the corresponding ethylic ethers. One of these acids melts at 94° , and boils at 206° – 211° , is very soluble in water, distils slowly with aqueous vapour, and is converted by treating its sodium salt with sodium-amalgam into α -crotonic acid. The other acid (to which the following description applies) melts at 59.5° , is but slightly soluble in water, and passes over very easily with aqueous vapour, and is converted by sodium-amalgam into liquid crotonic acid.

Chlorocrotonic acid, purified by repeated distillation from adhering colouring matter, forms white, very light needle-shaped crystals; from a concentrated aqueous solution it separates in colourless transparent four-sided prisms with oblique end-faces. It melts at 59.5° to a colourless liquid, which solidifies again in the crystalline form at 55.5° . Heated above its melting point it partly sublimes, and begins to boil at 194.8° (corr.); the liquid distillate solidifies very quickly to a white dense crystalline mass. It has a faint somewhat pungent odour and acid taste. When kept in close vessels it sublimes even at ordinary temperatures; 1 pt. of it dissolves in 79 pts. water at 7° ; in alcohol and ether it dissolves very easily. It is a rather strong acid, quickly decomposing carbonates.

Potassium Chlorocrotonate, $C^4H^5ClO^2 \cdot K + H^2O$, prepared by neutralising the acid with potassium carbonate and gradual evaporation over sulphuric acid, forms small colourless plates and needles apparently belonging to the rhombic system; they are very soluble, become moist in the air, but effloresce over oil of vitriol. The **sodium salt** $2C^4H^5ClO^2 \cdot Na + H^2O$, prepared in like manner, forms satiny crystals, often in feathery groups, also very soluble in water and in alcohol, and efflorescing over sulphuric acid. An **acid ammonium salt**, $C^4H^5ClO^2 \cdot (NH^4)$, $C^4H^5ClO^2 + H^2O$, gradually separates in crystalline crusts from a solution of the acid in excess of ammonia left over sulphuric acid. The **thallium salt**, prepared by heating the acid with thallium carbonate and water, separates on cooling as a crystalline powder, and the solution on further evaporation deposits elongated monoclinic tables containing $C^4H^5ClO^2 \cdot Tl + H^2O$. The **silver salt** $C^4H^5ClO^2 \cdot Ag$ is a white crystalline precipitate, nearly insoluble in cold water, and separating from a hot-saturated aqueous solution in feathery groups of laminae having a satiny lustre and quickly blackening when exposed to light.

The **barium salt** $(C^4H^5ClO^2)_2 \cdot Ba, H^2O$, obtained by neutralisation, crystallises in shining, mostly four-sided prisms with oblique end-faces, sometimes flattened into tables; it is easily soluble in water. The **calcium salt** $(C^4H^5ClO^2)_2 \cdot Ca + 3H^2O$ forms hollow prisms, very soluble in water, efflorescing over sulphuric acid. The **magnesium salt** $(C^4H^5ClO^2)_2 \cdot Mg + 5H^2O$ forms thin transparent monoclinic tables, efflorescent and very soluble in water. The **manganese salt** $(C^4H^5ClO^2)_2 \cdot Mn + 2H^2O$ forms very soluble colourless rhombic crystals, mostly thick tables, which slowly effloresce over sulphuric acid. The **cobalt salt** $(C^4H^5ClO^2)_2 \cdot Co + 6H^2O$ forms very soluble rhombic tables having a peach-blossom colour and strong lustre, and quickly efflorescing over sulphuric acid. The **nickel salt** $(C^4H^5ClO^2)_2 \cdot Ni + 6H^2O$ forms light green crystals of similar form and properties. The **zinc salt** $2(C^4H^5ClO^2)_2 \cdot Zn + 5H^2O$ forms colourless shining rhombic tables, very soluble, and not efflorescing even over sulphuric acid. The **cupric salt** $(C^4H^5ClO^2)_2 \cdot Cu$, produced by boiling the crystallised acid with water and cupric carbonate, separates from the hot-filtered solution by slow evaporation in blue rhombic prisms, or in dark-green quadratic combinations of prism and pyramid, the former crystallising out at comparatively low, the latter at higher temperatures. The green crystals contain $2(C^4H^5ClO^2)_2 \cdot Cu + 3H^2O$; the blue crystals appear to contain more water, and turn green in the air-bath at 80° . The **lead salt** $(C^4H^5ClO^2)_2 \cdot Pb + 4H^2O$ forms concentric groups of silky needles, rather sparingly soluble in water, and efflorescing gradually over sulphuric acid.

Ethyl Chlorocrotonate, $C^4H^5ClO^2 \cdot C^2H^5$, is prepared by digesting the crystallised acid with twice its volume of absolute alcohol saturated with hydrochloric acid in a well-closed vessel at a gentle heat, for several days and with frequent agitation. When purified in the usual way, it is a colourless oily liquid, having a pleasant aromatic odour and cooling taste. Boils at 161.4° (corr.), and has a sp. gr. of 1.113 at 15° . Dissolves slightly in water, easily in alcohol and ether. Decomposed by heating with sodium carbonate. The **methylic ether** $C^4H^5ClO^2 \cdot CH^3$, prepared in like manner, is a colourless oily liquid, having a pungent ethereal odour and strongly cooling taste. Boils at 142.4° (corr.). Sp. gr. 1.143 at 15° . Less soluble in alcohol than the ethylic ether; nearly insoluble in water.

CROTONIC ALDEHYDE—CRYPTOPHANIC ACID. 513

CROTONIC ALDEHYDE. $C^4H^4O = CH^2=CH-CH^2-COOH$. *Tetra-crotyc aldehyde* (Kekulé, *Zeitschr. f. Chem.* [2] v. 572; Paterno & Amato, *ibid.* 637; Lwow, *ibid.* vi. 245).—Produced: 1. By heating acetic aldehyde with zinc chloride and a little water to 100° , the reaction consisting in the elimination of 1 mol. water from 2 mol. acetic aldehyde (Kekulé), as shown by the following equation, in which the eliminated atoms are enclosed in brackets:

2. By heating acetic aldehyde with ethylidene chloride in sealed tubes (Paterno & Amato):

Crotonic aldehyde is a colourless liquid, having an extremely pungent odour, and boiling at $103^\circ-105^\circ$ (Kekulé). In contact with the air it oxidises to a-crotonic acid (p. 509). By phosphorus pentachloride it is converted into a liquid chloride, $C^4H^4Cl^2$, having an ethereal odour, a sp. gr. of 1.138, and boiling at 125° . This chloride treated with alcoholic potash is converted into C^4H^4Cl , a liquid lighter than water, and having the odour of chlorinated hydrocarbons in general.

Crotonic aldehyde saturated with hydrochloric acid gas is converted by direct addition into chlorobutyric aldehyde, C^4H^4ClO , which crystallises in white needles insoluble in water, sparingly soluble in alcohol, melting at $96^\circ-97^\circ$, and scarcely volatilising with vapour of water (Kekulé).

Trichlorocrotonic Aldehyde.—A large quantity of aldehyde is now produced in Berlin in the purification of alcohol by passing it over charcoal, the alcohol being oxidised, partly by contact with the air, partly by oxygen condensed in the charcoal. Now when the mixture of aldehyde and alcohol thus produced is treated with chlorine, for the manufacture of chloral—hydrochloric acid being formed at the same time—this hydrochloric acid acts as a dehydrating agent upon the acetic aldehyde, converting it into crotonic aldehyde, in the same manner as the zinc chloride in the process above mentioned; and lastly this crotonic aldehyde, as fast as it is formed, is converted by the free chlorine into trichlorocrotonic aldehyde, $C^4H^4Cl^3O$ (*Communication made by Dr. Hofmann to the Chemical Society, April 21, 1870*).

CRUORIN. See BLOOD (p. 362).

CRYPTOPHYLLITE. A variety of mica occurring, together with lepidomelane, danalite, and a zircon-like mineral, in the granite of Rockport, Massachusetts. It forms six-sided prisms belonging to the rhombic system, often two inches long, having perfect basal cleavage and two optic axes inclined at an angle of 55° to 60° . Colour, dark emerald-green in the direction of the principal axis, brownish-red in the direction of the secondary axes. Streak, light-grey to greenish. Lustre on the cleavage-faces, resinous. Hardness = 2 to 2.5. Sp. gr. = 2.909. Analysis gave:

SiO ₂	SiF ₄	Al ₂ O ₃	Mn ² O ³	Fe ² O ³	FeO	MgO	K ² O	Li ² O
51.49	3.42	16.77	0.34	1.97	7.98	0.76	13.15	4.06 = 99.94

with traces of soda and rubidia, agreeing with the formula:

which is included in the general formula of the orthosilicates M^2SiO^4 or $2M^2O \cdot SiO^2$ (J. P. Cooke, jun., *Sill. Am. J.* [2] xliii. 217).

CRYPTOPHANIC ACID. $C^6H^4NO^4$ or $C^6H^4N^2O^{10}$ (Thudichum, *Chem. Soc. J.* [2] viii. 132).—An acid existing in normal human urine. To prepare it, the urine is treated with excess of milk of lime; the liquid filtered from the gypsum is acidulated and evaporated to a syrup; and this, after filtration from the salt-cake, is treated with strong alcohol, which separates calcium cryptophanate as a dark flaky mass. The

Sup.

L L

impure calcium salt is dissolved in water and mixed with solution of neutral lead acetate, whereby a dark-coloured precipitate is formed, from which the mother-liquor is to be filtered. The filtrate containing lead cryptophanate is treated with strong alcohol, whereby the lead salt is thrown down in white flakes, from which the acid may be liberated by hydrogen sulphide.

Cryptophanic acid is an amorphous gummy mass, transparent and nearly colourless, soluble in water in all proportions, less soluble in alcohol, which indeed produces a precipitate in the aqueous solution; either added to the alcoholic mixture produces a fresh precipitate. It has a freely acid taste, decomposes alkaline and earthy carbonates, forming aqueous solutions of the corresponding cryptophanates. Its solution forms with lead acetate a copious thick white precipitate soluble in excess of lead acetate; with mercuric acetate a similar precipitate; with silver nitrate a very slight precipitate. The free acid is not precipitated by mercuric chloride or by cupric acetate. An ammoniacal solution of silver nitrate mixed with ammonium cryptophanate immediately becomes very dark, and on standing almost black (red when diluted), depositing metallic silver as a black powder. Silver nitrate and excess of nitric acid, added to a solution of cryptophanic acid containing urea, produces after some time a specular deposit of metallic silver.

The cryptophanates of the alkali-metals are very soluble in water; the sodium salt is not precipitated from its aqueous solution by alcohol. The cryptophanates of the earth-metals are precipitated by excess of alcohol. Boiled with a great excess of alkaline cupric solution, they reduce the cupric to cuprous oxide, which remains in solution, but is deposited if the solution is concentrated and kept from access of air. The alkaline solution exhibits a blue fluorescence. With mercuric nitrate, the solutions of the earthy cryptophanates give a bulky white precipitate: hence the ordinary estimation of urea in urine by this reagent requires a correction for cryptophanic acid, which may amount to 5 to 10 per cent.

The composition of many of the metallic cryptophanates may be represented by the formula $C^3H^4N^2O^3M$, the acid $C^3H^4N^2O^3$ being regarded as bibasic. But there are also cryptophanates containing $C^3O^4H^4N^2N^2M^2$ or $(C^3O^4H^4N^2O^3)^2M^2$, and others containing $C^3O^4H^4N^2O^3M$: thus there is a calcium salt containing $(C^3O^4H^4N^2O^3)^2Ca^2$, and another containing $C^3O^4H^4N^2O^3Ca$. On the whole, perhaps the constitution of these salts is best represented by regarding cryptophanic acid as a quadribasic acid, containing in the free state $C^3O^4H^4N^2O^3 \cdot 4H^2O$; but they require further examination.

CRYPTOPINE. $C^3H^2NO^3$ (T. and H. Smith, *Pharm. J. Trans.* [2] viii. 595, 716).

—A base existing in very small quantity in opium, being found in the alcoholic wash-liquors of crude morphine. To separate it, the alcoholic liquid is nearly neutralised with dilute sulphuric acid; the alcohol is evaporated; and the residue, dissolved in hot water, is precipitated with excess of milk of lime. The precipitate, containing the cryptopine, together with many other substances, is exhausted with hot alcohol; the alcohol is distilled off; and the pitchy substance (chiefly containing thebaine) which separates from the watery residue, is repeatedly boiled with alcohol. The resulting solution, after standing for some days, solidifies to a soft crystalline mass of thebaine. This is pressed, dissolved in the smallest possible quantity of very dilute hydrochloric acid (so that the liquid does not become acid), and repeatedly evaporated to the crystallising point, whereupon hydrochloride of thebaine crystallises out first, and the last mother-liquors, after standing for a considerable time, yield hydrochloride of cryptopine (or a mixture of the hydrochlorides of thebaine and cryptopine). For the complete separation of the two bases, the last crystallisation is once more crystallised from the smallest possible quantity of hot water, and the soft cauliflower-like mass which separates is dried and boiled with 5 pts. of alcohol. The alcoholic solution then yields, first, several hard crystallisations of thebaine hydrochloride, and finally from the last mother-liquor, soft crystalline masses of cryptopine hydrochloride, to be decolorised with animal charcoal. Five tons of opium yielded only 5 oz. of this salt.

Cryptopine separated from the hydrochloride by ammonia crystallises from boiling alcohol in microscopic six-sided prisms or tables. It melts at 175° ; solidifies again at 171° ; is nearly insoluble in water, ether, turpentine-oil, and benzol, slightly soluble in alcohol (1 pt. in 1265), more soluble in chloroform. It forms neutral and acid salts, which have a bitter taste, with cooling after-taste. The neutral hydrochloride $C^3H^2NO^3 \cdot HCl + 5H^2O$ is distinguished by its inclination to separate under certain circumstances in the gelatinous form. The acid hydrochloride contains $C^3H^2NO^3 \cdot 2HCl + 6H^2O$; the platinochloride, $2(C^3H^2NO^3 \cdot HCl)PtCl_4$.

With strong sulphuric acid cryptopine produces a blue colour, changing to orange-

yellow on addition of saltpetre; if thebaine is present, the blue has a tinge of violet; the somewhat fainter blue produced in like manner by papaverine is changed to green by addition of saltpetre. From pseudomorphine, which is coloured brown by sulphuric acid and blue by ferric chloride, cryptopine is distinguished by its solubility in potash, and by not being coloured by ferric chloride.

CUMENE. $C^9H^{12} = C^8H^7.C^2H^5$.—See BENZENE, HOMOLOGUES OF (p. 295).

CUMENYL SULPHYDRATE or **CUMIC MERCAPTAN**, $C^9H^{12}S = C^8H^{11}SH$, is formed by the action of zinc and sulphuric acid on cumene-sulphuric chloride (obtained by trituration of the sodium-salt of cumene-sulphuric acid with phosphorus pentachloride, and mixing the product with water). It crystallises in inodorous nacreous laminae melting at $86^\circ-87^\circ$ (Beilstein u. Kögler, *Jahresb.* 1866, p. 559).

CUMIC or **CUMINIC ACID**, $C^{10}H^{12}O^2 = C^8H^{11}.COOH = C^8H^9(C^2H^5).COOH$ (ii. 178).

Bromocumic acid, $C^8H^{11}BrO^2$, is formed, together with cumic acid, by exposing fluely pulverised silver cumate to the action of bromine vapour. When the portion of the product which is soluble in ether is treated ten times with boiling water, the cumic acid dissolves, while the much more abundant insoluble portion consists, after recrystallisation from ether, of pure bromocumic acid. This acid is mostly crystalline, melts at 146° , is nearly insoluble in boiling, and quite insoluble in cold water, slightly soluble in cold alcohol, easily soluble in ether. Its silver salt is insoluble in water, and is not decomposed by water even at 150° (Naquet u. Longuinine, *Compt. rend.* lxii. 1031).

CUMIC or **CUMINICALDEHYDE**, $C^{10}H^{12}O = C^8H^{11}.CHO = C^8H^9(C^2H^5).CHO$.—Gerhardt found that this compound heated with potassium gives off hydrogen and forms cumyl-potassium, as represented by the equation $2C^{10}H^{12}O + K^2 = 2C^{10}H^{11}KO + H^2$. According to Church (*Phil. Mag.* [4] xxv. 522), the reaction is less simple, and the quantity of hydrogen evolved is smaller than the preceding equation requires. When a mixture of cumic aldehyde and benzene (or other hydrocarbon from coal-naphtha) is heated with sodium-amalgam, the sodium-compounds of cumyl alcohol and cumyl are produced in equivalent quantities, and on treating the product with water, these sodium compounds are decomposed, yielding cumyl alcohol and cumic aldehyde:

At the same time there is formed a viscid oily body, boiling above 300° , having the composition of dicumyl, $(C^8H^{11}O)^2$. This latter is more easily formed, together with cumyl cumate, by treating the product of the reaction of sodium on cumic aldehyde with cumyl chloride. If benzoyl chloride be used instead of cumyl chloride, the products are cumyl benzoate and cumyl-benzoyl:

According to Claus (*Jahresb.* 1866, p. 354), cumic aldehyde treated in ethereal solution with sodium-amalgam, yields, together with sodium cumate, a neutral body, C^8H^9O , which crystallises in needles, and is coloured violet-blue or cherry-red by strong sulphuric acid.

Cumic aldehyde, or Roman cumin-oil, oxidised with chromic acid is converted into terephthalic acid (De la Rue u. Müller, *Jahresb.* 1861, p. 426). According to Buliynsky, A. Erlenmeyer (*ibid.* 1866, p. 371), the products are cumic acid and a solid acid intermediate in composition between terephthalic acid, $C^8H^6O^4$, and insolinic acid, $C^8H^4O^4$.

CUMIDINE, C^8H^9N , or *Amidocumene*, $C^8H^9(H^2N) = C^8H^9(NH^2).C^2H^5$.—This base, formed by the action of ammonium sulphide on nitrocumene, is described in the Dictionary, vol. ii. p. 174, under the name of *Cumenylamine*, and regarded as homologous with benzylamine, which latter, at the time when that article was written, was supposed to be identical with toluidine. Subsequent researches have, however, shown that the hydrocarbons homologous with benzene give rise to two series of isomeric bases, the one series, viz. toluidine and its homologues, being formed by reduction of

nitrotoluene, &c., and having the amidogen-group NH^2 situated in the principal chain, the other series, viz. benzylamine and its homologues, being formed, like the bases of the ethyl series, by the action of ammonia on the corresponding alcoholic chlorides, and having the amidogen in one of the lateral chains. (See AROMATIC SERIES, p. 203.) Cumidine then is homologous, not with benzylamine, but with toluidine; the true cumenylamine, $\text{C}^6\text{H}^5 \cdot \text{C}^3\text{H}^6\text{NH}^2$, has not yet been discovered.

Cumidine is formed by distilling amidocumic acid (ii. 179) with anhydrous baryta, or solid potassium hydrate (Cahours, *Jahresb.* 1868, p. 324):

It may be conveniently prepared by reducing nitrocumene with tin and hydrochloric acid. The hot somewhat dilute filtrate yields shining laminae of *cumidine stannoso-chloride*, $\text{C}^8\text{H}^{12}\text{N} \cdot \text{HCl} \cdot \text{SnCl}^2$, from which, by precipitating the tin with hydrogen sulphide, *cumidine hydrochloride*, $\text{C}^8\text{H}^{12}\text{N} \cdot \text{HCl}$, is obtained in long prismatic crystals; and this salt decomposed by ammonia, yields cumidine as a white flocculent precipitate, which crystallises from hot water or from alcohol in long silky needles melting at 62° (L. Schaper, *Zeitschr. f. Chem.* [2] iii. 12).

CUMONITRILAMINE, $\text{C}^{10}\text{H}^{12}\text{N}^2$, or *Amidocumonitrile*, $\text{C}^{10}\text{H}^{10}(\text{NH}^2)\text{N}$ (Zumpelink, *Zeitschr. f. Chem.* [2] v. 437).—Cumonitrile, $\text{C}^{10}\text{H}^{11}\text{N}$, added by drops to a cooled mixture of strong nitric and sulphuric acids, is converted into crystalline nitrocumonitrile, $\text{C}^{10}\text{H}^{10}(\text{NO}^2)\text{N}$; and this compound subjected in alcoholic solution to the action of nascent hydrogen (from zinc and hydrochloric acid) is converted into cumonitrilamine. When the reaction is complete (i.e. when a sample mixed with water no longer becomes turbid) the liquid filtered from the zinc is mixed with sufficient caustic soda to redissolve the separated zinc-hydrate; the alcoholic layer which contains the base is decanted; the alcohol distilled off; the remaining liquid mixed with water and agitated with ether to dissolve out the base; and the ethereal solution separated from the watery layer is freed from ether over the water-bath. On distilling the remaining liquid over an open fire, the base passes over at about 305° as an oily aromatic liquid.

Cumonitrilamine is sparingly soluble in water, and crystallises therefrom in large needles; in alcohol and ether on the other hand it dissolves readily, and is not so easily obtained from these solutions in good crystals. It melts at about 45° , and boils at about 305° . With acids it forms well-crystallised salts. The *hydrochloride* crystallises in colourless six-sided tables; the *platinochloride*, $2(\text{C}^{10}\text{H}^{12}\text{N}^2 \cdot \text{HCl}) \cdot \text{PtCl}^4$, also crystallises well. The *sulphate* and *nitrate* crystallise in needles.

In the preparation of cumonitrilamine from nitrocumonitrile an intermediate compound is also produced.

CUMOYLIC ACID. Syn. with HYDROCINNAMIC ACID. See CINNAMIC ACID (p. 468).

CUMYLAMINE. $\text{C}^{10}\text{H}^{13}\text{N}$; better called CUMYLAMINE (q.v.).

CUMYL-BENZOYL. $\text{C}^{10}\text{H}^{11}\text{O} \cdot \text{C}^7\text{H}^5\text{O}$ (p. 505).

CUMYLENE-DIAMINE, $\text{C}^8\text{H}^{14}\text{N}^2 = (\text{C}^3\text{H}^5)^2 \cdot \text{H}^2\text{N}^2$, produced by distilling dinitrocumene with acetic acid and iron, is a splendidly crystalline base melting at 47° (Hofmann, *Compt. rend.* lv. 781).

CUPREIN. This name is given by Breithaupt to a hexagonal form of cuprous sulphide, Cu_2S , which, according to his observations, occurs in nature more frequently than the rhombic form, copper-glance (ii. 74). It forms hexagonal prisms, ∞P , of 120° , combined with 2P , P , and ∞P ; also twin-crystals. Angle $2\text{P} : \infty\text{P} = 117^\circ 53'$. Cleavage basal. Fracture uneven to conchoidal. Sp. gr. = 5.50 to 5.586. Hardness = $3\frac{1}{2}$. Colour blackish-grey, but lighter than that of copper-glance (*Jahresb.* 1863, p. 794).

CUPROSACETYL-COMPOUNDS. See ACETYLENE (p. 35).

CURARINE. According to W. Preyer (*Bull. Soc. Chim.* [2] iv. 238), this base has the composition $\text{C}^{16}\text{H}^{13}\text{N}$. It is very hygroscopic; has a very bitter taste; crystallises in colourless four-sided prisms; dissolves freely in water and alcohol, less easily in chloroform and amyl alcohol; and is insoluble in anhydrous ether, benzol, turpentine, and carbon bisulphide. It blues litmus very slightly, acquires a splendid and permanent blue colour in contact with sulphuric acid, purple-red with nitric acid, and violet with potassium dichromate and sulphuric acid (like that of strychnine, but more permanent). Its hydrochloride, nitrate, sulphate, and acetate are crystallisable. Dragendorff (*Zeitschr. f. Chem.* [2] iii. 28) also finds that curarine is quite distinct

from strychnine, and that a very active curara occurs in commerce, in which neither strychnine nor brucine can be detected. On the physiological action of curarine and curara, see Cl. Bernard, *Compt. rend.* lx. 1327; Bert, *Chem. Centr.* 1865, p. 229; Schnetzler, *N. Arch. ph. nat.* xxiv. 318; *Jahresb.* 1865, p. 456.

CURCUMIN. The resinous colouring matter of tumeric-root (ii. 186). Respecting the changes of colour which it exhibits with boric acid, see Schlumberger (*Bull. Soc. Chim.* [2] v. 194; *Jahresb.* 1866, p. 652). Boiled in alcoholic solution with boric acid, it forms a compound which separates from the cooled solution, on addition of water, as a cinnabar-red precipitate, and is decomposed by boiling with water, boric acid dissolving and a yellow resin separating. This resin, called *pseudocurcumin*, is distinguished from curcumin by not being reddened by boric acid, and by assuming a greenish-grey colour in contact with alkalis. It separates from its solutions on evaporation in vitreous dark yellow laminae, insoluble in water, soluble in ether and in benzol, very soluble in alcohol. When the orange-yellow solution of the boric acid compound is boiled with a mineral acid, it turns blood-red, and deposits on cooling a granular nearly black substance called *rosocyanin*, which, when purified by crystallisation from a mixture of hot alcohol and acetic acid, and washing with ether, forms a mass of interlaced needles with beautiful green reflex. The alcoholic solution of rosocyanin has a red colour, and when boiled becomes first blood-red and then yellow, in which state it contains pseudocurcumin. The red alcoholic solution mixed with a drop of soda or ammonia, acquires a pure blue colour, changing on saturation with an acid to the original rose-red tint (Schlumberger).

CYAMELIDE, $n\text{CNHIO}$, is produced, together with cyanic acid, when a mixture of urea and phosphoric anhydride in equivalent proportions is distilled at 40° , in a flask provided with a series of condensing tubes, a considerable quantity of cyanic acid condensing in the first, and cyamelide chiefly in the second (Wetzel, *Ann. Ch. Pharm.* cvii. 219). A solution of cyamelide in strong sulphuric acid deposits the unaltered substance, on dilution with water, as an amorphous precipitate; but if the solution be heated till decomposition begins (attended with evolution of carbon dioxide), water no longer forms a precipitate, but the diluted solution yields after some time crystals of anhydrous cyanuric acid (Wetzel, *ibid.* cxxxii. 222).

CYANACETIC ACID See ACETIC ACID (p. 19).

CYANAMIDE. $\text{CH}_3\text{N}^2 = \text{CN}(\text{NH}_2)$.—Beilstein & Geuther (*Ann. Ch. Pharm.* cviii. 88) obtained this compound by heating sodamide in a stream of carbon dioxide:

Cyanamide unites directly with *glycocine*, $\text{C}^2\text{H}_3\text{N}^2\text{O}_2$, forming glycoeyanamide, $\text{C}^2\text{H}_3\text{N}^2\text{O}_2$, and with *methyl-glycocine* or *sarcosine*, $\text{C}^3\text{H}_5\text{N}^2\text{O}_2$, producing creatine, $\text{C}^3\text{H}_5\text{N}^2\text{O}_2$ (p. 501).

Cyanamide unites with *aldehyde*, with elimination of water, forming the compound $\text{C}^2\text{H}_3\text{N}^2\text{O} = 3\text{CH}_3\text{N}^2 + 3\text{C}^2\text{H}_3\text{O} - 2\text{H}_2\text{O}$. This compound dissolves in alcohol, and is precipitated therefrom by ether, chloroform, benzol, aniline, and carbon bisulphide. It is decomposed by heat, giving off an oily body having the odour of an organic base. A similar compound is formed with *valeral* (Knop, *Ann. Ch. Pharm.* cxxx. 253).

Dicyanodiamide. $\text{C}^2\text{H}_3\text{N}^4 = \text{N}_2\left\{\begin{smallmatrix} \text{CN} \\ \text{H} \end{smallmatrix}\right\} = (\text{CN})^2(\text{NH})^2$ (ii. 189).—Strecker (*Kurzes Lehrbuch d. organischen Chemie*) represents this compound by the structural formula

This formula suggests the possibility of replacing one or both of the imidogen groups NH, which are connected with only one carbon-atom (and may therefore be expected to be more loosely attached than the other two) by oxygen, which would give the compounds

The second of these is dicyanic acid, $\text{C}^2\text{H}_3\text{N}^2\text{O}_2$, which Poesagen obtained from cyanocarbamide (see DICYANIC ACID); the first is dicyanamidic acid, a compound holding an intermediate position between dicyanic acid and dicyanodiamide, just as

ammelide and ammeline are intermediate between cyanuric acid and cyanuramide or melamine:

Dicyanamic acid is produced by boiling dicyanodiamide with baryta-water as long as ammonia is thereby evolved. On removing the excess of baryta with carbonic acid, a solution of barium dicyanamate is obtained, which, when slightly acidulated with nitric acid and mixed with silver nitrate, yields the *silver salt* $\text{C}^2\text{H}^2\text{N}^2\text{OAg}$ as a white curdy precipitate, soluble in ammonia, and crystallising therefrom by slow evaporation in thin colourless laminae, mostly grouped in tufts. The *copper salt* is obtained by decomposing the silver salt with a moderately warm solution of cupric chloride, and separates on cooling in sky-blue shining crystals containing $(\text{C}^2\text{H}^2\text{N}^2\text{O})^2\text{Cu} + 8\text{H}_2\text{O}$, which give off 6 mol. water at 90° , assuming a dark green colour; at a higher temperature the salt blackens and decomposes. It dissolves sparingly in cold, more easily in warm water; the aqueous solution when heated to boiling deposits a dark green insoluble powder.

By passing hydrogen sulphide through water in which the cupric salt is suspended, and evaporating the filtrate, the *hydrogen salt* or *free acid* $\text{C}^2\text{H}^2\text{N}^2\text{O}$ is obtained in groups of small white needles.

Dicyanamic acid contains the elements of cyanamide, CN^2H^2 , and cyanic acid, CNHO , and its potassium salt may be produced by heating cyanamide with potassium cyanate in a test-tube, or by leaving cyanamide for twenty-four hours in contact with aqueous solution of potassium cyanate. Part of the cyanamide then dissolves, and on heating the liquid with nitric acid to decompose the remaining cyanic acid, a solution is obtained which yields the salts above described with silver nitrate and cupric chloride (F. Hallwachs, *Zeitschr. f. Chem.* [2] iv. 515).

CYANAMIDOBENZOIC ACID. See Benzoic Acid (p. 318).

CYANIC ACID. CNHO or $\text{N} \equiv \text{C} - \text{OH}$ or $\begin{array}{c} \text{CN} \\ \text{H} \end{array} \text{O}$.—The physical properties of this acid have lately been investigated by Troost and Hautefeuille (*Zeitschr. f. Chem.* [2] v. 149, 188, 497, 629). 1. The vapour-density was found in two determinations to be 1.51 and 1.50, the calculated number being 1.488. To prevent condensation of the cyanic acid vapour to cyamelide, the vapour evolved by heating dry cyanuric acid or pure cyamelide to 440° , was passed into a globe previously exhausted of air and heated to the temperature at which it was to be afterwards sealed.

2. The absolute coefficient of expansion of the liquid acid was found to be = 0.000300 from -20° to -14° ; 0.0006999 from -20° to 0° ; and = 0.0008450 from -3° to 0° . It increases therefore very rapidly as the temperature rises.

3. The sp. gr. of the liquid acid is 1.1558 at -20° , whence, by means of the expansion coefficient above given, the sp. gr. at 0° is found to be 1.140.

4. The tension of the vapour of cyanic acid evolved from cyanuric acid or cyamelide increases with the temperature, and the transformation ceases as soon as the cyanic acid vapour exerts upon the solid isomeric compound from which it is formed, a pressure which is determinate for each temperature, viz.,

Temp.	Tension	Temp.	Tension	Temp.	Tension
160°	56 mm.	195°	125 mm.	251°	285 mm.
170	68	215	157	330	740
180	94	227	180	350	1,200

5. The transformation of 1 gram of cyanic acid into cyamelide is accompanied by the evolution of 410 units of heat; on the other hand, 1 gram of cyamelide, in passing into cyanuric acid, absorbs 76 units of heat: hence cyanuric acid in changing into cyamelide must give off heat. This allotropic transformation, contrary to what is generally observed, is accompanied by a decrease of density at a temperature near 20° : for the density of cyanuric acid is 2.768 at 0° ; 2.500 at 19° ; 2.228 at 24° ; 1.725 at 48° , whereas that of cyamelide is 1.974 at 0° and 1.774 at 24° .

6. *Heat of Combustion of Cyanic Acid and its Polymerides.*—Cyanuric acid is completely oxidised by a moderately concentrated solution of hypochlorous acid, yielding water, carbon dioxide, and nitrogen; cyanic acid in like manner yields carbon dioxide

and nitrogen chloride, whereas cyanamide is only imperfectly oxidised even by very concentrated hypochlorous acid. Cyanuric acid thus burnt gives out 1,940 heat units for 1 gram, therefore 260,260 units for 1 equivalent of the acid. The heat of combustion of cyanic acid is obtained by adding to this number, 1,940, the quantity of heat given off by 1 gram of cyanic acid in passing into cyanuric acid, viz. 334 units: hence the heat of combustion of cyanic acid is 2,274 units for 1 gram or 97,780 units for 1 eq. Direct oxidation of cyanic acid by hypochlorous acid to water, carbon dioxide, and nitrogen chloride, gave 2,320 heat units for 1 gram of the acid; and its decomposition by sulphuric acid into ammonia and carbonic acid gives 2,260: mean of all the determinations, 2,290 heat units for 1 gram of cyanic acid. Hence, with the aid of the determinations above given of the heat absorbed and evolved in the molecular transformations of these bodies, it is found that the heat of combustion of cyanamide is 1,880 heat units for 1 gram, and that of cyanuric acid 1,936, which last number differs but little from that directly determined, viz. 1,940.

CYANIC ETHERS. Of these ethers there are two series. Those of the first series, discovered by Wurtz in 1848, are resolved by water, assisted by acids or bases, into carbon dioxide and an alcoholic ammonia; thus:

where R' denotes an alcohol-radicle such as methyl or ethyl. These bodies in fact react like alcoholic derivatives of carbimide, $N \left\{ \begin{array}{c} CO'' \\ H \end{array} \right.$, and may therefore be designated as alcoholic carbimides, pseudocyanates, or isocyanates (they were originally called alcoholic cyanates). They are produced by distilling a mixture of the potassium salts of cyanic acid and methylsulphuric, ethylsulphuric acid, &c.

The second series, discovered by Cloez, consists of ethers which are decomposed by hydration into cyanic or cyanuric acid and an alcohol; thus:

or rather perhaps,

These therefore, though originally called by their discoverer *isocyanates*, are the true alcoholic cyanates or cyanic ethers. They are formed by the action of cyanogen chloride on the sodium-alcohols:

The difference of structure between the two classes of ethers may be further illustrated by the following formulæ:

The alcoholic carbimides are fully described in vol. ii. pp. 195-197 as **CYANIC ETHERS**.

Of the true alcoholic cyanates, the ethyl-compound was discovered by Cloez in 1857 and described under the name *Cyanetholine* (ii. 189); but its properties, together with those of the methyl ether, have since been more completely investigated (Cloez, *Thèses de la Faculté des Sciences de Paris*, août 1866).

Methyl cyanate, $C^2H^3NO = \frac{CN}{CH^3}O$, is prepared by dissolving sodium by small portions in pure methyl-alcohol mixed with about twice its weight of anhydrous ether (2 at. sodium to 5 mol. methyl-alcohol), and slowly passing a current of gaseous cyanogen chloride (rather more than the theoretical quantity) to the bottom of the retort containing the mixture. The liquid immediately becomes hot; sodium chloride is precipitated; and on distilling the filtered liquid, methyl cyanate remains as an oil which may be purified by repeated washing with water, and dehydrated in a dry vacuum.

Methyl cyanate is a colourless or slightly yellow liquid having a sp. gr. of 1.1746 at 15°; decomposed by heat into a volatile portion and a solid residue; converted by aqueous potash or ammonia into methyl-alcohol and cyanuric acid; with dry hydrochloric acid gas or the concentrated aqueous acid, it yields methyl chloride and crystallised cyanuric acid.

If the methyl-alcohol used in the preparation of this ether is not quite anhydrous, secondary products are also formed. In one experiment Cloez obtained a white substance insoluble in water, which was precipitated together with the sodium chloride, and when freed from that salt by water, and dissolved in boiling alcohol, formed crystals having the composition of dimethyl-allantoïn, $C^6H^{10}NO^3$ or $C^4H^4(CH^3)^2NO^3$. This substance melts at 225°, and is considerably modified when heated above 230°. Baryta-water decomposes it, eliminating ammonia, and forming a salt which yields a white precipitate with silver nitrate.

Ethyl cyanate, $\begin{matrix} CN \\ C^2H^5 \end{matrix} O$, is produced in like manner by the action of cyanogen chloride on a solution of sodium ethylate in absolute alcohol. It is a colourless oily liquid, having a sp. gr. of 1.271 at 15°, an odour like that of sweet oil of wine, and an ethereal bitter taste, with an acrid and persistent after-taste. Heated for several hours to 120°–150°, it gives off, first alcohol, then a mobile liquid which dissolves in the alcohol, and an oily liquid which separates. In the retort there remains a solid yellowish vitreous residue, which when pulverised and treated with hot alcohol, leaves an insoluble portion having nearly the composition of trigenic acid. The oily liquid, washed and dried, distils without alteration at about 195°, and appears by analysis to consist of unaltered ethyl cyanate. This ether is not altered by contact with air; acids gradually separate from it the theoretical quantity of cyanuric acid. With potash or ammonia it yields alcohol and potassium or ammonium cyanurate.

Amyl cyanate, $\begin{matrix} CN \\ C^5H^{11} \end{matrix} O$, is obtained like the preceding compound, but is difficult to purify. Its reactions are similar to those of the methylic and ethylic ethers.

CYANIDE OF HYDROGEN. CNH. *Hydric Cyanide. Hydrocyanic Acid. Prussic Acid. Formonitrile.*—Produced: 1. By direct union of nitrogen with acetylene under the influence of the electric spark: $C^2H^2 + N^2 = 2CNH$ (Berthelot). See ACETYLENE (p. 35).

2. By oxidation of methylamine. When a strong solution of methylamine is set on fire, the hydrogen chiefly burns, and hydrocyanic acid is found in the residual liquid: $NH^2CH^3 + O^2 = 2H^2O + CNH$ (Tollens, *Zeitschr. f. Chem.* [2] ii. 516).

3. By the action of chloroform on ammonia:

The reaction is greatly facilitated by adding to the mixture a small quantity of alcoholic potash (Hofmann).

Preparation.—1. The decomposition of mercuric cyanide by hydrochloric acid does not yield more than two-thirds of the theoretical quantity of hydrocyanic acid. This loss is due to the combination of the hydrocyanic acid with the mercuric chloride formed in the reaction, the compound thus produced requiring a rather high temperature to decompose it. This inconvenience may however be obviated by addition of sal-ammoniac, which unites with the mercuric chloride and prevents it from laying hold of the hydrocyanic acid. The process thus modified yields about 95 p. c. of the calculated quantity of hydrocyanic acid (Bussy a. Buignet, *Ann. Ch. Phys.* [4] iii. 233).—2. Hydrocyanic acid may be prepared by distilling a mixture of equal parts of crystallised stannous chloride and mercuric cyanide, the acid passing over, while mercury and stannic oxychloride remain behind (Kletziusky, *Zeitschr. f. Chem.* [2] ii. 127).

Combination with Water.—Anhydrous prussic acid mixes with water in all proportions; in equal weights, or 3 mol. water to 2 mol. hydrogen cyanide, it forms a true chemical compound. The mixture of the anhydrous acid with water is attended with a lowering of temperature and with a contraction of volume, which attains its maximum, amounting to $\frac{1}{100}$ of the total volume of the mixed liquids, with the proportions just stated (Bussy a. Buignet, *Ann. Ch. Pharm.* [4] iii. 231; *Bull. Soc. Chim.* [2] i. 412).

Reactions.—1. According to Bussy a. Buignet (*J. Pharm.* [3] xlv. 465), the decomposition of the acid which is set up on exposure to light (ii. 218) continues after it is

laced in the dark. The acid prepared with yellow prussiate and sulphuric acid is more stable than that obtained with mercuric cyanide and hydrochloric acid.—2. A mixture of hydrocyanic acid vapour and hydrogen subjected to the action of the electric spark yields acetylene and nitrogen, the reaction being the inverse of that which takes place in the synthesis of hydrocyanic acid above mentioned; neither of these opposite reactions ever takes place completely (Berthelot, *Compt. rend.* lxxvii. 1141).—3. Hydrocyanic acid mixed with hydrochloric acid and alcohol, and treated with granulated zinc, is converted into methylamine: $\text{CNH} + 2\text{H}^2 + \text{CH}_3\text{N}$ (Mondius, *Ann. Ch. Pharm.* cxxxi. 129).—4. When dry mercuric cyanide is heated to dull redness in a stream of gaseous hydriodic acid, the hydrocyanic acid at first evolved is resolved, by the further action of the hydriodic acid, into ammonia and marsh gas: $\text{CNH} + 3\text{H}^2 = \text{NH}^3 + \text{CH}^4$ (Berthelot, *Jahresh.* 1867, p. 348).—5. Hydrocyanic acid mixed with hydrogen dioxide in aqueous solution gradually yields a crystalline precipitate of oxamide: $2\text{CNH} + \text{H}^2\text{O}^2 = \text{C}^2\text{H}^2\text{N}^2\text{O}^2$. Oxamide is likewise formed on heating a mixture of potassium cyanide and manganese dioxide with a small quantity of sulphuric acid (Attfeld, *Chem. Soc. J.* [2] i. 94).—6. When anhydrous prussic acid is carefully poured, so as not to mix, on phosphorus trichloride, and the liquid is left in an atmosphere of aqueous vapour, it is converted in a short time into a mixture of phosphorous acid, sal-ammoniac, and formic acid (Wehrhane u. Hübner, *Jahresh.* 1864, p. 300).

7. When hydrocyanic acid is heated with acetic acid to 200° in a sealed tube, they partly unite, producing formacetamide: $\text{CHN} + \text{C}^2\text{H}^3\text{O}^2\text{OH} = \text{N}(\text{CHO})(\text{C}^2\text{H}^3\text{O})\text{H}$; this however is immediately decomposed into acetamide and carbon monoxide, the latter escaping when the tube is opened: $\text{N}(\text{CHO})(\text{C}^2\text{H}^3\text{O})\text{H} = \text{CO} + \text{N}(\text{C}^2\text{H}^3\text{O})\text{H}^2$. Free hydrocyanic acid is also produced by the decomposition of another portion of the formacetamide: $\text{N}(\text{CHO})(\text{C}^2\text{H}^3\text{O})\text{H} = \text{CHN} + \text{C}^2\text{H}^3\text{O}^2$ (Gautier, *Ann. Ch. Pharm.* cl. 188).

Detection.—A hot solution of potassium cyanide mixed with picric acid assumes a deep blood-red colour due to the formation of picrocyanic acid (iii. 433). Free hydrocyanic acid does not produce this reaction; it must therefore be previously saturated with an alkali. The reaction is said to be more delicate than that with iron salts (C. D. Braun, *Zeitschr. f. anal. Chem.* iii. 464). The deep brown-red colour produced on agitating an alkaline solution of potassio-cobaltous cyanide with air (p. 476) may also be made available for the detection of hydrocyanic acid, the solution being first mixed with excess of alkali, and then with cobalt chloride and tartaric acid (Braun, *loc. cit.*).

COMPOUNDS OF HYDROGEN CYANIDE OR FORMONITRILE WITH HYDRACIDS. *Hydrochloride*, $\text{CHN} \cdot \text{HCl}$. *Methenylammonium chloride*, $(\text{CH})^{\text{H}} \left\{ \text{N} \cdot \text{Cl} \right\}$ (Gautier, *Compt. rend.* lxx. 410, 472).—When anhydrous hydrocyanic acid is saturated with dry hydrochloric acid gas at -10° , then heated in a well-closed flask, and left to cool, the liquid after a certain time becomes very hot, and the hydrochloride $\text{CHN} \cdot \text{HCl}$ separates in crystals. By repeating this treatment several times, the greater part of the hydrocyanic acid may be converted into this compound. To purify the product, it is first heated in the open flask to 40° – 50° , then quickly pulverised in a dry atmosphere, and exposed for a few minutes to the same temperature.

It is white, crystalline, inodorous; has a saline and acid taste; dissolves in water, absolute alcohol, and glacial acetic acid, but decomposes quickly in each of these solvents; quite insoluble in ether. It is very hygroscopic and quickly decomposes in contact with the air. Even in a dry vacuum it gradually decomposes and volatilises. When dissolved in water, it is quickly resolved into formic acid and sal-ammoniac. In absolute alcohol at 30° it is converted into hydrochloride of methenyl-diamine, $\text{N}^2(\text{CH})^{\text{H}^2} \cdot \text{HCl}$ (*q.v.*):

Glacial acetic acid dissolves methenylammonium chloride, eliminating hydrochloric acid, but the acetate which is probably formed cannot be separated from the excess of acetic acid, since it decomposes at 150° – 200° in the manner represented by the following equation:

Chlorine and *bromine* act upon methenylammonium chloride with aid of heat, eliminating hydrochloric or hydrobromic acid, and forming compounds analogous to the propionitrile compounds described by Engler (p. 524). *Dry ammonia* converts it into chloride and cyanide of ammonium. With *potash*, it forms *potassium chloride*, *potassium formate*, and *ammonia*. The alcoholic solution of formonitrile hydrochloride forms with platinic chloride a crystalline precipitate, which however contains sal-ammoniac.

Hydrobromide. $\text{CHN} \cdot \text{HBr}$ (Gal, *Bull. Soc. Chim.* [2] iv. 431).—Prepared by passing pure dry hydrobromic acid gas into well-cooled anhydrous hydrocyanic acid. The liquid then becomes opaline, and after a while deposits a very light solid mass, which, when freed from excess of acid by standing over caustic potash, forms very hygroscopic granules, nearly insoluble in ether and chloroform, and resolved by water into hydrobromic and hydrocyanic acids, which latter is quickly converted into ammonium formate. According to Gautier, the analysis of this compound leads, not to the formula given by Gal, but to $2\text{CHN} \cdot 3\text{HBr}$.

Hydriodide. $\text{CHN} \cdot \text{HI}$ (Gautier, *Bull. Soc. Chim.* [2] iv. 89).—Produced by passing gaseous hydriodic acid into cooled hydrogen cyanide, or by passing the mixed vapours of the two into a large flask. The white compound, after washing with ether, separates from alcohol in crystals apparently of rhombohedral form; it is inodorous, has a saline bitter taste, and sublimes at 300° – 400° without previous fusion. It is decomposed by water and potash into ammonia, hydriodic acid, and formic acid.

CYANIDES, ALCOHOLIC. Of these compounds there are two classes, both (when containing monatomic alcohol-radicles) being represented by the general formula CNR . In the one class, consisting of the bodies long known as hydrocyanic ethers or nitriles, the alcohol-radicle is in direct union with the carbon; in the other, discovered independently by Hofmann and by Gautier in 1867, and designated as isocyanides, carbylamines, or carbamides, it is combined directly with the nitrogen. The former are analogous in structure to the alcoholic cyanates, the latter to the isocyanates (p. 519); thus:

The monatomic carbamides are likewise analogous to the carbotriamines, such as guanidine, $\text{N}^3 \begin{Bmatrix} \text{C}^{\text{iv}} \\ \text{H}^{\text{i}} \end{Bmatrix}$, methyl-carbotriamine or methyluramine, $\text{N}^3 \begin{Bmatrix} \text{CH}^{\text{iv}} \\ \text{H}^{\text{i}} \end{Bmatrix}$, diphenyl carbotriamine or melaniline, $\text{N}^3 \begin{Bmatrix} \text{C}^{\text{iv}} \\ (\text{C}^{\text{vi}}\text{H}^{\text{v}})^{\text{i}} \end{Bmatrix}$, &c.

The most characteristic distinction between the nitriles and the carbamides is afforded by their reaction with hydrating agents (acids and alkalis). The nitriles heated with alkalis are resolved into ammonia and an acid containing the same number of carbon-atoms: e.g.,

The carbamides, on the other hand, are attacked with difficulty by alkalis, but are quickly decomposed by aqueous acids, yielding formic acid and the amine corresponding to the alcohol-radicle: e.g.,

* The carbamides are sometimes represented by formulae containing bivalent carbon, viz. $\text{N}^{\text{iii}} \begin{Bmatrix} \text{O}^{\text{v}} \\ \text{R}^{\text{i}} \end{Bmatrix}$; but their relation to the carbimides is more plainly exhibited by the formulae above given, the four units of equivalence of the carbon-atom being attached in the one case to the nitrogen alone, and in the other, half to the nitrogen and half to the oxygen.

The carbamides are further distinguished from the nitriles by their lower boiling points, their pungent odour and poisonous character, and by the much greater readiness with which they unite with gaseous hydrochloric acid and other anhydrous haloid acids.

1. Nitriles.

These compounds are formed : 1. By dehydration of the ammonium salts of organic acids containing the corresponding alcohol-radicles: *e.g.*,

2. By heating potassium cyanide with an alcoholic iodide or neutral metallic sulphate, or with the potassium salt of methyl-sulphuric, ethyl-sulphuric, and phenyl-sulphuric acids, &c. (ii. 202).

The following reactions are exhibited by the nitriles and not by the carbamides :

a. When heated with *zinc and dilute acids*, they take up 4 at. hydrogen and are converted into primary amines (Mendius, iv.) :

β. They unite directly with 2 at. *bromine*, acetonitrile, for example, forming the compound $\text{C}^2\text{H}^2\text{NBr}^2$ or $\text{C}^2\text{H}^2\text{BrN}$.HBr (Engler).

γ. They unite with 1 mol. *hydrogen sulphide*, forming sulphuretted amides: *e.g.*,

δ. They unite directly with many *chlorides* of the more electronegative radicles, propionitrile, for example, forming the compounds $\text{C}^2\text{H}^2\text{N}.\text{BCl}^3$; $\text{C}^2\text{H}^2\text{N}.\text{COCl}^3$; $\text{C}^2\text{H}^2\text{N}.\text{CNCl}$; $\text{C}^2\text{H}^2\text{N}.\text{SbCl}^3$; $\text{C}^2\text{H}^2\text{N}.\text{AuCl}^3$; $(\text{C}^2\text{H}^2\text{N})^2.\text{PtCl}^4$; $(\text{C}^2\text{H}^2\text{N})^2.\text{SiCl}^4$; and $(\text{C}^2\text{H}^2\text{N})^2.\text{TiCl}^4$.

ε. With fuming sulphuric acid they form sulpho-acids and disulpho-acids: *e.g.* acetonitrile yields sulphacetic and disulphometholic acids; thus :

and

Methyl Cyanide or Acetonitrile. $\text{C}^2\text{H}^2\text{N} = \text{N} \equiv \text{C} - \text{CH}^3$.—This compound is fully described (as cyanide of methyl) in vol. ii. p. 257. When quite pure it boils, according to Engler at 76.5° to 77.5° (corr. 77.6°); according to Gautier (*Bull. Soc. Chim.* [2] ix. 2) at $81^\circ - 82^\circ$. When 6 pts. acetonitrile are heated to 100° in a sealed tube with 1 pt. bromine till the vapours of bromine disappear, and the product is then distilled, acetonitrile bromide, $\text{C}^2\text{H}^2\text{NBr}^2$, passes over (together with excess of acetonitrile) in crystalline crusts, which may be purified by careful sublimation. It forms regular prismatic crystals, probably belonging to the rhombic system. It melts with previous sublimation at 65° , dissolves easily but with decomposition in alcohol, ether, and water, and in contact with moist air gives off hydrobromic acid, and is converted into a mixture of ammonium bromide, ammonium acetate, acetamide, and crystalline di-monobromacetamide, $\text{N}(\text{C}^2\text{H}^2\text{BrO})^2\text{H}$. This last compound is gradually deposited from an alcoholic solution of the bromide mixed with water, in thin needle-shaped crystals. Silver nitrate added to an alcoholic solution of acetonitrile-bromide throws down only half the bromine: hence the compound must be regarded as *brom-acetonitrile hydrobromide*, $\text{C}^2\text{H}^2\text{BrN}.\text{HBr}$. A *dihydrobromide*, $\text{C}^2\text{H}^2\text{N}.2\text{HBr}$, is formed by passing dry hydrobromic acid gas through acetonitrile, heating the resulting crystalline mass, and again passing the gas through it. The compound then sublimes and collects in the cooled dry receiver as a yellowish-white crystalline mass. It melts at $47^\circ - 50^\circ$, begins to sublime at the same temperatures, and is decomposed by water

or by exposure to the air, with formation of acetic acid, hydrobromic acid, and ammonia:

(Engler, *Ann. Ch. Pharm.* cxxix. 24; lxxxiii. 137; cxlii. 65; cxlix. 306; *Jahresb.* 1864, p. 324; 1865, p. 310; 1867, p. 358).

Acetonitrile heated with sodium yields, together with sodium cyanide, a base, $\text{C}^2\text{H}^3\text{N}^+$, homologous with cyanethine (A. G. Baeyer, *Zeitschr. f. Chem.* [2] iv. 515).

Acetonitrile heated to 200° in a sealed tube with 1 mol. *glacial acetic acid* is partly converted into diacetamide, which passes over on subsequent distillation between 210° and 215° and solidifies in crystals: $\text{C}^2\text{H}^3\text{N} + \text{C}^2\text{H}^3\text{O} \cdot \text{OH} = \text{N}''(\text{C}^2\text{H}^3\text{O})^2\text{H}$ or

Ethyl Cyanide or Propionitrile. $\text{C}^3\text{H}^4\text{N} = \text{C} \left\{ \begin{array}{l} \text{N} \\ \text{C}^2\text{H}^3 \end{array} \right.$ (ii. 211).—The great differ-

ences of boiling point and other physical properties assigned to this compound by different chemists are doubtless attributable to the difficulty of obtaining it pure; indeed, most of the methods of preparing it appear to yield a mixture of the true nitrile with the isomeric compound, ethyl isocyanide or ethyl-carbamine, to which is due the intolerable odour of the ordinary preparation. Gautier appears to have obtained the purest propionitrile by treating the crude product of the distillation of barium ethylsulphate and potassium cyanide with an acid (which decomposes the ethyl-carbamine), then agitating it with mercuric oxide, distilling, and treating the distillate with a large quantity of calcium chloride, which removes a compound of the nitrile with alcohol, leaving the nitrile itself to be further purified by rectification. Propionitrile thus prepared has an alliaceous odour and boils at 88.5° .

Action of Bromine and Hydrobromic Acid (Engler, *loc. cit.*).—When hydrobromic acid gas is passed in excess into propionitrile, a yellow crystalline mass is formed consisting of the hydrobromide $\text{C}^3\text{H}^4\text{N} \cdot 2\text{HBr}$. It melts at 50° – 55° , sublimes at a slightly higher temperature, and decomposes slowly in contact with dry, quickly in contact with moist air, yielding propionic acid. Its decomposition with water is represented by the equation:

According to Gautier, anhydrous *hydriodic acid* also unites directly with propionitrile.

Bromopropionitrile Hydrobromide, $\text{C}^3\text{H}^4\text{BrN} \cdot \text{HBr}$, is prepared, like the corresponding compound of acetonitrile, by heating 10 pts. propionitrile with 1 pt. bromine to 100° in a sealed tube. The crystalline product purified by sublimation melts at 64° , and begins to sublime at 72° , with partial decomposition, in stellate groups of crystalline crusts. It is decomposed by water, like bromacetonitrile hydrobromide, yielding *dimonobromopropionamide*, $\text{N}(\text{C}^3\text{H}^4\text{BrO})^2\text{H}$.

Action of Hydrochloric Acid and Chlorine.—Dry hydrochloric acid gas is dissolved by propionitrile, but without at first appearing to enter into definite combination, even when the solution is heated to 100° in sealed tubes; if, however, it be left to itself in a sealed vessel for a month, crystals of a hydrochloride, $\text{C}^3\text{H}^4\text{N} \cdot \text{HCl}$, are formed, apparently belonging to the monoclinic system. This compound dissolves very sparingly in ether, but freely in alcohol, chloroform, and water. Its aqueous solution is comparatively little altered by boiling; but when left to itself it is gradually converted into *sal-ammoniac* and propionic acid: $\text{C}^3\text{H}^4\text{N} \cdot \text{HCl} + 2\text{H}^2\text{O} = \text{NH}^4\text{Cl} + \text{C}^3\text{H}^5\text{O}^2$. The hydrochloride softens at 95° , melts at 121° , and quickly becomes uncrystallisable. When strongly heated in the air, it burns, leaving scarcely a trace of carbon (Gautier, *Compt. rend.* lxxiii. 921).

Respecting the action of chlorine on propionitrile, see vol. iv. p. 736.

Action of Acetic Acid (Gautier, *Ann. Ch. Pharm.* cl. 189).—Propionitrile heated with excess of acetic acid in a sealed tube for fifteen to twenty hours is in great part converted into propionic acid and triacetodiamide:

The portion of the resulting liquid which passes over on distillation between 212° and 217° becomes filled in the course of twenty-four hours with long silky needles of triacetodiamide. This compound is soluble in water, alcohol, and ether, is converted into ammonium acetate by heating with water to 200° , and resolved by potash into ammonia and acetic acid.

Together with the triacetodiamide there is also formed another amide, which crystallises very slowly from the mother-liquor of the triacetodiamide, and may be obtained almost without the latter by heating a mixture of propionitrile and acetic acid in molecular proportions to 200° for only a few hours. The liquid boils at 220°, and yields crystals of propiodiacetodiamide, $C^3H^4N^2O^2 = N^2(C^3H^4O)(C^3H^3O)^2H^2$:

The compound treated with caustic soda gives off ammonia and yields acetate and propionate of sodium.

Propyl Cyanide or Butyronitrile. $C^4H^5N = C \begin{Bmatrix} N \\ CH^2CH^2CH^2 \end{Bmatrix}$ (i. 698).—This compound is strongly attacked by potassium, forming potassium cyanide, and giving off a mixture of hydrogen and a gaseous hydrocarbon, which appears to be denser than that evolved in like manner from acetonitrile. Butyronitrile treated with phosphorus pentachloride forms a compound containing $(C^4H^5) - N \equiv P^+Cl^-$. It is a colourless transparent liquid, decomposed by water, with formation of hydrochloric acid, phosphorous acid, and butyronitrile (Henke, *Ann. Ch. Pharm.* cvi. 272).

Isobutyronitrile, $C^4H^5N = C \begin{Bmatrix} N \\ CH(CH^3)^2 \end{Bmatrix}$ is produced by heating isopropyl iodide in a sealed tube with potassium cyanide and alcohol. It boils at 80°, and when heated with potash yields potassium isobutyrate and ammonia (Morkownikoff, *Bull. Soc. Chim.* 1866, p. 53).

Butyl Cyanide or Valeronitrile. $C^5H^7N = C \begin{Bmatrix} N \\ C^4H^7 \end{Bmatrix}$ (ii. 272).

Amyl Cyanide or Capronitrile, $C^6H^9N = C \begin{Bmatrix} N \\ C^5H^9 \end{Bmatrix}$, is best prepared, according to Wurtz (*Ann. Ch. Phys.* [3] li. 358), by heating the oxalate, chloride, or iodide of amyl with pure potassium cyanide (obtained by calcining the ferrocyanide). The valeronitrile thus obtained was optically dextrogyrate, rotating the red ray 3.17° in a tube 200 millim. long. Most probably, however, this property is not constant; the nitrile prepared from inactive amyl alcohol would doubtless be itself inactive.

Heptyl Cyanide or Caprylonitrile, $C^8H^{11}N = C \begin{Bmatrix} N \\ C^7H^{11} \end{Bmatrix}$, obtained by heating ammonium caprylate, $C^8H^{15}O^2.NH^4$, with phosphoric anhydride, is a clear colourless liquid, having a highly aromatic odour, like that of cinnamon oil, and a sweetish, aromatic, slightly burning taste. Sp. gr. 0.8201 at 13.3°. Boiling point 194°–196°. It is easily inflammable, burns with a bright smoky flame; mixes with alcohol and ether; yields ammonia and potassium caprylate when boiled with alcoholic potash (E. Follotár, *Zeitschr. f. Chem.* [2] iv. 666).

Octyl Cyanide or Pelargonitrile, $C^9H^{13}N = C \begin{Bmatrix} N \\ C^8H^{13} \end{Bmatrix}$, is produced by boiling octyl iodide (from castor-oil alcohol) with potassium cyanide and alcohol, and separates on the surface as an oily layer on addition of water. When purified it forms a colourless liquid, having a peculiar aromatic odour, a sp. gr. of 0.8187 at 14°, boiling at 206°, decomposing and turning brown when distilled; miscible with alcohol and ether (Follotár).

Cetyl Cyanide or Margaritrile. $C^{18}H^{35}N = C \begin{Bmatrix} N \\ C^{17}H^{35} \end{Bmatrix}$ (i. 843).

Allyl Cyanide or Crotonitrile, $C^3H^3N = C \begin{Bmatrix} N \\ C^3H^3 \end{Bmatrix}$, is obtained: 1. By heating allyl iodide with an alcoholic solution of potassium cyanide (Claus, *Ann. Ch. Pharm.* cxxxi. 58).—2. By decomposition of myronic acid, viz. by precipitating an aqueous solution of potassium myronate with silver nitrate, and treating the precipitate (iii. 1075) suspended in water with hydrogen sulphide. The product, after repeated distillation with water, yields an oily layer of crotonitrile:

Crotonitrile is a neutral colourless oil, having an agreeable alliaceous odour, and a burning aromatic taste. Sp. gr. 0.8389 at 12.8°. Vapour-density 2.32 (calc. 2.31). Boils at 118° (corr. 118.3°). By boiling with alcoholic potash, it is resolved into ammonia and crotonic acid:

(Will a. Körner, *Ann. Ch. Pharm.* cxxv. 267).

Phenyl Cyanide or Benzonitrile. $C^H^N = C^H^N.CN$ or $O \begin{Bmatrix} N \\ C^H^N \end{Bmatrix}$ (i. 563).

—Hofmann (*Compt. rend.* liv. 388) obtains this compound by distilling a mixture of aniline and oxalic acid.* The carbon monoxide resulting from the decomposition of the oxalic acid unites with an atom of hydrogen in the aniline, producing formanilide, $C^H^N.H \begin{Bmatrix} CHO \\ N \end{Bmatrix}$, which, by elimination of H^2O , is converted into benzonitrile. This compound is also produced by the action of cyanogen bromide on potassium benzoate (Cahours, *Ann. Ch. Phys.* [3] lii. 200):

When the vapour of *sulphuric anhydride* is slowly passed into cooled benzonitrile, the latter is converted into amidosulphobenzoic acid (Engelhardt, *Ann. Ch. Pharm.* cxviii. 343). Benzonitrile treated in alcoholic solution with *zinc* and *hydrochloric acid* takes up 4 at. hydrogen and is converted into benzylamine, $C^H^N.CH^2NH^2$ (Mondius, *ibid.* cxxi. 129).

Benzonitrile heated to 140° – 150° with *bromine* in a sealed tube, solidifies and yields a sublimate which appears to consist of $C^H^N.NBr^2$; and the solidified mixture, after being freed from a viscid substance by treatment with cold ether, yields a crystalline compound containing $C^H^N.NBr$, or rather perhaps $C^H^N.N^2Br^2$. This compound heated with lime gives off ammonia, carbon dioxide, and benzonitrile, and yields a white sublimate having the composition and properties of cyaphenine, $C^H^N.N^2$ (Engler, *Ann. Ch. Pharm.* cxxxiii. 137).

A solid compound of benzonitrile with hydrobromic acid, $C^H^N.2HBr$, is produced by passing the vapour of hydrobromic acid into benzonitrile. It melts at 70° , and is resolved by water into benzamide and hydrobromic acid:

A certain quantity of benzoic acid is formed at the same time, according to the equation:

(Engler, *Ann. Ch. Pharm.* cxlix. 307).

A *hydrochloride* of benzonitrile (*chlorure de benzamidyle*) is formed by the action of phosphorus pentachloride on benzamide:

It is resolved by heat into hydrochloric acid and benzonitrile (Gerhardt, *Traité*, iv. 762).

With *sodium*, benzonitrile yields sodium cyanide and cyaphenine, together with another compound (Hofmann, *Zeitschr. f. Chem.* [2] iv. 726).

Nitrobenzonitrile, $C^H^N(NO^2)N$, obtained by the action of fuming nitric acid on benzonitrile, is moderately soluble in water, crystallises therefrom in needles, is decomposed by heat, and when boiled with acids or alkalis, yields ammonia and ortho-nitrobenzoic acid (i. 564). Nitrobenzonitrile is also produced by dehydration of nitrobenzamide with phosphoric anhydride or phosphorus pentachloride; it melts at 115° (Engler, *Zeitschr. f. Chem.* [2] iv. 613; *Ann. Ch. Pharm.* cxlix. 297).

Paranitrobenzonitrile is obtained by the action of phosphoric anhydride on paranitrobenzamide (p. 258), as a thick oily liquid having a high boiling point, and solidifying very quickly. It is nearly insoluble in water, dissolves easily in alcohol and ether, slowly in hydrochloric acid, with which it forms a crystalline compound. From alcohol it crystallises in white nacreous scales, which melt at 139° , and then distil without decomposition. Heated with hydrochloric acid to 130° , it yields *paranitrobenzoic acid* (Engler, *loc. cit.*).

Amidobenzonitrile. $C^H^N.N^2 = C^H^N(NH^2)N$.—This base, isomeric with cyanilide (iv. 440), and with the hitherto unisolated diazotoluene (v. 867), is produced: 1. By treating nitrobenzonitrile in alcoholic solution with zinc and hydrochloric acid till the liquid on dilution exhibits a slight turbidity (if the action be longer continued, the base is partly resolved into ammonia and benzonitrile, which latter takes up more hydrogen and is converted into benzylamine). The liquid on cooling deposits a crystalline compound not yet examined, and from the remaining solution the amidobenzonitrile may be separated by ammonia (Hofmann, *Zeitschr. f. Chem.* [2] iv. 726). —2. By heating the compound $C^H^N.N^2S$ (*in vacuo*) to a few degrees above 100° , whereupon it gives off H^2S and leaves amidobenzonitrile; this process does not, however, yield a pure product (Hofmann). —3. Amidobenzoic cyanide, $C^H^N.NO^2.2CN$, subjected

to dry distillation, yields amidobenzonitrile (together with gases, water, ammonium carbonate, and ammonium cyanide), as an oil, which may be purified by solution in hydrochloric acid, treatment with animal charcoal, precipitation with ammonia, and crystallisation (Griess, *Zeitschr. f. Chem.* [2] iv. 725).

Amidobenzonitrile crystallises in colourless needles or prisms, melting at 53° (Griess), at 52°, and boiling at 288°–290° (Hofmann). It dissolves easily in alcohol, ether, and boiling water, but is nearly insoluble in cold water (Griess). The *sulphate* and *nitrate* crystallise well, the latter in four-sided tables; the *picrate* is very sparingly soluble (Hofmann). The *hydrochloride* $C_6H_5N^2.HCl$ forms rhombic tables easily soluble in alcohol and in cold water; the *platinochloride* $2(C_6H_5N^2.HCl).PtCl_4$, yellow, four-sided tables, easily soluble in water. The *argentonitrate*, $C_6H_5N^2.AgNO_3$, obtained by adding silver nitrate to the aqueous or alcoholic solution of the base, forms white laminae. With *bromine-water* the aqueous solution of the base gives a brominated compound crystallising in needles (Griess).

Amidobenzonitrile boiled with strong *hydrochloric acid* yields sal-ammoniac and amidobenzoic hydrochloride, $C_6H_5NO_2.HCl$. With *chloroform* and *alkalis* it yields the intolerably smelling formonitrile, $C_6H_5N^2$, which is resolved by acids into formic acid, amidobenzoic acid, and ammonia, whereas the isomeric formonitrile of phenylenediamine is resolved by similar treatment into formic acid and phenylenediamine (Hofmann).

When nitrobenzonitrile is treated with *ammonium sulphide*, a sulphuretted base, $C_6H_5N^2S_2$, containing the elements of amidobenzonitrile and hydrogen sulphide, is produced, which crystallises from boiling water in white shining needles, easily soluble in alcohol and ether, and forming a crystalline hydrochloride and platinochloride. At a few degrees above 100° it is resolved, though not completely, into H_2S and $C_6H_5N^2$. This base has the constitution of thiobenzylene-diamide, $N^2(C_6H_5)S_2H_2$, and is isomeric with sulphocarbonyl-phenyl-diamide, $N^2(CS)(C_6H_5)H_2$, produced by the action of ammonia on phenyl sulphocyanate (Hofmann, *Proc. Roy. Soc.* x. 599).

Paramidobenzonitrile is obtained by the action of tin and hydrochloric acid, or better of zinc and hydrochloric acid, on paranitrobenzonitrile, and separates, on saturating the product with soda and evaporating, as an oil which solidifies on cooling, and may be purified by recrystallisation from aqueous alcohol. It dissolves easily in alcohol and ether, sparingly in water, and crystallises from a mixture of 1 pt. alcohol and 1 pt. water, by slow cooling, in colourless needles melting at 74°. It dissolves easily in acids, forming for the most part crystallisable salts. The *hydrochloride* $C_6H_5N^2.HCl$ forms thin laminar colourless crystals, easily soluble in water, melting when heated, and decomposing at a higher temperature. The *platinochloride* $2(C_6H_5N^2.HCl).PtCl_4$ forms small crystalline needles. By prolonged heating with zinc and hydrochloric acid, it is decomposed, yielding sal-ammoniac and benzylamine (Engler, *Zeitschr. f. Chem.* [2] iv. 615; *Ann. Ch. Pharm.* cxlix. 302).

Paranitrobenzonitrile treated with *ammonium sulphide* yields a base, $C_6H_5N^2S_2$, isomeric with that obtained by Hofmann from nitrobenzonitrile. It crystallises from alcohol in yellowish white stellate masses; melts at 170°; dissolves in hydrochloric acid, and may be separated therefrom by fixed alkalis (Engler).

Paranitrobenzonitrile is slowly reduced by sodium-amalgam, yielding a weak base, probably consisting of the azo-compound $N(C_6H_5)N$ (Engler).

Naphthyl Cyanide. $C_{10}H_7N = C \begin{smallmatrix} N \\ | \\ C_6H_7 \end{smallmatrix}$ (Hofmann, *Compt. rend.* lxiv. 387; lxvi. 473; lxvii. 547).—Produced: 1. By distilling naphthylamine with oxalic acid. The reaction takes place by two stages: the oxalic acid first splits up into water, carbon dioxide, and carbon monoxide, which latter fixes itself upon the naphthylamine, converting it into naphthyl-formamide; and the naphthyl-formamide is then resolved by the heat into water and naphthyl cyanide (Hofmann).

and

The distillate thus obtained is a mixture of naphthyl cyanide, naphthyl-formamide, naphthylloxamide, naphthylamine oxalate, naphthalene, and water. It is treated with

a current of steam, which carries along with it a considerable quantity of a brown opaque oil heavier than water. On separating this oil from the water by agitation with ether, evaporating the ether, and distilling the residue, naphthalene passes over at 218°-220°, and naphthyl cyanide at 290°-300°, as a light yellow liquid, which solidifies to a crystalline mass when left for some time in a cold room, more quickly in a freezing mixture, and when once solidified does not return to the liquid state at ordinary temperatures. It may be obtained perfectly pure by recrystallising it several times from alcohol, in which it is very soluble, and finally precipitating it from the alcoholic solution by water. It then separates as an oil which solidifies in a few minutes (Hofmann).

2. By distilling a mixture of cyanide and naphthylsulphite of potassium (Merz, *Zull. Soc. Chim.* ix. 335; x. 47):

Naphthyl cyanide is heavier than water, melts at 35.5°, and boils at 296° (corr.). When boiled with *alcoholic soda* it gives off only traces of ammonia; but on adding water to the mixture, crystals are deposited consisting of menaphthoxylamide, $\text{C}^{\text{H}}\text{H}^{\text{C}}\text{NO} = \text{naphthyl cyanide} + 1 \text{ mol. water}$. The menaphthoxylamide, as soon as it is formed, is decomposed by the soda, with evolution of ammonia and formation of menaphthoxylic acid, $\text{C}^{\text{H}}\text{H}^{\text{C}}\cdot\text{CO}^{\text{H}}$, an acid related to naphthalene in the same manner as benzoic acid to benzene:

Naphthyl cyanide combines but slowly with nascent hydrogen; but when heated to 100° with alcoholic solution of ammonium sulphide it readily takes up H^{S} , and is converted into menaphthothiamide, $\text{C}^{\text{H}}\text{H}^{\text{C}}\text{NS}$ (Hofmann).

2. Alcoholic Isocyanides or Carbamines.

These ethers are produced: 1. By distilling a monamino with chloroform (Hofmann): *e.g.*,

2. By treating 1 mol. of an alcoholic iodide with 2 mol. silver cyanide, a double cyanide of silver and the alcohol-radicle is then formed; and on distilling this compound with a very strong aqueous solution of potassium cyanide, a double cyanide of silver and potassium is formed, and the isocyanide of the alcohol-radicle distils over: it may then be dried over calcium chloride and rectified. By this reaction Gautier has prepared the isocyanides of methyl, ethyl, isopropyl, and butyl. The ethyl-compound was obtained some years ago in an impure state by E. Meyer, by distilling potassium-silver cyanide with potash (ii. 212).

The isocyanides are also formed in small quantity in the preparation of the nitriles, and to them is due the intolerable odour of the crude distillates.

Methyl Isocyanide or Methyl-carbamine. $\text{CH}^{\text{H}}-\text{N}\equiv\text{C}$ or $\text{N}^{\text{H}}\text{H}^{\text{C}}$. (Gautier, *Compt. rend.* lxx. 468, 862; lxxi. 1214).—Prepared, as above described, by heating 2 mol. silver cyanide with 1 mol. methyl iodide to 130°-140° in a close vessel, and decomposing the resulting double cyanide with potash. When dried with calcium chloride and purified by rectification, it is a colourless mobile liquid having a specific gravity of 0.7567 at 14°, boiling at 58°-59°, not solidifying at -45°. It has a powerful odour, like that of phosphorus and of artichokes. Its vapours are acrid and very deleterious, almost immediately producing nausea, vertigo, headache, and

depression. Water dissolves about $\frac{1}{10}$ pt. of it at 15°. When heated with water in a sealed tube, it is resolved into formic acid and methylamine:

With dry acids (pure hydrogen-salts) it unites immediately, saturating them completely like ammonia, and forming crystallisable salts. The hydrochloride and hydrobromide are very easily obtained by directing the dry gaseous acids on the surface of the liquid kept very cool. The combinations with oxygen-acids are more difficult to obtain, on account of the violence of the reaction. All these salts are decomposed by water, with production of formic acid and methylamine. *Alcoholio-*
iodides combine with methyl isocyanide at ordinary temperatures, whereas acetonitrile does not unite with these bodies at any temperature between 0° and 200°.

Methyl-carbamide is very easily oxidised. When it is brought in contact with mercuric oxide in a cooled vessel, and the mixture is then gradually heated in a water-bath to 40°-50°, metallic mercury separates and methyl isocyanate or methyl-carbimide distils over:

A considerable portion of this body is, however, converted into a compound of methyl cyanurate and formamide, which may be obtained in crystals by heating the liquid remaining in the flask to 160° , and exhausting with boiling alcohol. The reaction is:

This compound melts and partially sublimes at 175°, but decomposes when heated above 250°. It dissolves in water, alcohol, and ether, and crystallises from water in beautiful laminae. Heated with potash to 200° it gives off a little ammonia. An ethereal solution of methyl-carbamine treated in the manner above described yields, in addition to the preceding products, a crystalline body which melts at 163°, boils at 168° under a pressure of 24 mm., and consists of $N^2 \left\{ \begin{matrix} (CO)^2 \\ (CH_2)^2 \end{matrix} \right\} \cdot N \left\{ \begin{matrix} (CHO)^2 \\ (CH_2)^2 \end{matrix} \right\} \cdot H$. Similar products are obtained by oxidising methyl-carbamine in ethereal solution with silver oxide; but they remain at first in combination with that oxide. On evaporating the ether, a white substance remains, which quickly yields metallic silver and further products of oxidation (Gautier, *Compt. rend.* lxxii. 804; *Zeitschr. f. Chem.* [2] iv. 675).

Methyl Isocyanide or Methyl-carbamine. $N\{C\}_{III}^{\text{I}}$ (Gautier, *loc. cit.*).—Prepared like the preceding. Does not solidify at -68° . Boils between 78° and 79° . Sp. gr. 0.7688 at $+4^{\circ}$. crystallisable salts. It unites with acids like methyl-carbamine, forming products, together with ethylamine. The hydrochloride boiled with water or an alkaline solution, it yields formic acid and ethylamine. The hydrochloride boiled with potash yields the same products, together with ethyl-formamide:

Ethyl-carbamine is violently oxidised by *silver oxide*, with formation of ethyl cyanate, and a crystalline body, $C^1H^3N^1O^1$, soluble in alcohol and boiling above 200° :

When ethyl-carbamine dissolved in 4 vol. ether is oxidised by *mercuric oxide*, the chief products are a crystallisable body, $C^6H^{12}N^4O^2$, melting at 112° , and liquid formamide:

The crystalline body may be regarded as a compound of ethyl-formamide with ethyl-carbodiimine:

Ethyl-carbamine and methyl-carbamine heated in sealed tubes to 190° remain for the most part unaltered; but on opening the tubes and distilling off the more volatile portion, an oily liquid remains, which explodes violently when more strongly heated. Gautier regards these liquids as polymerides of the carbamines.

Isopropyl Isocyanide or **Isopropyl-carbamine**, $C^3H^7N = N \left\{ \begin{smallmatrix} C \\ CH(C^2H^5) \end{smallmatrix} \right.$ (Gautier, *Compt. rend.* lxxvii. 723), is produced by acting upon silver cyanide with isopropyl iodide, and decomposing the double cyanide $NC(C^3H^7).NCAg$ by boiling with a concentrated aqueous solution of potassium cyanide. It is a liquid smelling like the carbamines previously described, soluble in alcohol and ether, very slightly soluble in water, having a sp. gr. of 0.7596 at 0°, boiling at 87°, not solidifying at -68°. It unites readily with dry haloid acids, forming crystallisable salts. Treated with aqueous hydrochloric acid, it is transformed, by two successive degrees of hydration, first into isopropyl-formamide, then into isopropylamine formate:

Butyl Isocyanide or **Butyl-carbamine**, $C^4H^9N = N \left\{ \begin{smallmatrix} C \\ C^4H^9 \end{smallmatrix} \right.$, prepared like the preceding, is a colourless liquid, having an offensive odour, nearly insoluble in water, boiling at 114°-117°, and having a sp. gr. of 0.7833 at 0°. When cooled to -66° it does not crystallise, but becomes pasty and opaque. Water and mineral acids act upon it less violently than on the preceding carbamines. Heated with aqueous acids it takes up 2 mol. water and is completely transformed into butylamine and formic acid (Gautier, *Bull. Soc. Chim.* [2] xi. 211; *Zeitschr. f. Chem.* [2] v. 445).

Amyl Isocyanide or **Amyl-carbamine**. $C^5H^{11}N = N \left\{ \begin{smallmatrix} C \\ C^5H^{11} \end{smallmatrix} \right.$ (Hofmann, *Ann. Ch. Pharm.* cxliv. 114; *Jahresh.* 1867, p. 363).—Prepared by distilling an alcoholic solution of amylamine with chloroform and potash:

Purified like the phenyl compound. It may also be obtained, like the preceding carbamines, by decomposing silver cyanide with amyl iodide, &c. It is a colourless liquid having a pungent odour of amyl alcohol and prussic acid together, boils at 137° (acetonitrile at 146°). Its vapour produces an intensely bitter taste upon the tongue and a suffocating sensation in the throat. It is violently attacked by hydrochloric acid, the reaction taking place by several stages, and finally resulting, after the liquid has been heated to the boiling point, in the production of amylamine and formic acid.

Phenyl Isocyanide or **Phenyl-carbamine**. $C^6H^5N = N \left\{ \begin{smallmatrix} C \\ C^6H^5 \end{smallmatrix} \right.$ (Hofmann, *loc. cit.*).—This compound, isomeric with benzonitrile, is obtained by distilling a mixture of aniline, chloroform, and alcoholic potash; rectifying the pungent-smelling distillate; treating the portion which goes over after the water and alcohol, with oxalic acid to precipitate the aniline contained in it; dehydrating the residual brown oil with potassium hydrate, and rectifying it.

Pure phenyl-carbamine thus obtained is a mobile liquid, blue by reflected, green by transmitted light, and retaining these colours even after rectification in a current of steam. Its odour is pungently aromatic, and at the same time like that of prussic acid. Its vapour acts on the throat and tongue like that of the amyl-compound, but less strongly. It boils at 160° (benzonitrile at 191°), but with partial decomposition, the temperature quickly rising to 230°, and a brown inodorous oil distilling over, which solidifies in the crystalline form on cooling. It unites very easily with metallic cyanides (benzonitrile unites with them but slowly), forming, with silver cyanide in particular, a beautifully crystallised compound. It is scarcely attacked by alkalis, but is easily decomposed even by dilute acids, and with great evolution of heat by concentrated acids, yielding, as ultimate products, formic acid and aniline, with methenyl-diphenyldiamine and phenyl-formamide as intermediate products; thus:

CYANIDES, METALLIC. It cannot at present be decided whether these salts are analogous in constitution to the nitriles $\text{N} \equiv \text{C}-\text{R}$, or to the carbamines $\text{C} \equiv \text{N}-\text{R}$; their conversion by the action of water into ammonia and a salt of formic acid may be explained with equal facility on either view. Silver cyanide heated with ethyl iodide yields ethyl carbamine, $\text{N} \begin{Bmatrix} \text{C}^{\text{H}} \\ \text{C}^2\text{H}_5 \end{Bmatrix}$; and potassium cyanide

similarly treated yields chiefly propionitrile, $\text{C} \begin{Bmatrix} \text{N} \\ \text{C}^2\text{H}_5 \end{Bmatrix}$: whence it might be inferred that some metallic cyanides are analogous to the nitriles, others to the carbamines. It is possible also that the same metallic cyanide may exist sometimes in one modification, sometimes in the other; indeed, the propionitrile obtained from potassium cyanide is always more or less mixed with ethyl-carbamine (p. 524). Similar remarks apply to hydrogen cyanide, which is usually regarded as formonitrile, $(\text{GH})^{\text{C}}\text{N}$, but may perhaps be also capable of assuming the form of carbamine, NCH .

AMMONIUM CYANIDE, NH_4CN , is formed in the combustion of coal-gas which has passed through aqueous ammonia. If the gas be burnt in a long tube and the condensed products passed into water, a solution of ammonium cyanide is obtained; if the flame be made to pass over potash-solution or milk of lime, the liquid, after a few minutes, is found to contain considerable quantities of cyanide; and on shaking up the potash-solution with finely divided iron, potassium ferrocyanide is obtained (De Rumilly, *Compt. rend.* lxx. 865). When dry ammonia gas is passed over pure wood-charcoal heated in a glass tube to the highest temperature of a gas-furnace, a small quantity of ammonium cyanide is formed, together with a mixture of nitrogen and hydrogen gas (Weltzien, *Ann. Ch. Pharm.* cxxxii. 224).

BARIUM CYANIDES.—Barium platinoeyanide, BaPtCy_4 , is produced by the mutual action of platinous or platinic chloride with barium carbonate and dilute hydrocyanic acid. With platinic chloride the reaction is:

Double cyanides of barium with other metals are formed in like manner by the mutual action of barium carbonate, hydrocyanic acid, and the nitrates, carbonates, cyanides, acetates, or, best of all, the soluble sulphates of the several metals (Weselsky, *J. pr. Chem.* ciii. 566).

CHROMIUM CYANIDES.—On the preparation and properties of the chromi-cyanides $6\text{M}^{\text{C}}\text{Cy}_4.\text{Cr}^2\text{Cy}_6$ and $3\text{M}^{\text{C}}\text{Cy}_2.\text{Cr}^2\text{Cy}_6$ (ii. 205), see Kaiser (*Ann. Ch. Pharm. Suppl.* iii. 163; *Jahresb.* 1864, p. 302) and Stridsberg (*ibid.* p. 304). A solution of potassium chromi-cyanide treated with sodium-amalgam is immediately coloured red, in consequence of reduction to *potassium chromocyanide*, $4\text{KCy}.\text{Cr}^{\text{C}}\text{Cy}_2$. The solution of this latter salt is decomposed by dilution and by heating. It gives a red-brown precipitate with zinc salts, green with chromic salts, red with cobalt salts, and green with manganous salts (Descamps).

COBALT CYANIDES (Descamps, *Compt. rend.* lxvii. 330).—Cobalt forms two series of double cyanides analogous to the ferro- and ferri-cyanides. *Potassium cobaltocyanide*, $\text{K}^{\text{C}}\text{Co}^{\text{C}}\text{Cy}_4$, is formed in the first instance on dissolving cobaltous cyanide in aqueous potassium cyanide; but under ordinary circumstances it is immediately converted into the cobaltic-cyanide. When a concentrated solution of potassium cyanide is poured into a vessel containing cobaltous cyanide, the latter being in excess, and all rise of temperature avoided, a greenish solution of cobaltous cyanide in potassium cyanide is formed, which when left to itself, becomes red on the surface from formation of potassium cobaltocyanide, and deposits a green powder consisting of *potassio-cobaltous cobaltocyanide*. If on the other hand a slight excess of potassium cyanide be added, a deep red solution of *potassium cobaltocyanide* is quickly produced; it is necessary however to keep the liquid cool; otherwise the cobaltocyanide is immediately converted into colourless cobaltic-cyanide, with evolution of hydrogen. By quickly evaporating the solution in a vacuum, a few red needles of the cobaltocyanide are obtained, but the greater part suffers decomposition. A better method is to precipitate the salt from its aqueous solution with alcohol, and wash it with the

same liquid; if it be then redissolved in water, a more stable and crystallisable solution will be obtained.

Potassium cobaltocyanide is red, very deliquescent, insoluble in alcohol and ether; alterable on exposure to air, but more permanent under alcohol. Its solution is decomposed by boiling into potassium cobalticyanide and cobalt sesquioxide; this decomposition is much accelerated by a trace of potash, and is almost instantly brought about in dilute solutions by addition of potassium cyanide. The cobaltocyanides of sodium and barium are also red. The solution of the potassium salt forms a reddish precipitate with zinc salts; flesh-coloured with manganous sulphate; yellow with lead acetate; orange-coloured with mercuric salts; rose-coloured with cadmium salts. On mixing a concentrated solution of cobalt nitrate with a concentrated alkaline solution of cobaltous cyanide, a green precipitate is formed consisting of potassio-cobaltous cobaltocyanide, $\text{Co}^{\text{K}^2}\text{Cy}^4$, Co^{Cy^2} . The same compound is formed on pouring a solution of potash on cobaltous cyanide. It is insoluble in water, permanent in the dry state, and dissolves very easily in potassium cyanide, reproducing potassium cobaltocyanide.

The colourless solution of potassium cobalticyanide treated with sodium-amalgam is quickly converted into the red cobaltocyanide (Descamps).

Cobalticyanides. $\text{M}^{\text{K}^2}(\text{Co}^2)^{\text{K}^2}\text{Cy}^{12}$.—Several of these salts are described in vol. ii. pp. 205, 206. The barium salt $\text{Ba}^{\text{K}^2}\text{Co}^2\text{Cy}^{12} + 20\text{H}^2\text{O}$ may be prepared by treating a mixture of cobaltous sulphate and barium carbonate with hydrocyanic acid; and in this salt the barium is easily replaced by other metals or by compound radicles (e.g. phenylammonium and tolylammonium), by treating the solution with the corresponding sulphates. In this manner the following salts have been obtained:

$\text{Na}^{\text{K}^2}\text{Co}^2\text{Cy}^{12} + 4\text{H}^2\text{O}$	Large crystals.
$(\text{NH}^4)^{\text{K}^2}\text{Co}^2\text{Cy}^{12}$	Colourless tables, or with a faint tinge of yellow.
$(\text{C}^6\text{H}^5\text{N})^{\text{K}^2}\text{Co}^2\text{Cy}^{12}$	Crystals rarely quite colourless, more frequently with the aspect of smoky topaz.
$(\text{C}^7\text{H}^{10}\text{N})^{\text{K}^2}\text{Co}^2\text{Cy}^{12}$	Nearly colourless crystals resembling nitre.
$\text{Sr}^{\text{K}^2}\text{Co}^2\text{Cy}^{12} + 20\text{H}^2\text{O}$	Very large crystals, easily soluble in water.

(Weselsky, *Wien. Acad. Ber.* lx. 261; *Chem. Centr.* 1870, p. 92.)

Cobalticyanides containing three metals are obtained by leaving mixed solutions of the preceding cobalticyanides to crystallise. On evaporating, the triple salt separates out if it is less soluble than the mixed double salts, or remains in the mother-liquor in the contrary case, after the latter have crystallised out. These triple salts likewise crystallise with very great facility, forming large and beautiful crystals. The following have been prepared:

$(\text{NH}^4)^{\text{K}^2}\text{Na}^{\text{K}^2}\text{Co}^2\text{Cy}^{12}$	$\text{Ba}^{\text{K}^2}(\text{NH}^4)^{\text{K}^2}\text{Co}^2\text{Cy}^{12} + 22\text{H}^2\text{O}$
$\text{Ca}^{\text{K}^2}(\text{NH}^4)^{\text{K}^2}\text{Co}^2\text{Cy}^{12} + 10\text{H}^2\text{O}$	$\text{Ba}^{\text{K}^2}\text{K}^{\text{K}^2}\text{Co}^2\text{Cy}^{12} + 22\text{H}^2\text{O}$
$\text{Ca}^{\text{K}^2}\text{K}^{\text{K}^2}\text{Co}^2\text{Cy}^{12} + 18\text{H}^2\text{O}$	$\text{Ba}^{\text{K}^2}\text{Li}^{\text{K}^2}\text{Co}^2\text{Cy}^{12} + 30\text{H}^2\text{O}$
$\text{Sr}^{\text{K}^2}(\text{NH}^4)^{\text{K}^2}\text{Co}^2\text{Cy}^{12} + 20\text{H}^2\text{O}$	$(\text{C}^6\text{H}^5\text{N})^{\text{K}^2}\text{Co}^2\text{Cy}^{12} + 3\text{H}^2\text{O}$
$\text{Sr}^{\text{K}^2}\text{K}^{\text{K}^2}\text{Co}^2\text{Cy}^{12} + 18\text{H}^2\text{O}$	$(\text{C}^7\text{H}^{10}\text{N})^{\text{K}^2}\text{Co}^2\text{Cy}^{12} + 3\text{H}^2\text{O}$

The last salt is prepared by mixing one half of a solution of barium cobalticyanide with aniline sulphate, the other half with toluidine sulphate, mixing the filtered solutions, and leaving the mixture to evaporate: it forms groups of large efflorescent crystals having the colour of beryl (Weselsky).

A solution of barium cobalticyanide mixed with excess of baryta-water and left to evaporate under the air-pump, yields the compound $\text{Ba}^{\text{K}^2}\text{Co}^2\text{Cy}^{12} \cdot \text{BaH}^2\text{O}$, in somewhat unstable crystals which absorb carbonic acid from the air. A mixed solution of cobalticyanide and chloride of barium yields the salt $\text{Ba}^{\text{K}^2}\text{Co}^2\text{Cy}^{12} \cdot \text{BaCl}^2 + 16\text{H}^2\text{O}$, in tabular crystals more stable than the preceding compound. A warm solution of phenylammonium-cobalticyanide saturated with aniline becomes turbid on cooling, from separation of the excess of aniline, and the clarified liquid evaporated under the air-pump yields the compound $(\text{C}^6\text{H}^5\text{N})^{\text{K}^2}\text{Co}^2\text{Cy}^{12} \cdot 2(\text{C}^6\text{H}^5\text{NO})$, in groups of faintly coloured bulky prisms, somewhat readily decomposable, the aniline being eliminated by boiling (Weselsky).

COPPER CYANIDES.—*Cupric Cyanide*, CuCy^2 , can be obtained in the pure state only by treating recently precipitated cupric hydrate with hydrocyanic acid. It is an easily alterable, amorphous, green powder, which gives off half its cyanogen at a temperature below 100° , leaving white cuprous cyanide, Cu^{Cy^2} . The latter melts at a dull red heat, decomposes at a bright red heat, quickly turns dark blue in ammoniacal solution,

and unites with the cyanides of the alkali-metals, forming double salts, $\text{MCy} \cdot \text{Cu}^2\text{Cy}^2$, sparingly soluble in cold water, and easily decomposed by acids, with separation of cuprous cyanide. The potassium salt and the ammonium salt (the latter obtained by spontaneous evaporation of a solution of cuprous cyanide in ammonium cyanide) crystallise in anhydrous rectangular prisms, the aqueous solution of which is precipitated by metallic salts, with formation of analogous double cyanides. Mercuric salts give a white, silver salts a bluish-grey, cupric salts a green precipitate, consisting of cuproso-cupric cyanide, $\text{CuCy}^2 \cdot 2\text{Cu}^2\text{Cy}^2$ (Lallemand, *Bull. Soc. Chim.* [2] ii. 271; *Compt. rend.* ix. 1142; *Jahresh.* 1864, p. 300; 1865, p. 391). According to Schiff & Bech. (*Bull. Soc. Chim.* [2] iii. 373), an ammoniacal solution of the white ammoniacal compound $2\text{NH}^3 \cdot \text{Cu}^2\text{Cy}^2$ boiled in an open vessel deposits on cooling shining violet crystals of the compound $\text{N}^2\text{H}^4\text{CuCy}^2 \cdot 2\text{N}^2\text{H}^4\text{Cu}^2\text{Cy}^2$.

GOLD CYANIDES.—*Potassio-auric iodocyanide*, $\text{KAu}^{\text{III}}\text{Cy}^2\text{I}^2$, is easily formed by the action of iodine on potassio-aurous cyanide, $\text{KAu}^{\text{I}}\text{Cy}^2$, and may be crystallised from warm water, in which it is much more soluble than in cold water. It forms brown, shining, long capillary needles. The corresponding barium salt forms brown highly lustrous scales. The corresponding bromine-compounds are reddish-yellow; the chlorine-compounds nearly colourless. The double aurocyanides behave with various reagents in the same manner as the corresponding platine compounds (p. 536); thus the copper salt $\text{Cu}^2\text{Au}^2\text{Cy}^4$ takes up bromine without decomposition (Blomstrand, *Zeitschr. f. Chem.* [2] v. 439).

IRON CYANIDES.—The general formulæ of the double cyanides of iron ($\text{Fe} = 56$) containing monatomic and diatomic metals may be illustrated by the following examples:

Ferrocyanides.—The ammonio-nickel ferrocyanide, which, according to Reynoso, is deposited in violet needles from the solution of nickel ferrocyanide in excess of ammonia, has, according to Gintl (*Zeitschr. f. Chem.* [2] iv. 625), the composition $\text{Ni}^2\text{FeCy}^6 \cdot 12\text{NH}^3 + 9\text{H}^2\text{O}$. When exposed to the air it gives off ammonia, and is converted into a light green powder, $\text{Ni}^2\text{FeCy}^6 \cdot 2\text{NH}^3 + 9\text{H}^2\text{O}$; and at about 100° , into a dark brown powder, $\text{Ni}^2\text{FeCy}^6 \cdot 2\text{NH}^3 + 4\text{H}^2\text{O}$, which at higher temperatures undergoes complete decomposition, giving off water and ammonium cyanide, and leaving a black bulky powder consisting of iron, nickel, and carbon. The original violet compound undergoes the same changes over sulphuric acid as when exposed to the air. Heated in a current of dry ammonia gas to a temperature not above 100° , it is converted into a blue compound, $\text{Ni}^2\text{FeCy}^6 \cdot 8\text{NH}^3 + 4\text{H}^2\text{O}$. The crystalline salt deposited from ammoniacal cobalt solutions on addition of potassium ferrocyanide undergoes similar changes when exposed to the air or left over sulphuric acid (Gintl).

Potassium Ferrocyanide in neutral solution is oxidised by hydrogen dioxide to ferri-cyanide, with formation of potassium hydrate:

On the other hand, potassium ferri-cyanide is reduced by hydrogen dioxide to ferrocyanide and hydroferrocyanide:

and on this reaction depends the blueing of a mixture of potassium ferri-cyanide and ferric chloride by hydrogen dioxide (Weltzien, *Ann. Ch. Pharm.* cxxxviii. 129).

Trisodio-potassic ferrocyanide, $\text{KNa}^3\text{FeCy}^6 + 9\text{H}^2\text{O}$, is obtained, according to Reindel (*Zeitschr. f. Chem.* [2] iv. 601), by the action of sodium hydrate on potassium ferrocyanide, or by treating sodium ferri-cyanide with potash and milk-sugar or alcohol. It forms large, shining, light-yellow crystals which give off 44 p. c. water at 10° . On exposure to the air it slowly effloresces; over sulphuric acid it quickly gives off the whole of its water. According to Wyrsohoff (*ibid.* p. 663), it contains 12 mol. water, like sodium ferrocyanide, $\text{Na}^3\text{FeCy}^6 + 12\text{H}^2\text{O}$, with which it is isomorphous.

Rubidium Ferrocyanide (v. 129).

Thallium Ferrocyanide (v. 748).

Yttrium Ferrocyanide, Y^3FeCy^6 , crystallises by slow evaporation of the solution obtained by boiling yttria with Prussian blue, in well-developed non-efflorescent crystals: it dissolves in water with yellow colour; is insoluble in alcohol. Potassium ferrocyanide forms in solutions of yttrium salts a granulo-crystalline precipitate, which when dried is a heavy, white, soluble powder probably consisting of $(\text{Y}^3\text{K}^3)\text{FeCy}^6$ (Popp, *Ann. Ch. Pharm.* cxxxi. 179).

Ferricyanides.—**Ammonium Ferricyanide**, $(\text{NH}_4)^+\text{Fe}^2\text{Cy}^{12}$, is used in printing calico with aniline black. **Ammonio-potassic ferricyanide**, $(\text{NH}_4)^+\text{K}^+\text{Fe}^2\text{Cy}^6$, is obtained by boiling a solution of 8 grms. potassium ferricyanide and 4.85 grms. ammonium sulphate in 10 litres of water, and carefully evaporating the filtered mother-liquor. It crystallises in oblique rhombic prisms, soluble in 1.8 pt. water at ordinary temperatures (Schaller, *Bull. Soc. Chim.* [2] ii. 93).

Silver Ferricyanide.—An ammoniacal compound of this salt, $\text{Ag}^+\text{Fe}^2\text{Cy}^{12} \cdot 3\text{NH}_3 + \text{aq.}$, of dingy carmine-red colour and crystalline structure, is produced by gradually adding aqueous ammonia to moist, recently precipitated silver ferricyanide, or by adding potassium ferricyanide to a solution of silver mixed with a quantity of ammonia just sufficient to form a clear liquid. The compound is quite insoluble in water, either cold or hot, but is partially decomposed by hot water. Dilute acids decompose it, abstracting all the ammonia. With caustic alkalis it yields ammonia, silver oxide, and an alkaline ferricyanide, which by further action is decomposed, with separation of ferric oxide and formation of argento-potassic cyanide. It dissolves in excess of ammonia, forming a yellow liquid which decomposes, especially when heated or exposed to light, with evolution of nitrogen and separation of silver ferrocyanide:

The same decomposition is produced by water, with aid of light or heat, ammonia being first separated, and then acting as above (Gintl, *Zeitschr. f. Chem.* [2] v. 702).

Nitroferri-cyanides or Nitroprussides $\text{M}^2\text{Fe}(\text{NO})\text{Cy}^2$.—Hadow (*Chem. Soc. J.* [2] iv. 341) supposes that these salts contain the radicle N^2O^3 instead of NO, on the ground that nitrogen dioxide has no action on a solution of potassium ferricyanide acidulated with sulphuric acid, whereas on passing nitrous acid vapours (from nitric acid and starch) into the solution, a nitroferri-cyanide is formed. Städelér, on the other hand (*Zeitschr. f. Chem.* v. 559), maintains the correctness of Gerhardt's formula above given, and explains the formation of the nitroferri-cyanides in Playfair's reaction (ii. 250) by supposing that the nitric acid first converts the ferro-cyanide into ferricyanide, and is itself reduced to nitrous acid, which then transforms the ferricyanide into nitroprusside; thus:

and

Hadow further adduces, in support of his view, the formation of potassium nitroferri-cyanide, together with potassium chloride and mercuric cyanide, by digesting a solution of potassium ferricyanide with mercuric chloride, acetic acid, and an alkaline nitrite, supposing that the reaction takes place as shown by the equation:

Ferricyanide.

Nitroferri-cyanide.

According to Städelér, however, the mercuric chloride is by no means essential to this reaction, the nitroferri-cyanide being produced even more readily when a solution of the ferricyanide mixed with potassium nitrite is acidulated with acetic acid, or better with a dilute mineral acid, and left to stand for some time or boiled, the reaction taking place in the manner previously explained.

Weith (*Zeitschr. f. Chem.* [2] iv. 104) assigns to sodium nitroprusside the formula $(\text{NO})^+\text{Fe}^2\text{Na}^{12}$, which he bases on the fact that when nitroprussides are boiled with alkalis, $\frac{1}{2}$ of the iron is separated as oxide, and a quantity of nitrite is formed corresponding to 8.89 to 9.19 p. c. NO in the nitroprusside. Städelér shows, however, that the reaction may be equally well explained by Gerhardt's formula; thus:

The orange-coloured precipitate formed in ferrous salts by potassium cyanide is, according to Städelér, a potassio-ferrous cyanide, KFe^2Cy^6 , formed according to the equation:

When heated with a solution of potassium nitrite, it is converted into nitroferri-cyanide; thus:

The iron is however precipitated, not as ferrous, but as ferric oxide, and at the same time ammonia is evolved, these results being due to the oxidising action of the nitrite and the nitroferriocyanide. If a solution of ferrous sulphate be first precipitated with an alkali, and the precipitate then treated with potassium nitrite, it becomes dingy green, and is converted on heating into black ferroso-ferric oxide, with copious evolution of ammonia :

If a solution of potassium nitroferriocyanide mixed with alkali be shaken up for a few seconds with ferrous sulphate without heating it, the whole of the iron separates as ferric oxide, even if 4 or more equivalents of ferrous oxide are present to 1 eq. of nitroferriocyanide (Städeler).

The orange-coloured precipitate of potassio-ferrous cyanide is resolved, by boiling with potash out of contact with air, into ferrous hydrate and potassium ferrocyanide (Fresenius, *Ann. Ch. Pharm.* cvi. 210) :

MANGANESE CYANIDES.—The cyanides of manganese unite with the cyanides of the alkali-metals and alkaline earth-metals, forming compounds analogous to the ferro- and ferri-cyanides.

Manganocyanides. $\text{M}^{\cdot}\text{Mn}^{\cdot}\text{Cy}^{\cdot}$ (Eaton a. Fittig, *Ann. Ch. Pharm.* cxlv. 157; *Jahresb.* 1867, p. 373; Decamps, *Bull. Soc. Chim.* 1868 [2] ix. 443).—These salts are easily oxidised on exposure to the air and converted into manganicyanides.

Potassium Manganocyanide, $\text{K}^{\cdot}\text{MnCy}^{\cdot} + 3\text{H}^{\cdot}\text{O}$, is prepared: 1. By digesting manganous carbonate or cyanide (the precipitate obtained by adding potassium cyanide to a manganous salt) with a concentrated solution of potassium cyanide heated to 40° – 50° . The liquid filtered after an hour deposits the manganocyanide in crystals. It is also produced by reducing the manganicyanide with sodium-amalgam (Descamps).—2. By digesting solid potassium cyanide with a strong solution of manganous acetate, a green precipitate is formed, at first consisting of the compound $\text{KCy}^{\cdot}\text{MnCy}^{\cdot}$; but this gradually disappears, and the surface of the liquid becomes covered with a layer of dark blue crystals of hydrated potassium manganocyanide, which give off their water when dried over sulphuric acid (Eaton a. Fittig). Potassium manganocyanide crystallises in square tables of a deep violet colour, which decompose in contact with the air into potassium manganicyanide and manganic oxide. When heated in the air it yields manganic oxide and potassium cyanate. Its solution in potassium cyanide gives a violet precipitate with zinc salts. When treated with water it yields a green precipitate identical with that which is produced in the first instance on digesting solid potassium cyanide with manganous acetate. This same precipitate, $\text{KC}^{\cdot}\text{MnCy}^{\cdot}$, is also formed when a manganous salt is added in excess to a strong solution of potassium cyanide, and when a manganous salt is added to potassium manganocyanide. From this last mode of formation Descamps infers that it consists of *manganopotassio manganocyanide*, $(\text{MnK}^{\cdot})\text{MnCy}^{\cdot}$.

Sodium Manganocyanide, $\text{Na}^{\cdot}\text{MnCy}^{\cdot} + 8\text{H}^{\cdot}\text{O}$, obtained, like the potassium salt, by mixing a solution of sodium cyanide with manganous acetate, dissolving the resulting blue-grey precipitate in excess of sodium cyanide, and cooling the concentrated solution, forms large transparent amethyst-red octohedrons, or, if crystallised from a solution containing alcohol, long apicular crystals. An *ammonio-manganous manganocyanide*, $\text{Mn}(\text{NH}^{\cdot})^{\cdot}\text{MnCy}^{\cdot}$, has been obtained in the same manner as the corresponding potassium salt. **Barium Manganocyanide,** $\text{Ba}^{\cdot}\text{MnCy}^{\cdot}$ (at 100°), prepared like the sodium salt, crystallises in concentric groups of blue crystals more stable than the potassium and sodium salts. The calcium salt $\text{Ca}^{\cdot}\text{MnCy}^{\cdot}$ separates as a blue crystalline precipitate on adding alcohol to a mixture of manganous acetate and calcium cyanide.

Manganicyanides. $\text{M}^{\cdot}\text{Mn}^{\cdot}\text{Cy}^{\cdot}$.—These salts, partly described in vol. ii. p. 253, have been further examined by Eaton a. Fittig (*loc. cit.*). They are produced by the action of the air or of heat upon the manganocyanides. The solutions of the potassium and sodium salts form a blue precipitate with ferrous salts; rose-coloured precipitates with zinc and cadmium salts; all these precipitates quickly decompose. The potassium salt forms anhydrous red-brown prisms or tables. The sodium salt $\text{Na}^{\cdot}\text{Mn}^{\cdot}\text{Cy}^{\cdot}$ crystallises, with 8 mol. water, in octohedrons which are nearly black by reflected, pale violet by transmitted light; or with 4 mol. water in red prisms. The barium salt $\text{Ba}^{\cdot}\text{Mn}^{\cdot}\text{Cy}^{\cdot}$, and the calcium salt $\text{Ca}^{\cdot}\text{Mn}^{\cdot}\text{Cy}^{\cdot}$, are obtained by spontaneous evaporation as light red crystalline masses.

PALLADIUM CYANIDES (Rössler, *Zeitschr. f. Chem.* [2] ii. 175; *Jahresb.* 1866, p. 290).—Palladious cyanide, PdCy^{\cdot} , is not decomposed by acids or by mercuric oxide;

it dissolves in ammonia, forming palladammonium cyanide, $(N^2H^4Pd)Cy^2$, and in potassium cyanide, forming a double salt; its solution in hydrocyanic acid leaves the unaltered cyanide on evaporation.

Potassio-palladium cyanide, $2KCy \cdot PdCy^2$, crystallises with $3H^2O$ in colourless monoclinic prisms, or step-like aggregates of pyramidal forms, which give off 2 mol. water on exposure to the air. The *sodium salt*, $2NaCy \cdot PdCy^2 + 3H^2O$, separates from the solution of palladium cyanide in prussic acid and caustic soda, in crystals isomorphous with those of the potassium salt; the two salts crystallise together from a mixed solution in slightly efflorescent needles. The *barium salt*, $BaCy^4 \cdot PdCy^2 + 4H^2O$, obtained by decomposing the corresponding copper salt with baryta-water, forms large monoclinic crystals. The *calcium salt* $CaCy^2 \cdot PdCy^2 + 4H^2O$, and the *magnesium salt*, also with 4 mol. water, are prepared like the sodium salt, and crystallise in needles.

The double palladium and platinum cyanides are isomorphous and crystallise together from solution. A *magnesium salt*, $MgPtCy^4 \cdot MgPtCy^4 + 14H^2O$, crystallises with difficulty in very soluble tufts of orange-red needles, which become emerald-green at 100° , then colourless, and at 200° give off all their water and turn lemon-yellow. On moistening or breathing upon them, the same series of colours is produced in the reverse order; the solution is quite colourless.

PLATINUM CYANIDES.—A perfectly neutral solution of platinum chloride forms with mercuric cyanide a yellowish-white flocculent precipitate of platinum cyanide, $PtCy^2$, which dissolves in hydrocyanic acid, and is precipitated therefrom only after long boiling. This reaction does not interfere with the separation of palladium and platinum by mercuric cyanide, because the platinum in the solutions is always present, not as platinum, but as platinic chloride, which is not affected by mercuric cyanide. The precipitability of platinum chloride by this reagent affords the means of preparing all the platinum double cyanides directly and free from admixture, namely by precipitating an exactly neutralised solution of platinum chloride with mercuric cyanide, and treating the precipitate with hydrocyanic acid, with addition of the base to be introduced (Rössler, *loc. cit.*).

Ditscheiner (*Wien. Akad. Ber.* i. [2] 373; *Jahresh.* 1865, p. 293) has described the crystalline forms of certain platino-cyanides prepared by Schrötter. The *rubidium salt* forms greenish-yellow, slightly fluorescent, monoclinic prisms; the *rubidio-baric salt*, yellowish-white monoclinic prisms; the *ammonium-magnesium salt* $(NH^4)^2PtCy^4 \cdot MgPtCy^4 + 6H^2O$, cherry-red, strongly fluorescent crystals belonging to the rhombic system.

Potassio-platinum cyanide, $K^2Pt^2Cy^4$, takes up iodine with great facility, forming *potassio-platinic iodocyanide*, $K^2Pt^2I^2Cy^4$ or $2KI \cdot PtCy^4$, which separates in large brown shining crystals. When treated with chlorine and bromine, it gives up iodine, and is converted into the corresponding chloro- or bromo-cyanide. Similar salts of other electro-positive metals are easily obtained. $BaBr^2 \cdot PtCy^4$ crystallises in large, apparently quadratic tables; the *zinc salt* in cubes; the *copper salt* $CuCl^2 \cdot PtCy^4$ in small quadratic pyramids. The *hydrogen salt* $2HBr \cdot PtCy^4$ is very soluble and crystallises in needles. Chlorine acts on bario-platinum cyanide, $BaPtCy^4$, in the same manner as the corresponding potassium salt (ii. 265), converting it into the platinic cyanide $BaPtCy^4$. Bromine acts upon the potassium salt, not on the barium salt; the zinc salt takes up chlorine without perceptible decomposition; but if the potassium salt be first made to unite with iodine, this element may afterwards be replaced by chlorine without further decomposition. When bario-platinum cyanide is heated with water or boiled with excess of silver nitrate, the chlorine is simply removed and not replaced; the chlorine may also be removed by reducing agents (Blomstrand, *Zeitschr. f. Chem.* [2] v. 439).

SILVER CYANIDE.—By heating this compound with ammonia, or any metallic cyanide with an ammoniacal solution of silver, *argentammonium cyanide*, NH^4AgCy , is obtained in large monoclinic crystals, very much like those of selenite. In contact with water they decompose with a hissing noise, and give up all their ammonia (Weith, *ibid.* 380).

THALLIUM CYANIDES (v. 748).—*Thallio-platinum Cyanide*, $2TlCy \cdot PtCy^2$, obtained by spontaneous evaporation of a solution of thallium carbonate in hydro-platinum cyanide, in blood-red needles with metallic-green surface iridescence (Carstanjen, *Jahresh.* 1867, p. 281).

Detection and Estimation of Cyanogen in Cyanides.—Fröhde (*Pogg. Ann.* cxix. 317) recommends for the detection of cyanogen in solid compounds, the conversion of the latter into sulphocyanates, by fusion with sodium hyposulphite. A small

quantity of the anhydrous hyposulphite is fused in a test-tube or in the loop of a platinum wire, with a trace of the substance to be tested, till sulphur begins to volatilise, and the fused mass is dipped into a few drops of ferric chloride solution, whereupon, if cyanogen is present, the well-known blood-red colour is produced.

To apply this method to the quantitative analysis of double cyanides, the compound, carefully mixed with 4 or 5 pts. of barium hyposulphite, is heated in a covered porcelain crucible till the vapours begin to burn on lifting up the lid, and the mass is treated with water. The residual metallic sulphides are dissolved in hydrochloric or nitromuriatic acid; the metals are determined by the usual methods; the filtrate, freed from baryta by a few drops of ammonium sulphate, is supersaturated with hydrochloric acid and evaporated; and the residue is ignited with sal-ammoniac to convert the sulphate into chloride (Fröhde, *Zeitschr. anal. Chem.* iii. 181).

To detect cyanogen in presence of chlorino, the solution may be precipitated with silver nitrate and the precipitate digested with aqueous potash. If a cyanide is present, the diluted filtrate yields a precipitate when supersaturated with nitric acid (Barff, *Laboratory*, p. 345).

CYANINE. See CHINOLINE-BLUE (p. 431).

CYANOGEN. The molecule of free cyanogen is represented by the formula

On the formation of cyanogen see CYANIDES (p. 531). Fröhde is of opinion that the deleterious action of the fumes of burning carbon may be due, not only to the oxides of carbon, but likewise to cyanogen produced in the combustion; in the imperfect combustion of coal he has detected cyanogen by the smell (*Zeitschr. f. Chem.* [2] ii. 540).

Troost & Hautefeuille (*Compt. rend.* lvi. 735, 795; *Zeitschr. f. Chem.* [2] iv. 420) have studied the formation of cyanogen and paracyanogen by the decomposition of the cyanides of mercury and silver, and have obtained results differing in several particulars from those of Thaulow (iv. 342). When mercuric cyanide is decomposed in sealed tubes at different temperatures, the relative quantities of cyanogen and paracyanogen produced vary according to the temperature and pressure, the largest proportion of paracyanogen being formed at a comparatively low temperature (350°) and under high pressure. Silver cyanide begins to decompose at a little above 350°. When slowly heated to 440°, and kept at that temperature for some time, it decomposes without fusion or incandescence. If the decomposition be performed in a vacuum, 17 p. c. of the cyanogen evolved is converted into paracyanogen; under ordinary atmospheric pressure, 20 p. c.; and in sealed tubes under a pressure of 60 atmospheres, 64 p. c. If the silver cyanide be slowly heated to 600° under the ordinary pressure, it likewise decomposes without fusion or incandescence, but both these effects are produced when it is very quickly heated. In both cases, however, more than half the cyanogen is evolved as gas, the quantity of paracyanogen formed never exceeding 41 p. c. When the cyanide is heated to the same temperature in sealed tubes, the pressure then amounting to about 80 atmospheres, 76 p. c. paracyanogen is obtained. The paracyanogen is merely mixed, not combined, with the reduced silver, for the latter may be easily extracted by trituration with mercury. The cyanogen gas obtained from silver cyanide has exactly the same properties as that from mercuric cyanide.

The best way of preparing paracyanogen is to heat mercuric cyanide in portions of 5 grms. in sealed tubes to 440° (in boiling sulphur) for 24 hours. About 40 p. c. of the cyanogen is then converted into paracyanogen, which at that temperature remains quite unaltered. It may be freed from mercury by heating it to 440° in a stream of cyanogen gas.

Paracyanogen heated to 860° is completely converted into gaseous cyanogen, which condenses to a liquid in the colder parts of the sealed apparatus. When heated in a vacuum to only 440°, it gives off gaseous cyanogen condensed in its pores, but the actual conversion of the paracyanogen into cyanogen does not begin till it is heated to about 500°; above 550°, a perceptible though very slow decomposition into carbon and nitrogen takes place. Experiments made between 502° and 640° showed that paracyanogen, within certain limits of temperature, is partially converted into cyanogen, and that this conversion attains its limit as soon as the cyanogen exerts upon the paracyanogen a pressure determinate for each temperature. The conversion of paracyanogen into cyanogen takes place very quickly, but that of cyanogen into paracyanogen is very slow. The most favourable temperature for the conversion of

cyanogen into paracyanogen is about 500° ; but it takes place at 440° , or even at 350° , though very slowly.

Reactions of Cyanogen.—1. When cyanogen gas is passed into strong aqueous hydrochloric acid, the liquid after some hours deposits crystals of oxamide, $C^2N^2H^4O^2$, while a small quantity of ammonium oxalate remains in the liquid. Strong aqueous hydriodic acid treated with cyanogen also very quickly yields oxamide, iodine being likewise separated, while hydrocyanic acid and ammonium iodide remain in solution (Schmitt a. Glutz, *Zeitschr. f. Chem.* [2] iv. 480). According to Berthelot (*Jahresb.* 1867, p. 347), cyanogen and aqueous hydriodic acid yield as chief products ammonia and ethane:

together with oxalic acid and its products of decomposition. When a mixture of cyanogen gas with 12 vol. hydrogen iodide is heated for an hour to dull redness, the cyanogen is resolved into nitrogen and carbon, which latter is deposited in graphitic scales.

Nascent hydrogen, evolved from hydrochloric acid and tin, converts cyanogen into ethylene-diamine, $C^2N^2 + H^2 = N^2(C^2H^4)H^4$ (Fairley, *Chem. Soc. J.* [2] ii. 362).

CYANOGEN BROMIDE. CNBr.—This compound may be prepared in the same manner as the solid chloride (*infra*) by passing bromine-vapour into a mixture of 1 pt. hydrogen cyanide and 4 pts. anhydrous ether (Gautier). The crystals CNBr, heated in a sealed tube to 130° – 140° for six or eight hours, are converted, with partial decomposition, into an amorphous mass coloured yellowish by free bromine. The same product is more easily obtained, and as a perfectly white mass, by heating the crystallised bromide with anhydrous ether. It is a polymeric modification, most probably $C^2N^2Br^2$, insoluble in benzol and absolute alcohol, nearly insoluble in anhydrous ether, melting at a temperature above 300° , and boiling at a still higher temperature, but apparently not volatilising without decomposition. When exposed to moist air or heated with water to 100° in a sealed tube, it is converted into cyanuric acid (Eghis, *Zeitschr. f. Chem.* [2] v. 376).

The great diversities of melting point (4° to 40°) assigned by different chemists to ordinary cyanogen bromide (ii. 277) may perhaps be attributed to admixture of this polymeric modification.

CYANOGEN CHLORIDE. The liquid chloride has, according to Salet (*Bull. Soc. Chim.* [2] iv. 105), the vapour-density 2.13, whence its molecular formula is CNCl (calc. 2.129): it follows therefore that the gaseous chloride is merely the vapour of the liquid chloride. Gautier (*ibid.* v. 403) prepares the liquid chloride by rapidly passing chlorine into a mixture of 1 pt. hydrogen cyanide and 4 pts. water, contained in a retort connected with an inverted condenser. If the stream of chlorine be interrupted as soon as the liquid turns green, the formation of the intermediate compound, $2CyCl.CyH$, is prevented, and the whole of the hydrocyanic acid is converted into the oily chloride. The product is purified by distillation over mercuric oxide as in Wurtz's method (ii. 280).

According to Regnault, liquid cyanogen chloride boils at 12.66° , under a pressure of 760 mm. and solidifies at about -7° (*Jahresb.* 1863, pp. 70, 74).

To prepare solid cyanogen chloride, $C^2N^2Cl^2$, Gautier passes a slow stream of chlorine into a mixture of 1 pt. hydrogen cyanide and 4 pts. anhydrous ether. Viscid drops are then formed, which soon solidify, even if there is no excess of chlorine present. After 24 hours' rest, there is obtained an aggregate of well-defined, apparently monoclinic crystals, having the consistence of wax. If the solution of the hydrogen cyanide is too concentrated, or the stream of chlorine too rapid, or if the liquid be heated, the product obtained after evaporating the ether is a pasty deliquescent mass, which gives off hydrochloric acid on exposure to the air. Solid cyanogen chloride melts at 140° and solidifies again at 130° .

CYANOGEN SELENIDE. $(CN)^2Se$, is formed on introducing dry silver cyanide into a solution of selenium bromide in carbon bisulphide. It is sparingly soluble in that liquid, and crystallises therefrom in colourless or light yellow laminae having a satiny lustre. When exposed to moist air, they turn red from separation of selenium. Boiling water decomposes the compound immediately into selenium, selenious acid, and hydrocyanic acid; fused with potash it gives off ammonia and leaves a red residue of potassium selenide (R. Schneider, *Pogg. Ann.* cxxix. 364).

CYANOGEN SULPHIDE. $(CN)^2S$, is formed in like manner (together with an easily decomposable compound) by adding 2 pts. silver cyanide to 1 pt. sulphur

chloride mixed with 10 to 12 pts. carbon bisulphide, and separates from the heated and filtered liquid in colourless laminae having a pungent odour. It decomposes spontaneously, losing its penetrating odour, and yielding a yellow substance, probably pseudosulphocyanogen (Schneider, *loc. cit.*; also *Zeitschr. f. Chem.* [2] iv. 504).

CYANURIC ACID. $C^3N^3H^3O^3$.—Formation from cyamelido (p. 517). The crystals of anhydrous cyanuric acid thus obtained are quadratic octohedrons (Voit, *Jahresb.* 1864, 305); those of the hydrated acid are monoclinic (ii. 289).

CYANURIC ETHERS. The cyanuric ethers described in vol. ii. pp. 292-294 are properly carbo-triamides, e.g. $N^3 \left\{ \begin{smallmatrix} (CO)^3 \\ (C^2H^3)^3 \end{smallmatrix} \right\}$, and are resolved by boiling with alkalis into carbonic acid and the corresponding monamines. The true cyanuric ethers or alcoholic cyanurates, $C^3 \left\{ \begin{smallmatrix} N^3 \\ (OR)^3 \end{smallmatrix} \right\}$, have recently been discovered by Hofmann (*Deut. Chem. Ges. Ber.* 1870, 269; *Zeitschr. f. Chem.* [2] vi. 492). They are formed, together with the alcoholic cyanates (p. 519), when gaseous cyanogen chloride is passed into a solution of sodium methylate, ethylate, &c., in the corresponding alcohol, and are resolved by boiling with alkalis into cyanuric acid and in alcohol; e.g. $(CN)^3(OCH^3)^3 + 3H^2O = (CN)^3(OH)^3 + 3CH^3OH$. Phenyl cyanurate, $(CN)^3(OC^6H^5)^3$, is obtained by the action of cyanogen chloride on sodium phenate dissolved in absolute alcohol. All these ethers are crystalline. The formation of the methylic and ethylic cyanurates is accompanied by that of ethers of amido- and diamido-cyanuric acid.

CYAPHENINE. nC^2H^3N . *Kyaphenine* (iii. 449).—This compound, which Cloez obtained by heating potassium cyanate with benzoyl chloride, is also produced by heating benzonitrile bromide, C^6H^5NBr (or the precipitate thrown down by water from the alcoholic solution of the crude product obtained by the action of bromine on benzonitrile), with lime; also by heating this bromide by itself to 150° - 160° : consequently it is always found amongst the products of the action of bromine on benzonitrile (Engler, *Ann. Ch. Pharm.* cxxxiii. 137).

Cloez assigned to cyaphenine the formula $C^{21}H^{15}N^3$, regarding it as an analogue of cyanethine, $C^8H^{15}N^3$; but according to Engler (*ibid.* cxlix. 310), this supposed analogy does not rest on any satisfactory foundation. Cyaphenine does not appear to form salts with acids; it does not give off ammonia when boiled with alcoholic potash, and only traces when heated therewith in sealed tubes to 150° (the ammonia which Cloez obtained was perhaps derived from the decomposition of admixed benzonitrile); and when heated with a large excess of fuming hydriodic acid in sealed tubes to 220° , it yields only benzoic acid (not a polymeride thereof) and a very small quantity of an oil, probably hexane.

CYMENE. $C^{10}H^{14}$.—See BENZENE, HOMOLOGUES OF (p. 302).

CYTIMINE. This base, discovered by Barlow and obtained by reduction of nitrocymene, is isomeric (not identical, as stated in vol. ii. p. 297) with monocymylamine, which is produced, together with di- and tri-cymylamine, by the action of ammonia on cymyl chloride. Regarding cymene as methyl-propyl-benzene, $C^6H^5 \left\{ \begin{smallmatrix} CH^3 \\ C^3H^7 \end{smallmatrix} \right\}$, the difference of structure between the two isomeric bases may be represented by the following formulæ:

CYTOLITE. A zirconium silicate found in the granite of Rockport, Massachusetts, in brown-red crystals similar to those of the zircon of Expaill, but having their end-faces curved (hence its name). Sp. gr. 3.895 to 4.04 (Cooke); 3.850 to 3.970 (Knowlton). Hardness, before ignition, 5 to 5.5; after ignition, 7 to 7.5. Gives by analysis, 26.18 to 26.48 silica, 60.00 to 61.33 zirconia, and 4.56 to 4.58 water, together with small quantities of the oxides of the cerium metals, iron, uranium, and tin, and traces of copper, manganese, magnesium, and fluorine (Knowlton, *Sill. Am. J.* [2] xlv. 224; *Jahresb.* 1867, p. 988).

CYTISINE. $C^9H^{12}N^3O$ (Husemann a. Marmé, *Zeitschr. f. Chem.* [2] i. 161; Husemann, *ibid.* v. 677).—A poisonous alkaloid occurring in the ripe seeds of *Cytisus Laburnum*, and other species of the same genus; obtained in an impure state by Chevallier a. Lassaigue (ii. 301). To obtain it, the extract of the seeds prepared with slightly acidulated water, purified by precipitation with basic lead acetate, and evaporated, is mixed with tannic acid; the resulting precipitate, mixed with litharge

and dried over the water-bath, is treated with alcohol, which dissolves out the cytisine; and the solution evaporated to a syrup is strongly acidulated with nitric acid and boiled with 6 to 8 vol. absolute alcohol. The solution thus obtained, after being decanted from a resinous body which separates on cooling, yields an abundant crystallisation of cytisine nitrate, which, by repeated crystallisation from boiling water, is obtained in large colourless well-defined crystals. This salt dried, pulverised, and boiled with highly concentrated potash-ley, yields cytisine as a clear colourless oily layer which solidifies on cooling. It is then removed, rinsed with a little cold water, again fused with potash, and after separation and rinsing as before, is left for some time in an atmosphere containing carbonic acid, to convert the free potash which adheres to it into carbonate; lastly, it is dissolved in absolute alcohol, and the solution is evaporated to a syrup, whereupon it solidifies on cooling to a dazzling white crystalline mass.

Cytisine is not deliquescent. It has a bitterish caustic taste, melts at 154.5° (corr.), and sublimates when cautiously heated in very thin flexible needles or laminae. It dissolves in water and alcohol in almost all proportions, but is nearly insoluble in ether, chloroform, benzol, and carbon bisulphide. It is one of the strongest of the vegeto-alkaloids, expelling ammonia from its salts even at ordinary temperatures. It does not reduce cupric oxide.

Cytisine is a polycyclic base. The only one of its salts that crystallises well is the nitrate, $C^{20}H^{27}N^3O \cdot 2HNO^3 + 2H^2O$, which separates from water or dilute alcohol in thick transparent prisms. It has a more bitter taste than the free base, dissolves in less than its own weight of boiling water, and crystallises out almost completely on cooling. It is slightly soluble in dilute alcohol, quite insoluble in absolute alcohol and in ether. The sulphate, phosphate, formate, acetate, propionate, butyrate, valerate, oxalate, and tartrate, are all deliquescent and impossible or difficult to crystallise.

The hydrochloride is easily soluble in water, less soluble in absolute alcohol. The solution evaporated over the water-bath leaves a salt which, after drying at 120° , contains $C^{20}H^{27}N^3O \cdot 3HCl$. The platinumchloride, $C^{20}H^{27}N^3O \cdot 2HCl \cdot PtCl^4$, is precipitated in orange-yellow flocks, gradually changing into an aggregate of microscopic needles. The mother-liquor yields on evaporation light yellow crystalline nodules containing $C^{20}H^{27}N^3O \cdot 4HCl \cdot PtCl^4$. The aurochloride, $C^{20}H^{27}N^3O \cdot 2HCl \cdot 2AuCl^3$, forms tufts of slender needles. Mercuric chloride forms no precipitate in solutions of the hydrochloride; but on adding it to a solution of the free base containing not more than 1 pt. in 1,000, it throws down a white precipitate of the compound $C^{20}H^{27}N^3O \cdot 2HgCl^2$, which gradually changes into hard roundish crystalline masses, easily soluble in hydrochloric and in nitric acids.

Reactions of Cytisine.—Potassio-cadmio iodide and potassio-mercuric iodide produce, even in very dilute solutions of the nitrate, white flocculent precipitates, afterwards becoming crystalline. A solution of iodine in potassium iodide forms in the weakest solutions, a dark red-brown precipitate, amorphous at first, but converted on standing into beautiful dark red translucent prisms. Bromine-water is an equally delicate test, producing a fiery orange-yellow precipitate, and a slight turbidity even in solutions diluted 15,000 times. Sodium phosphomolybdate forms in the strongly acidulated solution a yellow precipitate; tannic acid forms little or no precipitate in acid solutions, but in a solution neutralised with soda it forms a copious white flocculent precipitate. An alcoholic solution of picric acid forms with the free base or the nitrate, a light-yellow precipitate which soon becomes crystalline. Strong sulphuric acid dissolves cytisine without colour. On adding to the solution small pieces of potassium dichromate, it assumes a pure yellow colour, changing to dirty brown and finally to green; sodium molybdate produces no alteration; a drop of nitric acid colours the solution orange-yellow after a few minutes.

The unripe seeds and pods of the laburnum contain another basic substance called laburnine, likewise poisonous, but less powerfully basic than cytisine. To obtain it, the aqueous extract, purified with basic lead acetate, is precipitated by sodium phosphomolybdate, and the precipitate, after drying with chalk, is boiled with alcohol. The base separated, for further purification, from its platinum salt, forms light crystalline groups of hydrated monoclinic prisms. It is very soluble in water, dissolves with difficulty in alcohol, scarcely at all in ether, and gives off ammonia when treated with potash, even at ordinary temperatures (Husemann & Marmé, *loc. cit.*).

D

DACITE. Greenstone-trachyte occurring at several localities in Transylvania (*Jahresb.* 1867, p. 1020).

DAMALURIC ACID. $C^4H^4O^2$.—An acid of the acrylic series, extracted by Städele (ii. 301), together with damolic acid, from cows' urine. According to W. Werner (*Zeitschr. f. Chem.* [2] iv. 413), it crystallises in rhomboidal needles melting at 50° – 53° , or by evaporation in a vacuum, in prisms which melt at 39° – 40° when recently crystallised, but whose melting point rises to 50° after they have been exposed for some time to the air. This prismatic modification is optically levogyrate, the ordinary modification dextrogyrate.

Damaluric and damolic acids are obtained in the same preparation as taurylic acid (v. 701). The oily mixture of these acids is agitated with sodium carbonate; the evaporated saline solution, freed from taurylic acid by agitation with ether, is distilled with sulphuric acid; and the distillate is saturated with barium carbonate. The filtered solution deposits, first crystals of barium damolate, then the damalurate—from which the pure acid may be obtained—and lastly salts of fatty acids more or less impure (Städele).

DAMBONITE. $C^4H^4O^4$ (A. Girard, *Compt. rend.* lxvii. 820).—A crystallised saccharine substance existing in a peculiar kind of caoutchouc exported from the French colony of Gaboon on the west coast of Africa. This caoutchouc, which differs in appearance from other species, is not obtained from trees of the genus *Ficus*, or from Euphorbiaceae, but from climbing plants the botanical species of which is unknown. The exuded juice, coagulated by exposure to the air, is kneaded into loaves called by the natives *n'dambo*. These loaves often contain a white liquid which gradually alters, the caoutchouc then losing its valuable properties. A quantity of the caoutchouc thus altered having been heated to convert it into tar, the workmen observed, amongst the condensed volatile products, a white sweet substance crystallised in needles. This substance is dambonite; it exists ready-formed in the Gaboon caoutchouc. The pure recently imported caoutchouc-juice, if evaporated at a gentle heat, dries up to a coloured crystalline mass, from which the pure dambonite is easily extracted by solution in alcohol. The sample examined by Girard yielded 0.5 p. c.

Dambonite is white, easily soluble in water and in alcohol of ordinary strength, sparingly soluble in absolute alcohol. It melts at 190° , and when cautiously heated sublimes at 200° – 210° , without decomposition, in long slender shining needles. From alcohol it crystallises in six-sided prisms; from water, with difficulty, in oblique prisms containing $2C^4H^4O^4 \cdot 3H^2O$. Dilute sulphuric acid does not act upon it; the hot strong acid carbonises it; cold nitric acid dissolves it without alteration; hot nitric acid oxidises it to oxalic and formic acids. Concentrated alkalis do not act upon it even at 100° , but they considerably diminish its solubility in water. Lime-water, baryta-water, and lead acetate give no precipitates. It does not reduce alkaline cupric solutions, and is not susceptible either of alcoholic or of lactic fermentation. It unites with *potassium iodide*; a mixture of the warm alcoholic solutions of the two bodies deposits, on cooling, beautiful crystals of the compound $KI \cdot 2C^4H^4O^4$.

DAMBOSE. $C^4H^4O^4$ (Gerard, *loc. cit.*).—Dambonite is decomposed by hydriodic acid, even at ordinary temperatures, and quickly at 100° , by hydrochloric acid also at 110° , yielding methyl iodide or chloride and dambose, a crystallisable sugar isomeric with glucose:

To prepare dambose, dambonite is heated to 100° in sealed tubes with excess of fuming hydriodic acid; the solution decanted from the separated methyl iodide is mixed with alcohol of 95 p. c., which precipitates the dambose completely as a white powder; the precipitate is washed with alcohol and dissolved in a small quantity of boiling water; and this solution is mixed with 100 times its volume of boiling alcohol. The dambose is then deposited on cooling in beautiful six-sided prisms. It is easily soluble in water, though less soluble than dambonite, and crystallises from water in rather thick anhydrous prisms, whereby it is distinguished from inosite,

which it otherwise resembles. It is very slightly soluble in aqueous alcohol, insoluble in absolute alcohol.

Dambosé is a very stable substance, not being decomposed at 230°, at which temperature however it melts and begins to become coloured; at a higher temperature it suffers decomposition. It is not fermentable. Bromine does not attack it at 160°, but at 180° hydrobromic acid and a brominated substitution-product are formed. Phosphorus pentachloride attacks it at 150°, forming hydrochloric acid and a product smelling like camphor. Fuming nitric acid dissolves it without alteration at ordinary temperatures, but boiling nitric acid converts it into oxalic acid.

Dambosé triturated with cold strong sulphuric acid dissolves to a colourless syrup which, when diluted with water and neutralised with barium or lead carbonate, yields easily soluble gummy salts, which are permanent at 150°, and are precipitated by alcohol from their aqueous solutions. The barium salt contains $C^8H^{16}S^2O^{12}Ba =$

$C^8H^{16} \left\{ \begin{smallmatrix} SO^2 & O \\ Ba & O \end{smallmatrix} \right\} O^6$; the lead salt, $C^8H^{16}S^2O^{12}Pb$. Dambosulphuric acid separated from

either of these salts dries up in a vacuum to a thick syrup, which dissolves in water and in alcohol, and decomposes in moist air, with separation of dambosé. This acid instantly reduces alkaline cupric solution, a property not exhibited by free dambosé.

Concentrated alkalis do not act upon dambosé at ordinary temperatures, and metallic salts do not precipitate its aqueous solution; but on adding an alcoholic solution of ammoniacal lead acetate to an aqueous solution of dambosé, a white precipitate soluble in water is produced, which when dried at 120° has the composition $(C^8H^8O)^2Pb \cdot PbO$. In like manner a solution of baryta in wood-spirit forms a white, easily decomposable precipitate, which when dried at 110° appears to have the composition $(C^8H^8O^2)BaO$.

The reactions above described show that dambosé is a polyatomic alcohol, and dambonite its methylic ether:

Dambosé.

Dambonite.

DANALITE. A mineral resembling rhodonite, occurring in the granite of Rockport, Massachusetts; flesh-coloured to grey, translucent, brittle, with slightly conchoidal fracture; hardness 5.5 to 6; sp. gr. 3.427. From its internal crystalline structure it appears to consist of holohedral forms of the regular system. Analysis gave 31.73 p.c. SiO_2 , 27.40 FeO , 17.51 ZnO , 6.28 MnO , 13.88 GlO and 5.48 S (= 102.28), whence it is inferred to be an isomorphous mixture of a regular silicate with the sulphides of zinc and iron, and perhaps of manganese: $(MO.GlO)SiO_2 + MS$ (J. F. Cooke, jun., *Sill. Am. J.* [2] xlii. 73).

DAPHNIN and **DAPHNETIN** (ii. 303). According to Rochleder (*Wien. Akad. Ber.* xlviii. [2] 236; *Jahresb.* 1863, p. 591), daphnin is isomeric or polymeric with resculin, and daphnetin dried at 100° with hydrated resculin. Daphnetin dried at 220° in a stream of carbon dioxide gives off 1 mol. water, and has then the same composition as resculin.

DECYLIC COMPOUNDS. Compounds derived from the fundamental hydrocarbon $C^{10}H^{22}$, decyl hydride or diamyl (p. 105). This hydrocarbon, obtained by Pelouze and Cahours from American petroleum, and by Wurtz by treating diamylene with bromine (ADDENDA, vol. v. p. 1090), is likewise produced by the action of hydriodic acid on coal-tar cymene, $C^{10}H^{14}$; and, together with other hydrocarbons of the same series, by the action of hydriodic acid on naphthalene, $C^{10}H^8$, and acenaphthene, $C^{10}H^{10}$ (Berthelot, *Jahresb.* 1867, pp. 346, 592, 596, 710).

Decylene, $C^{10}H^{18}$, produced by the action of alcoholic potash on decyl chloride, $C^{10}H^{21}Cl$ (v. 1091), unites with bromine, forming $C^{10}H^{18}Br^2$, which when heated till it begins to decompose, and then treated with alcoholic potash, yields a mixture of decylene precipitable by water, and bromodecylene, $C^{10}H^{18}Br$. This last compound, separated by fractional distillation, is a colourless liquid which gradually turns brown, has a sp. gr. of 1.109 at 15°, and boils at about 215°. Heated for six hours to 180° in closed vessels with a saturated alcoholic solution of potash, it yields a mixture of ethyl-decenylic ether, $(C^2H^5)(C^{10}H^{19})O$, and decenylyene, $C^{10}H^{18}$, which may be separated by fractional distillation finally over sodium. Decenylyene has a faint alliaceous odour, boils at about 165°, and when treated with bromine in a cooled vessel, forms at first the liquid dibromide $C^{10}H^{16}Br^2$, which by several hours' contact with

excess of bromine, is converted into a thick oily tetrabromide, $C^4H^4Br^4$ (Reboul a. Truchot, *Bull. Soc. Chim.* [2] viii. 422).

DEHYDRACETIC ACID. $C^3H^3O^4$ (Geuther, *Jenaische Zeitschr.* ii. 387; iv. 241; *Jahresb.* 1865, p. 303; *Zeitschr. f. Chem.* [2] iv. 655).—An acid said to be produced by the action of hydrochloric or carbonic acid on the sodium salt of ethyl-diacetic acid (Wanklyn's sodium triacetyl, p. 15); also, according to R. Brandes (*Jahresb.* 1866, p. 307), in the rectification of methyl-diacetic acid, $C^3H^3O^4$, and by the action of carbon dioxide on sodium methyl-diacetate at 170° . To prepare it, the brown substance which remains when sodium ethyl-diacetate is heated in a stream of carbon dioxide is dissolved in water; the solution, freed from colouring matter by agitation with ether, is supersaturated with hydrochloric or acetic acid; and the dehydracetic acid thereby separated is purified by recrystallisation from ether, and then from water; it is thus obtained in orthorhombic crystals. It melts at 108.5° – 109° , boils at 269.6° , dissolves in about 1,000 pts. water at 6° , more abundantly in boiling water, and in alcohol and ether. It is monobasic; its sodium salt $C^3H^2O^4Na + H^2O$ forms long needles soluble in water; the barium salt $(C^3H^2O^4)^2Ba + H^2O$, rhombic tables; the calcium salt $(C^3H^2O^4)^2Ca$ (at 150°), thick rhombic prisms. The solution of the barium salt forms crystalline precipitates with silver nitrate, zinc acetate, and cupric acetate, but not with lead acetate.

DELPHININE. This alkaloid, obtained from the seeds of *Delphinium Staphisagria* (ii. 310), has the composition $C^{24}H^{25}NO^2$; its platinochloride is nearly white, insoluble in water, ether, and alcohol, and contains $2(C^{24}H^{25}NO^2.HCl).PtCl^4$ (J. Erdmann, *Jahresb.* 1864, p. 450).

DELVAUXITE. This mineral from Liège consists, according to Church (*Chem. News*, x. 145), of $2Fe^2O^3.P^2O^5 + 3H^2O$ (at 100°). The air-dried mineral gives off 16.9 p. c. water at a red heat. A specimen from Nenacovic, near Lodenic in Bohemia, analysed by E. Boricky (*Jahresb.* 1867, p. 1001), exhibited the composition $2CaO.P^2O^5 + 5FeO^3.P^2O^5 + 16H^2O$, assigned to the mineral by v. Hauer (ii. 310).

DEOXYBENZOIN. $C^{14}H^{12}O$.—See BENZOIN (p. 332).

DESOXYANISOÏN. $C^{14}H^{14}O^4$.—A crystalline substance produced by the action of dilute sulphuric acid on hydranisoïn or isohydranisoïn. It is very soluble in alcohol and ether, and melts at 95° (A. Kossel, *Zeitschr. f. Chem.* [2] v. 562). See ANISOÏN (p. 175).

DEVILLIN. A calcio-cupric sulphate found, together with langite, in Cornwall. (See SULPHATES.)

DEXTRIN. Limpricht (*Jahresb.* 1865, p. 673) has obtained this substance from the flesh-juice of the horse. The liquid freed from albumin and from substances precipitable by baryta-water, yielded on careful evaporation, first crystals of creatine, then a gelatinous mass, from which, by repeated solution in water and precipitation with alcohol, dextrin was obtained, exhibiting all the properties of that prepared from starch. 200 lb. of the flesh of a young horse yielded about 400 grams of dextrin.

Dextrin dissolves in acetic anhydride at 150° , forming triacetyl-dextrin, $C^6H^7(C^2H^3O)^3O^4$. The same compound is formed by the action of acetic anhydride upon starch at 160° . It is insoluble in water, but dissolves in glacial acetic acid, and is precipitated therefrom by water in white amorphous flocks. By caustic alkalis it is easily resolved into acetic acid and dextrin (Schützenberger a. Naudin, *Compt. rend.* lxxiii. 814; *Zeitschr. f. Chem.* [2] v. 264).

DIACETAMIDE. Formation from acetonitrile (p. 524).

DIALLYL. See ALLYL.

DIALOSE. A substance somewhat resembling disintegrated cellulose, obtained from the pericarp of a Chinese leguminous plant (a species of *Dialium*). It swells up in water to a bulky colourless jelly, the gummy solution of which is not precipitated by baryta-water, basic-lead acetate, or alcohol. The desiccated amorphous substance dissolves in strong sulphuric acid, but does not thereby acquire the property of becoming coloured by iodine (Payen, *J. Pharm.* [4] iv. 339).

DIALURIC ACID. $C^4H^4N^2O^4$.—This acid may be regarded as derived from alloxan, $C^4H^4N^2O^4$, by fixation of 2 at. hydrogen, or from barbituric acid, $C^4H^4N^2O^3$, by fixation of 1 at. oxygen (v. 961). It may also be regarded as tartronyl-urea,

To prepare dialuric acid from uric acid, Baeyer (*Ann. Ch. Pharm.* cxxvii. 1) converts

the latter into alloxan by Schlieper's method (treatment with hydrochloric acid and potassium chlorate), and mixes the hot solution of the alloxan (decolorised, if necessary, by animal charcoal) at once with a solution of tin in hydrochloric acid containing a quantity of tin equal to that of the uric acid employed. A quantity of hydrochloric acid is then added sufficient to make up the volume of the mixture to 4 litres for each pound of uric acid used. The liquid, after standing for a day, deposits dialuric acid (about 50 p. c. of the uric acid) in stellate groups of short four-sided prisms, having a faint yellowish colour. The mother-liquor does not yield any further quantity. To prepare dialuric acid from alloxantin, sodium-amalgam is added to a thick pulp of the latter, with constant stirring, as long as any action takes place, and the sodium dialurate, formed according to the equation,

is decomposed with hydrochloric acid.

Dialuric acid heated with acetic acid and an alkaline nitrite is converted into allantoin, without the formation of any other organic compound; probably thus:

(W. Gibbs, *Zeitschr. f. Chem.* v. 604).

DIBARBITURIC ACID. See URIC ACID, DERIVATIVES OF (v. 962).

DIBENZYL. See BENZYL (p. 334).

DICYANIC ACID, $\text{C}^2\text{N}^2\text{H}^2\text{O}^2$, is produced, according to Pönsen (*Ann. Ch. Pharm.* cxxviii. 339; *Jahresb.* 1863, 353), by the action of nitrous acid on cyanurea (cyano-carbamide) suspended in water:

It crystallises from hot water in efflorescent monoclinic prisms containing 3 mol. water. It is bibasic, forming acid and neutral salts, e.g. $\text{C}^2\text{N}^2\text{HAgO}^2$ and $\text{C}^2\text{N}^2\text{Ag}^2\text{O}^4$. According to Hallwachs, however (*Zeitschr. f. Chem.* [2] vi. 353), Pönsen's cyanurea is nothing but impure ammeline, and his dicyanic acid is most probably identical with cyanuric acid.

Hofmann has lately shown that the crystalline body produced on bringing phenyl cyanate in contact with triethylphosphine, which he formerly regarded as phenyl cyanurate (iv. 611), is in reality diphenyl-isodicyanate or diphenyl dicarbodi- amide, $\text{N}^2(\text{CO})^2(\text{C}^6\text{H}^5)^2$ (*Deut. Chem. Ges. Ber.* 1871, 246).

DICYANODIAMIDE. See CYANAMIDE (p. 517).

DIDYMIUM. Di. Atomic Weight 96.—Bunsen (*Pogg. Ann.* cxviii. 100) has made a very exact examination of the absorption-spectrum of didymium salts. As the breadth of the dark bands varies with the thickness and concentration of the absorbing solution, it is necessary to ensure that the light, in its passage through the liquid, is always exposed to the action of the same quantity of the absorbing substance. If then l and l' denote the thickness of two transparent layers of didymium salt, solid or liquid, and d , d' the quantities of didymium contained in a unit of volume of these layers, the condition just mentioned will be satisfied if $ld = l'd'$, that is to say, if the thicknesses of the two layers are inversely proportional to the quantities of didymium contained in them. By examining the spectra of various didymium salts in ordinary and in polarised light, with a very powerful spectral apparatus (four flint-glass prisms of 60° , and three of 45°) and a magnifying power of 40^\times , Bunsen finds that the dark bands vary in breadth, and to a certain extent also in position, accordingly as the ordinary or the extraordinary ray is used; with unpolarised light intermediate results are obtained. Moreover, the positions of minimum illumination vary according to the nature of the salts: in didymium chloride (molec. wt. 167), didymium sulphate (mol. wt. 92), and didymium acetate (mol. wt. 214), the bands are shifted towards the red end of the spectrum in the order of the molecular weights of the respective salts. The

positions of the principal absorption-bands on Bunsen's scale (SPECTRAL ANALYSIS, vol. v. p. 382) are as follows:

α 49-56; β 71-75; δ 27-31; γ 91-93; β' = 76-80.

The others occupy the divisions 21-23, 30-31, 41-42, 68-69, 96, 98-101, 114-119. The bands α , β , β' , γ , remain the longest, as the solution is more and more diluted. α and β are the bands discovered by Gladstone (ii. 322).

Bunsen has also devised the following method of converting the dark bands of the absorption-spectrum into bright ones: A small quantity of didymium oxide is fused with phosphorus salt in a loop of platinum wire so as to obtain an amethyst-coloured bead free from bubbles, and this bead is placed before the slit of the spectroscope, between an incandescent capillary platinum wire serving as the source of light, and a small convex lens of short focus, so adjusted as to throw the image of the bead upon the slit. The stronger absorption-bands will then be distinctly seen, especially Di α . If the bead be then gradually heated by a non-luminous flame placed below it, the band Di α will increase in breadth and intensity, so long as the bead does not become red-hot; but as soon as the temperature of bright redness is attained, this band disappears completely; and if the incandescent platinum wire which serves as the source of light be gradually moved farther off, the dark band α will be replaced by a similar but luminous band upon a dark ground. Indications of a similar inversion are likewise exhibited by the other absorption-bands (*Ann. Ch. Pharm.* cxxxi. 255).

Quantitative Estimation.—The quantity of didymium contained in a mixture may be approximately estimated by the spectral method, viz. by dissolving a decigram of the substance under examination in an acid, placing the solution in a calibrated test-tube before the slit of a spectroscope, and ascertaining the degree to which it must be diluted in order that it may exhibit an absorption-spectrum equal in intensity to that produced by a solution containing a decigram of pure didymium oxide in every 10 cubic centimetres, placed in a tube of the same diameter and examined by the same spectroscope. The quantity of didymium in the original solution may then be calculated by a proportion, inasmuch as the quantity of water added to it will be greater or less in proportion to the quantity of didymium present (Balz a. Bunsen, *Ann. Ch. Pharm.* cxxvii. 1).

Separation from Lanthanum.—No exact method of separating didymium from lanthanum has yet been discovered, but the following approximate method is given by Lamour and Deville (*Bull. Soc. Chim.* [2] ii. 339). The solution of the mixed nitrates is evaporated to dryness in a shallow platinum capsule; and the residue, after being heated for a few minutes to 400°-500°, is treated with water, which dissolves chiefly the lanthanum salt, leaving undissolved a flocculent powder consisting of basic didymium nitrate, $3\text{DiO} \cdot \text{Di}(\text{NO}_3)_3 \cdot 5\text{H}_2\text{O}$. This is separated by filtration, and the evaporated solution is treated three times in the same manner till nothing but colourless lanthanum nitrate passes into solution. The separated nitrates are then strongly ignited and the residual oxides weighed. The quantity of didymium oxide thus ascertained may be 5 or 6 p. c. too high; that of the lanthanum oxide proportionally too low.

DITHYL. See ETHYL.

DIETHYLACETONE. See KETONES.

DIFRANGULIC ACID. See FRANGULIC ACID.

DIGITALIN. According to Lefort (*J. Pharm.* [6] vi. 424), the diversities in the properties and reactions of digitalin, as described by different observers, are due to the existence of two modifications of this body. The more soluble (so-called German) digitalin is obtained from the seeds, the less soluble or crystallised variety from the leaves of the foxglove, in which this latter modification predominate. To prepare ordinary (crystallised) digitalin, Lefort exhausts the leaves at 40°-50° with a mixture of equal parts of water and alcohol; precipitates the extract with a slight excess of basic lead acetate; removes the excess of lead from the filtrate with sodium carbonate; and mixes the concentrated filtrate with tannic acid. The precipitated brown digitalin tannate is washed with lukewarm water, digested with finely pulverised lead oxide, and then treated with alcohol. The solution, after decolorisation with animal charcoal, yields on evaporation crystallised digitalin, while the more soluble modification remains in the mother-liquor.

Nativelle (*J. Pharm.* [4] ix. 255) prepares crystallised digitalin by mixing 100 pts of pulverised digitalis with a solution of 25 pts. neutral lead acetate in 100 pts. water,
 Sup. N N

leaving the whole to itself for 12 hours, and then exhausting with water. The residue is exhausted with alcohol of 50 p. c.; the solution is mixed with 4 pts. neutral lead acetate, filtered, decolorised with animal charcoal, again filtered, and mixed with a solution of 2 pts. sodium phosphate; and the liquid filtered from the resulting precipitate is freed from alcohol by distillation in the water-bath. The residue of the distillation contains crystals in suspension surrounded by a yellow very bitter substance. The whole is evaporated over the water-bath to about 10 pts.; and the precipitate is washed on a filter with cold water, pressed between paper, dissolved in twice its weight of warm alcohol at 60°, and left to stand in a cool place. The liquid then deposits crystals of an inactive substance, and afterwards yellowish radiate crystals of digitalin. These are recrystallised from alcohol of 80 p. c., with addition of animal charcoal, and the dried and pulverised crystals are drenched and strongly agitated with 20 pts. of pure chloroform, which dissolves only the digitalin, leaving the inactive substance behind. On distilling off the chloroform, colourless digitalin remains behind, which may be purified by repeated crystallisation from alcohol and boiling with animal charcoal.

Crystallised digitalin is neutral, inodorous, and has a very bitter persistent taste; soluble in chloroform in all proportions, in about 10 pts. alcohol of 90 p. c. at ordinary temperatures, more easily at the boiling heat, less easily in absolute alcohol, nearly insoluble in pure ether, and in water even at the boiling heat. Sulphuric acid dissolves it with green colour, changed to red by bromine-vapour, but becoming green again on addition of water. Hydrochloric acid dissolves it with greenish-yellow colour, and from this solution water precipitates it in the form of a resin. The analysis of pure digitalin leads to the formula $(C^{21}H^{40}O)^{12}$.

The crystalline substance insoluble in chloroform, originally mixed with the digitalin, is easily purified by recrystallisation from alcohol. It crystallises in slender colourless needles which are perfectly tasteless, neutral, and free from nitrogen. It is less soluble in alcohol than digitalin, nearly insoluble in ether, chloroform, and water. Sulphuric acid dissolves it with currant-red colour, changing to yellow on addition of water. It dissolves without colour in nitric acid, incompletely in hydrochloric acid. Its composition has not been ascertained (Nativelle).

DIMETHYLACETONE. See KETONES.

DIOXINDOL. See INDOL.

DIPHENOL. See PHENOL.

DIPHENYL. See PHENYL.

DIPTYL. This name is applied by Perkin to a radicle, C^9H^9O , belonging to the cinnamyl series, supposed to exist in coumarin, that substance having the composition of acetyl-diptyl, $C^9H^9O.C^2H^3O$ (p. 498).

DISPOLINE. $C^{11}H^{11}N$ (C. Gr. Williams, *Laboratory*, p. 109).—A base homologous with chinoline, obtained, together with many others, in the distillation of cinchonine with potash, and occurring in that portion of the crude distillate which boils between 282° and 304°. The solution of this distillate in hydrochloric acid is warmed with a little nitric acid, to decompose pyrrol and other impurities, and the solution filtered from the separated resinous mass, precipitated with platinum chloride, which throws down in the first instance the platinumchlorides of bases of higher molecular weight. The liquid filtered from this precipitate yields with platonic chloride an orange-coloured granular powder not fusible at 100°. On distilling this precipitate, neutralising the distillate with hydrochloric acid, and again precipitating with platonic chloride, a platinumchloride is obtained having the same composition as the preceding, viz. $2(C^{11}H^{11}N.HCl).PtCl$.

DISSOCIATION. See CHEMICAL ACTION (pp. 424-429).

DISTYROL. $C^{10}H^{24}$.—See CINNAMENE (p. 466).

DITOLYL. See TOLYL.

DIXYL. See XYL.

DRACYLIC COMPOUNDS. See BENZOIC ACID, DERIVATIVES OF (pp. 310, 313, 314, 316, 320, 321).

DRAGON'S BLOOD. See RESINS.

DRAGON'S BLOOD TREE. *Croton Erythraea*.—The juice of this tree (indigenous in Brazil) contains—besides tannin, gallic acid, mucus, pectin, albumin, sugar, colouring matter, resin, and mineral salts—an acid, called erythraemic acid, allied to tannic acid. This acid separates, on mixing the fresh juice with water, as a tasteless and scentless brick-red powder, insoluble in cold water and in ether, soluble in alcohol and in alkalis, precipitable by gelatin, ferric oxide, and lead salts (Peckolt, *Arch. Pharm.* [2] cviii. 142).

DRUPOSE. $C^{12}H^{20}O^8$ (J. Erdmann, *Ann. Ch. Pharm.* cxxxviii. 1).—A substance produced, together with glucose, by the action of boiling moderately diluted hydrochloric acid on glycodrupose, the stony concretions found in pears:

It is a greyish-red body, similar in structure and physical properties to glycodrupose. By boiling it with dilute nitric acid, and treating the residue with water, ammonia, and alcohol, yellowish-white granules are obtained, which dissolve in cuprammonia, and exhibit the composition and properties of cellulose, probably thus:

Glycodrupose. $C^{24}H^{40}O^{18}$.—The stony concretions in pears, produced by thickening and hardening of the cell-walls, consist of this substance, together with a small quantity of mineral matter. To obtain it, the pears, after prolonged boiling with water, are converted into a thick pulp by rubbing them through a metal sieve, and the concretions which settle to the bottom on mixing this pulp with a large quantity of water are purified by digestion with dilute acetic acid, washing with water, and treatment with alcohol and ether. It forms small grains of a faint yellowish-red colour, which when heated on platinum foil, burn away without previous fusion. When heated in a tube, it yields an acid distillate and pungent vapours. When boiled with alkalis, it turns brown; with dilute acids, red. On triturating it with strong sulphuric acid, and boiling the diluted solution for some time, a liquid is obtained which reduces cupric oxide in alkaline solution. Glycodrupose is insoluble in water, alcohol, ether, chloroform, benzol, carbon bisulphide, alkalis, cuprammonia, and most dilute acids, partially soluble in dilute nitric acid. When boiled with this acid, it yields cellulose coloured abundantly than drupose; also a small quantity of oxalic acid and dark coloured humous products.

DURENE. See PHOSPHATES.

DUODECYL COMPOUNDS. Also called *Lauryl compounds*. *Duodecane* or *Duodecyl Hydride*, $C^{24}H^{50}$, is one of the constituents of American petroleum. It boils at 196° – 200° , has a faint odour of turpentine, and is attacked by a mixture of nitric and sulphuric acids at the boiling heat, yielding a crystallisable and an oily body together with volatile acids. *Duodecyl chloride*, $C^{24}H^{48}Cl$, is a faintly yellowish, nearly isodorous liquid, boiling at 242° – 245° , and of sp. gr. 0.933 at 22° (Pelouze & Cahours, *Jahresb.* 1863, p. 530).

Duodecylene, $C^{24}H^{48}$, is one of the hydrocarbons obtained by Warren and Storer by destructive distillation of the lime-soap of Mountain oil; also from Rangoon tar. It has a sp. gr. of 0.8361 at 0° , and boils at about 212° (*Zeitschr. f. Chem.* [2] i. 220).

DURENE. *Tetramethyl-benzene*. $C^{10}H^{14} = C^6H^4(CH^3)_4$.—See METHYL-BENZENE under Methyl.

E

ECGONINE. $C^8H^{15}NO^2$.—A base obtained by heating cocaine with hydrochloric acid. (See COCAINE, p. 479.)

EGG. *Analysis of the Yolk* (J. L. Parke, *Med.-chem. Unters.* i. 209; *Jahresh.* 1867, p. 776).—The yolk separated from the white was exhausted with ether till the decanted liquid appeared colourless; the residue was then treated with alcohol at 45° – 50° , and filtered warm. The substances remaining on the filter (albuminoids and inorganic salts) were washed with water to remove soluble salts; the undissolved portion was dried, weighed, and incinerated; and the weight of the ash determined. The ethereal and alcoholic extracts freed from ether and alcohol by distillation in a vacuum were dried over sulphuric acid; and the residues, after being weighed, were separately saponified by boiling for about seven hours with strong alcoholic potash solution.

α . The saponified residue of the ethereal extract, after the ether had been completely expelled over the water-bath, was dissolved in water (at least a litre to 40 grm. of yolk), and agitated with ether to dissolve out the cholesterin; the remaining aqueous solution, after supersaturation with hydrochloric acid, yielded to ether the fatty acids, which were dried in a rarefied atmosphere. In the evaporated and aqueous solution the phosphoric acid was determined by fusion with sodium carbonate and nitre.— β . The residue of the alcoholic extract, saponified with alcoholic potash, and freed from alcohol by evaporation, was dissolved in a small quantity of water and supersaturated with hydrochloric acid; the fatty acids thereby separated were filtered off and determined directly; and the phosphoric acid was estimated in the filtrate.

100 pts. of yolk thus treated yielded :

	A Fresh Yolk	B On the 10th day of incubation	C On the 17th day of incubation
Ethereal extract :	31.391	23.542	35.417
containing { Cholesterin	1.750	1.281	1.461
{ Fatty acids	25.953	19.560	29.513
{ Protagon (calc.)	17.422	13.509	17.981
Alcoholic extract :	4.826	4.039	4.516
containing { Fatty acids	2.949	2.232	2.746
{ Protagon (calc.)	10.031	8.019	9.362
Soluble Salts	0.353	0.287	0.430
Albuminoids	15.626	14.201	18.042
Insoluble Salts	0.612	0.623	0.503
Total of Solid Matter	52.808	42.692	55.213

The quantity of protagon calculated from the phosphoric acid directly determined amounts, in the alcoholic extract, to more than the total weight of the latter, showing that another substance richer in phosphorus must also be present. This conclusion has been confirmed by Hoppe-Seyler (*Med.-chem. Unters.* i. 215), who finds that the portion of the yolk which is insoluble in ether, consists of a whitish, pasty, flocculent mass, which is dissolved by a solution of common salt to a clear-filtering liquid, and may be precipitated therefrom by a large excess of water and a few drops of acetic acid. The same substance is more easily obtained in a similar manner from caviare (the salted roe of the sturgeon). If the substances precipitated by water be treated with alcohol of 40° – 50° , and the liquid filtered warm, it leaves on evaporation a substance very much like protagon, which swells up in water, is precipitated by sodium chloride from the swollen mass, but always remains soft and forms oily drops. This is the phosphoretted compound in question; it appears to be identical with lecithin (iii. 566); it is moderately soluble in alcohol, and separates from the

saturated alcoholic solution when cooled below 0° in groups of slender silky needles. Ether containing water also separates crystalline globules from the alcoholic solution. The portion of the yolk which is insoluble in alcohol consists of salts and albuminous substances, which latter are insoluble in solution of common salt, and are coagulated thereby. They are identical with the so-called vitellin, and contain on the average 0.75 p. c. sulphur, but no phosphorus if the exhaustion with alcohol has been complete. The vitellin exists in the yolk in combination with the phosphoretted substance (lecithin), the combination being broken up by treatment with alcohol, which dissolves the phosphoretted body (see also Diakonow, *Med.-chem. Unters.* i. 221; *Jahresb.* 1867, pp. 774, 778).

Colouring Matter of the Yolk.—The ethereal extract of the non-coagulated yolk of hens' eggs yields on evaporation a yellow residue consisting of fat and colouring matter. After saponification with soda-ley, the colouring matter may be extracted from the saponified mass by agitation with ether, showing that yolk of egg does not contain any colouring matter of bile, since the sodium-compound of bilirubin is insoluble in ether. The ethereal solution just mentioned leaves on evaporation a deep golden-yellow fat, non-saponifiable or difficult to saponify, which gradually solidifies to a buttery mass in consequence of the separation of cholesterolin. This fat, comparatively rich in colouring matter, is very much like the fat containing hæmatoïdin which occurs in the ovaries. It is coloured pure blue by slightly concentrated nitric acid; dissolves with golden-yellow colour in ether and chloroform; and the solution previously mixed with alcohol is decolorised by nitric acid containing nitrogen tetroxide, without any previous play of colours. With carbon bisulphide an orange-coloured solution is obtained. Ammonia does not remove the colouring matter from its solution in chloroform. These properties seem to show that the colouring matter of egg-yolk is either hæmatoïdin or a body nearly allied thereto (*Städeler, J. pr. Chem.* c. 148).

Amylaceous Substance in Egg-yolk.—According to C. Dareste (*Compt. rend.* lxxiii. 1142), egg-yolk contains a considerable quantity of microscopic granules, which turn blue with iodine, and in form and structure are very much like starch. They are mostly very small, but a few are as large as the granules of wheat-starch. With the development of the embryo this amylaceous substance gradually disappears.

Egg-shells.—W. Wicke (*Ann. Ch. Pharm.* cxxv. 78) has analysed the egg-shells of several birds, with the following results:

	Heron	Gull	Pheasant	Goose	Hen	Duck
Calcium Carbonate .	94.60	91.96	93.33	95.26	93.70	94.42
Magnesium „ .	0.69	0.76	0.66	0.72	1.39	0.50
Phosphates	0.42	0.83	1.37	0.47	0.76	0.84
Organic Substances .	4.30	6.45	4.64	3.66	4.15	4.24

Wicke also finds that the colouring matters of egg-shells are identical with the green and brown colouring matters of bile (*Jahresb.* 1859, p. 642).

From experiments by Roussin (*ibid.* p. 640) on hens fed for several days before laying, with potatoes and oats, to which different mineral salts were added, it appears that the calcium carbonate in the normal shells may be more or less replaced by isomorphous salts, such as the carbonates of barium, strontium, and even of lead, but especially by magnesium carbonate. When alkaline bromides and iodides were added to the food, the alkaline chlorides in the white and yolk of the egg were partly replaced by these salts. The increase in the proportion of bromide or iodide was however attended with a diminution of the calcareous envelope, which ultimately disappeared altogether, leaving the egg surrounded only by a membrane. The addition of calcium arsenate to the food was fatal to some of the hens; nevertheless arsenic was found in the egg-shells.

H. Boes (*Pogg. Ann.* cxvii. 627) analysed a fossil egg-shell weighing 252 grams, found in the guano of the Chincha islands. The interior crystalline or slightly laminar mass contained, together with a small quantity of organic matter:

Potassium sulphate	Ammonium sulphate	Ammonium chloride	Sodium chloride
30.59	28.55	1.25	0.65 = 99.04.

The mass contained therefore 2 mol. potassium sulphate to 1 mol. ammonium

sulphate, by which salts the original constituents of the egg had been replaced. The still remaining portion of the original shell contained in 100 pts.:

CO ²	SiO ²	Org. matter	K ² O	Cl	CaO	(PO ³) ² Ca ²
0.91	0.45	2.07	2.33	8.84	0.34	77.82.

In the interior of the egg there was found at one part a small quantity of black humous substance soluble in potash.

EKMANITE. A hydrated ferrous silicate containing manganese and magnesium, occurring in dense finely laminated veins and bands in the iron mine of Brunsjö, in Grythyttan, Sweden. It varies somewhat in structure and composition, but the general result of the analysis leads to the formula $4\text{MO} \cdot 3\text{SiO}_2 + 3\text{H}_2\text{O}$ (L. J. Igelström, *Sahresb.* 1867, p. 995).

ELAÏDIC ACID. $\text{C}^{18}\text{H}^{34}\text{O}_2$.—This acid, like oleic acid, unites directly with bromine, without elimination of hydrobromic acid, forming the compound $\text{C}^{18}\text{H}^{32}\text{Br}_2\text{O}_2$, isomeric (or identical?) with dibromostearic acid. It is a white crystalline acid soluble in alcohol and ether, melting at 27° . It is monobasic; the barium salt is gummy and friable. By sodium-amalgam it is reconverted into oleic acid (Burg, *Bull. Soc. Chim.* [2] iii. 191).

ELALDEHYDE. See ALDEHYDE (p. 76).

ELECTRICITY. **Holtz's Electrical Machine** (Holtz, *Pogg. Ann.* 1865, cxix. 157; *Phil. Mag.* [4] xxx. 425; *Ann. Ch. Phys.* [4] viii. 201.—*Pogg. Ann.* cxvii. 320; cxxx. 128, 168, 287; *Ann. Ch. Phys.* [4] xiii. 440.—*Pogg. Ann.* cxxxvi. 171; *Ann. Ch. Phys.* [4] xvii. 503. Poggendorff, *Pogg. Ann.* cxxxiv. 304; cxxxix. 158. Riess, *Pogg. Ann.* cxxxi. 215; cxl. 168, 276. F. Kohlrausch, *Pogg. Ann.* cxxxv. 120).—This is a contrivance by which a very small initial charge is made to give rise to an indefinitely great quantity of electricity of high tension; its action may be described in general terms as equivalent to that of an electrophorus and a condenser combined together in such a way as to act upon each other alternately, the condenser being first charged by the electrophorus, then reacting upon it so as to increase the charge of the cake; next being charged by the electrophorus to a higher degree and reacting upon it more strongly than before; and so on, the charge of each becoming gradually greater and greater until the insulation is overcome. The form usually given to the machine is shown in fig. 11. Its construction is as follows. A circular plate of thin and very flat glass, mn , is mounted upon an insulating ebonite axle, so that it can rotate in a vertical plane, and a second glass plate, AA , also as thin and flat as possible, is fixed parallel to it, with its centre in the same horizontal line, and at a very short distance ($\frac{1}{8}$ to $\frac{1}{4}$ inch) from it. At the middle of the fixed plate there is a round hole, through which the axle of the movable plate can pass without touching, and there are two deep notches or *windows*, FF' , cut out at opposite ends of a diameter; at the back of the glass (that is, on the side turned away from the rotating plate) a piece of paper, p , about two inches broad is pasted along the lower edge of one of these openings, and a similar piece, p' , is pasted along the upper edge of the other opening, each of these pieces of paper having projecting from it a couple of tongues of stiff paper, nn' , long enough to project through the opening and just touch the movable plate; both the papers and their projecting tongues are well varnished. On the side of the movable plate which is farthest away from the fixed plate, and opposite to the two pieces of paper just mentioned, are two collectors, oo' , each consisting of a row of metal points projecting from an insulated metal arm to within a very small distance of the rotating plate. These collectors are connected with the main conductors of the machine, cc' , each of which is provided with a movable discharging rod, xx' , by means of which they can at will be placed in electrical connection with each other, or separated by any required interval. In order to put the machine in action, the two conductors are connected together, the movable plate is set rotating at a moderate speed, and while it is moving, an electrified body, such as a piece of ebonite excited by friction, or the cover of an electrophorus, is brought near to, or into contact with, one of the paper armatures. Both the papers then rapidly become strongly charged with opposite kinds of electricity, and if the knobs, rr' , of the discharging rods are separated to a short distance, a stream of sparks is seen to pass between them. These sparks become less frequent, but larger and brighter, if each of the conductors is connected with the inside coating of an uninsulated Leyden jar. The sparks also increase in size, but diminish in frequency, when the discharging knobs are moved farther apart, but if the distance between them is made greater than a certain limit, depending chiefly upon the insulation of the different parts of the machine, the sparks cease to

pass altogether, and, unless the knobs are quickly brought nearer to each other, the machine soon ceases to act.

The action of the machine may be explained, at least as to its general features, as follows. Suppose a positive charge to be given to one of the paper armatures: then, at all points in the neighbourhood of the paper, there will be a force acting which tends to drive positive electricity away from it, and to draw negative electricity near; and this force, acting successively upon each portion of the rotating plate as it passes between the paper and the points of the collecting comb, will, if sufficiently powerful, cause positive electricity to escape from the plate into the points, and negative electricity to escape from the points upon the plate. In consequence of this action, the comb of the second conductor (which, as we have said, is, to begin with, in metallic connection with the first) becomes positively electrified, while each portion of the glass plate passes the comb of the first conductor negatively electrified. But before any given part of the plate comes opposite to the points of the second conductor, its back is grazed by the tongues projecting from the second paper armature, and therefore negative electricity is repelled into this armature by the negative charge upon the front

FIG. 11.

surface of the plate: in this way, the second armature gradually acquires a negative charge. We now have, at the second side of the machine, what may be called a stream of glass flowing between a negatively electrified piece of paper and the positively electrified points of the second collecting comb; hence positive electricity escapes from the points upon the glass, and negative electricity passes from the glass into the points, and consequently the glass passes this row of points positively charged. Then, returning to the first side of the machine, we have the glass arriving opposite the tongues of the first armature with a charge of the same kind (positive) as this armature has already got, but of higher tension (because it is due to the inductive action of this armature aided by the condensing effect of the opposite charge upon the other armature), and therefore able to strengthen the original charge of the paper. Next, the glass passes between this more strongly charged armature and the corresponding row of points, which now give up negative electricity to it, not only in consequence of the inductive action of the charge upon the first piece of paper, but also of the reaction of the negative charge upon the second paper. Consequently, the glass passes the first row of points with a stronger negative charge than it had at first,

and therefore strengthens the charge of the second paper armature, which in its turn reacts more powerfully than before upon the glass, as it passes between it and the now more strongly positive row of points of the second conductor, and so causes it to return to the first armature with a stronger positive charge than before. In this way, as the rotation continues, the two pieces of paper on the fixed plate become more and more strongly charged with the opposite electricities, and therefore exert a stronger and stronger inductive action upon the rotating plate as it passes between them and the collecting combs. Supposing, for the sake of distinctness, that the side of the machine to which the positive charge is first given is the side on which the motion of the revolving plate is upwards, the action may be described in general terms as consisting in the convection of negative electricity from the first collecting comb to the second by the upper half of the revolving plate, and the convection of positive electricity in the opposite direction by the lower half; and since the motion of negative electricity in one direction is the same thing as the motion of positive electricity in the opposite direction, the action of both halves of the plate may be described as causing the transfer of positive electricity from side to side, in the direction of the motion of the lower half, which is compensated by a corresponding flow of positive electricity in the opposite direction through the conductors. It is this last-mentioned current which shows itself as a stream of sparks when the discharging rods of the conductors are separated.

From this explanation of the action of the apparatus, it will be seen that it depends essentially upon the charge of each part of the revolving plate being of the opposite sign to that of the armature which it last passed, and of the same sign as that of the one which it is approaching; but this cannot be, unless there is electrical communication between the two conductors. If the knobs of the conductors are separated too far, no electrical interchange can take place between them, and the armatures then represent two oppositely charged conductors of limited capacity, between which portions of glass are continually passing backwards and forwards conveying a part of the charge of each to the other, and thus soon equalising them: hence under these circumstances the machine ceases to act.

In order to charge a Leyden jar or battery by means of a Holtz's machine, it should be placed on an insulating support, and one of the coatings connected with one of the conductors, and the other with the other; or two jars may be charged at once by connecting their outer coatings together and connecting each conductor with the inner coating of one jar. The figure shows two small Leyden jars, π and π' , whose outer coatings are connected by the wire α , suspended from the conductors. By this arrangement of course the jars receive opposite charges. Some care is needed in trying to charge a jar to the highest point with one of these machines: if the knobs r r' are so far apart that a spark is unable to pass between them, the action of the machine ceases when the jar is charged so highly that the two halves of the revolving plate are no longer charged by the inductive action of the armatures they have respectively last passed, as highly as the armatures which they are approaching; and if the movement of the machine be continued beyond this point, the charge which the jar has already got will be destroyed; on the other hand, if the discharging knobs are nearer together, the jar is up to be discharged by them before it has acquired as high a charge as might be given to it. To remedy this inconvenience, Riess adds to the machine a third paper armature, with a third collecting comb opposite to it, halfway between the two armatures already spoken of. This additional armature has no projecting point, but is connected, by a strip of paper pasted along the edge of the fixed plate, with the armature which precedes it in relation to the direction of rotation of the revolving plate, and the additional collector is in metallic connection with the conductor which follows it, and likewise with the ground. The inner coating of the jar or battery to be charged is connected with the conductor which still remains insulated, and the outer coating is connected with the ground. The action of these additional parts is easily understood if we bear in mind that the additional armature is equivalent to an extension of the one with which it is connected, and that the additional collector takes the place of the one connected with the jar when this one has ceased to act in consequence of the jar being fully charged. The writer of this article has found that a Leyden jar may easily be charged to a high degree by a machine of the construction shown in fig. 11 (p. 551), if the jar is first insulated, one coating connected with one of the paper armatures, and then a conductor connected with the other armature, gradually brought near, and finally into contact with the other coating. During this process, the discharging knobs r r' should be at a moderate distance apart, and a stream of sparks should pass freely between them.

The electric current through a wire connecting the conductors of a Holtz's machine has been shown by Poggendorff to be independent of the resistance of the circuit,

and by F. Kohlrausch to be sensibly proportionall to the velocity of rotation. The latter found that a plate 40 centimetres in diameter, revolving 5 times in 3 seconds, produced a constant current capable of decomposing water at the rate of $3\frac{1}{2}$ millionths of a milligramme per second, or equal to that of a Grove's cell in a circuit of 48,000 mercurial units (about 45,000 B. A. units) resistance.

Besides the machine which has been described, Holtz has constructed machines acting upon the same general principle, but differing from this one considerably in arrangement; the construction has also been varied and simplified by Poggendorff, his most important alteration being the substitution of small holes, just large enough to let the tongues of the paper armatures pass through, for the large openings of Holtz's original form.

An electrical machine, acting essentially upon the same principles as Holtz's, but in which the inductive action is exerted upon sheets of tin-foil carried by revolving glass plates, was constructed by Töpler of Riga (*Pogg. Ann.* cxxy. 469; *Ann. Ch. Phys.* [4] viii. 313) at about the same time that the first machines were made by Holtz; but it has not yet come into such general use, and does not seem to have been made to yield such powerful effects as those that have been obtained from machines of the kind we have just described. A machine analogous in many respects to that of Holtz has also been recently described by Poggendorff (*Pogg. Ann.* cxli. 161); and a self-acting arrangement, nearly equivalent to Töpler's machine, but with a stream of water, instead of tin-foil, as the moving conductor, has been constructed by Sir William Thomson (*Proc. Roy. Soc.* xvi. 67).

Thomson's Electrometers. Several different forms of electrometer have been recently devised by Sir William Thomson, which are much more sensitive and accurate than any that had been constructed previously. For details respecting these instruments, we must refer to Professor Thomson's description of them (*Rep. Brit. Assoc.* 1867, p. 489): here we can only give the general principle of two of the most generally useful forms—the 'Quadrant Electrometer' and the 'Portable Electrometer.'

The most important part of the Quadrant Electrometer, and that from which it takes its name, is shown (as seen from above) in fig. 12. It consists of four quarters of a flat circular box of brass, with circular apertures in the centres of its top and bottom, each of the quadrants being supported by a glass stem. The alternate quadrants *a* and *d*, *b* and *c*, are connected by wires so as to form two pairs, as shown in the figure, and one of the two bodies whose electrical states are to be compared, such as the terminals of a galvanic battery, or the earth and any body supposed to be positively or negatively electrified, is put into electrical connection with each pair. The indications of the instrument are due to the movements of a broad needle, *n*, of thin sheet aluminium, which is electrified and suspended inside the box formed by the four quadrants by an insulating fibre of silk. If all the quadrants are in the same electrical condition, and the needle is suspended quite symmetrically within them, it is evident that it will be in equilibrium when its axis is in the same vertical plane with one of the diameters of the box; but if the alternate quadrants are differently electrified, each end of the needle will be repelled by the two which are electrified in the same way as itself and attracted by the other two, and it will thus be subject to a couple tending to set it oblique to the position shown in the figure. In order to render the smallest motion of the needle visible, a small and very light concave mirror is fixed to a platinum wire which passes through it and reflects the light of a lamp, which is allowed to fall upon it through a narrow slit, upon a divided scale at a distance of about a metre. In the instruments first made, the needle was caused to come to rest in the zero position by the directive force of a minute magnet fastened to it and acted on by a larger steel magnet outside the case of the electrometer; but in the most recent instruments, the directive force of a bifilar suspension by two fine silk fibres is substituted for that of the magnet. The insulation of the quadrants of the needle is made as perfect as possible by enclosing them in a glass jar containing a quantity of strong sulphuric acid at the bottom. The outside of this jar is partially coated with tinfoil, which, with the sulphuric acid inside, converts it into a Leyden jar: this serves to increase the electrical capacity of the needle,

FIG. 12.

and so to make it retain for a long time a nearly constant electrical condition. Electrical connection between the needle and the sulphuric acid forming the inner coating of the jar is made by means of a small platinum weight, suspended in the acid by a very fine platinum wire attached to a stouter platinum wire passing through the needle, an arrangement which also diminishes very much the oscillations of the needle.

In the *Portable Electrometer*, the body whose electrical state is to be tested is connected with an insulated brass disk, opposite the middle of which is a small square plate of aluminium, fixed to the shorter arm of a light lever of the same material, and kept at a constant electrical charge by being connected with the inner coating of a Leyden jar. The measurement is made by observing, by means of a suitable micrometric arrangement, the distance at which the disk exerts a given attractive force upon the aluminium plate. In using the instrument, an 'earth-reading' is first taken, by observing the position of the disk in which it exerts this force when both the disk and the outer coating of the Leyden jar are connected with the earth. Then the earth-reading, subtracted from the reading obtained when the disk is connected with the body to be tested, gives the electrical difference between this body and the earth expressed in terms of an arbitrary scale, the value of which can be ascertained, if required, by a special experiment with two bodies whose electrical states differ by a known amount. It is an obvious precaution, in order to obtain great accuracy, to take a second earth-reading, after making the experiment with the body to be examined, and if this differs from the first, to estimate the most probable earth-reading for the moment of the experiment with the body in question.

New forms of Galvanic Battery. Many attempts have been made to construct a galvanic cell which should combine the good qualities of the older forms of constant batteries (such as Daniell's, Grove's, Bunsen's) with greater convenience in use and the absence of the necessity for frequent examination or renewal; we will briefly describe a few of the newer forms.

1. *Walker's Platinised Carbon Battery.*—This is simply a modification of Smee's battery (ii. 427) in which the platinised platinum or silver is replaced by a plate of platinised gas-carbon. The carbon plates are platinised by being made for a short time the negative electrode in a weak solution of platonic chloride in dilute sulphuric acid. A battery of this construction, although in proportion to its size much cheaper than one of Smee's, appears to be at least equal to it in efficiency (C. V. Walker, *Phil. Mag.* [4] xviii. 73).

2. *Bichromate of Potassium Battery.*—When a battery of small resistance but considerable electromotive force is required occasionally, amalgamated zinc and gas-carbon, immersed in a solution of equal weights of potassic bichromate and hydric sulphate in about twenty times their weight of water, forms a very convenient combination. As the solution gradually attacks the zinc, even when the circuit is not completed, the zinc plate in cells, constructed on this principle, is generally fixed to a brass rod by which it can be drawn up out of the liquid or let down to any depth between two parallel plates of carbon.

3. *Chloride of Silver Battery.*—Messrs. Warren De la Rue and Hugo Müller (*Chem. Soc. J.* xxi. [new series, vi] 488) recommend, as a compact and convenient battery for use in cases where several hundred small cells are required to give a great electromotive force, one of the following construction: The electro-positive plates consist of pieces of Belgian zinc wire (English zinc being too impure for the purpose) $2\frac{1}{2}$ inches long and 0.2 inch in diameter; the electro-negative plates are formed by pieces of pure silver wire 0.03 inch in diameter, round which is cast a cylinder of silver chloride 0.22 inch in diameter. The silver wire projects about a fifth of an inch below the bottom of the cylinder of chloride and about an inch and a half above the top, so as to allow of its being connected with the zinc of the next cell. The liquid used is a solution of common salt in distilled water, 25 grammes to the litre (or 219 grains to the pint). A battery of this construction may be left to itself for weeks together, if the poles are not connected, without other injury than the evaporation of water. From the size of the plates employed, it is evident that its resistance must be very considerable; its electromotive force is about equal to that of a Daniell's cell (see p. 579).

4. *Sulphate of Mercury Battery.*—This may be described as a Bunsen's battery, in which the nitric acid is replaced by mercurous sulphate. As usually made, the zinc plate is in the form of a hollow cylinder, surrounding a porous vessel containing a rod of gas-carbon, and filled up with powdered mercurous sulphate and enough water to make it into a thick mud; outside the porous vessel and in contact with the zinc is dilute sulphuric acid. This battery, which was proposed by Marié-Davy, is recommended

as being very constant and requiring little supervision. It has come into use to some extent for telegraphic purposes (Wiedemann, *Galvanismus*, p. 271).

5. *Binoxide of Manganese Battery*.—This is another zinc and carbon battery, but the porous cell containing the carbon plate is filled up with a mixture of binoxide of manganese in coarse powder and small fragments of gas-carbon, the object of which is to increase the conductivity. Only one liquid is employed, namely a saturated solution of sal-ammoniac; the electro-positive metal is amalgamated zinc. Cells of this construction are said by the inventor, M. Leclanché, to remain in working order for months, or even a year, together, without requiring other attention than the occasional replacement of the water which has evaporated. It is extensively used for telegraphic purposes in France.

6. *Meidinger's Battery*.—This is a modification of Daniell's battery, and differs from the common form of it only in the arrangement of the parts and in not having any porous partition between the copper and zinc plate. Its construction will be understood by reference to fig. 13,* where A is a glass vessel 170 mm. high and 100 mm. wide at the bottom and to a height of 50 mm. from it; above this height it is 110 mm. wide, and on the shoulder, formed by the junction of the narrower part with the wider, rests the cylinder of amalgamated zinc, z, 90 mm. deep. Another slightly conical glass vessel, n, 75 mm. high, 65 mm. wide at the bottom and a little wider at the top, is cemented inside A, and contains a cylinder of sheet copper, c, to which is fixed a copper wire, w, insulated where it passes through the liquid by a glass tube or a covering of gutta-percha. A wide glass tube, b, constructed before the lamp so as to leave only a small opening at the bottom, which is about 20 mm. from the bottom of the vessel n, is supported by the cork or wooden lid k, and is nearly filled with crystals of sulphate of copper.

FIG. 13.

The liquid with which the cell is charged is a solution of sulphate of magnesia in rain or distilled water, from 50 to 125 grammes of the commercial salt being allowed for each cell. This liquid, entering the tube containing the sulphate of copper, forms a saturated solution which collects at the bottom of the vessel n in contact with the lower part of the copper plate. It is evident that such a cell cannot be moved about without danger of mixing the solutions, but when left at rest it is very constant (Meidinger, *Pogg. Ann.* cviii. 602). A simplified form of Meidinger's battery has been described by Pincus (*Jahresh. f. Chem.* 1868, p. 99).

7. *Sir William Thomson's Battery* (*Proc. Roy. Soc.* [1871] xix. 253; *Chem. Soc. J.* xxiv. 102).—This is another Daniell's battery in which the porous diaphragm is dispensed with. The cell is a round or rectangular glass jar with a flat bottom, which should be 10 centim. or more in depth, when permanence and ease of management are of more importance than very small internal resistance. A disk of thin sheet copper is laid upon the bottom of the cell, with a copper wire, insulated with gutta-percha, fastened to it to serve as electrode. A grating of zinc, also provided with an electrode, is supported in the upper part of the jar. A glass tube (the charging tube) a centimetre or more in internal diameter, expanded to a funnel at the top, is supported so that its lower open end may be about one centim. above the copper. A glass siphon, with a cotton-wick core, or a capillary glass tube, is placed so as to draw liquid gradually from a level about $1\frac{1}{2}$ centim. above the copper, and to discharge it at a level slightly higher than the upper surface of the zinc. To put the cell in action, the jar is filled with semi-saturated solution of zinc sulphate, and finely broken crystals of copper sulphate are placed in the funnel at the top of the charging tube. To keep the cell in working order, pure water, or water one quarter saturated with zinc sulphate, should be added from time to time to replace that drawn off by the siphon, so as to keep the liquid in contact with the zinc about half saturated with zinc sulphate.

8. *Siemens and Halske's Battery*.—Messrs. Siemens and Halske have also introduced a modified form of Daniell's battery, intended to remain in action for a considerable

* Drawn to a scale of $\frac{1}{2}$.

time without requiring attention. It is more complicated than Meidinger's and requires a porous cell of peculiar form : for a description and figure we must refer to *Pogg. Ann.* cviii. p. 608.

It is impossible to give any unqualified recommendation or condemnation of these or the many other batteries that have been proposed from time to time, since the qualities which are considered advantageous in a battery differ almost as much as the purposes to which it can be applied. Sometimes compactness is the chief thing to be aimed at, sometimes cheapness ; sometimes it is needful to be able to produce a current of short duration at any moment, sometimes a current is wanted to be of nearly constant strength for days together ; sometimes great electromotive force is required, and consequently a very large number of cells must be used (in such cases the chief desideratum is simplicity of construction, so that the labour of charging the cells may be as small as possible) ; and in other cases, again, other qualities assume the greatest importance. In most cases a little consideration of the chemical and mechanical structure of a galvanic cell will leave but little doubt as to whether or not it is suitable for any proposed purpose. For instance, it is obvious that cells in which the plates are small and far apart must have great internal resistance, and hence that a strong current can never be obtained from them, except by combining a great number of them abreast ; again, if it is needful to leave a battery charged for days or weeks at a time, ordinary Grove's, Bunsen's, or Daniell's cells would be unsuitable, on account of the gradual mixture of the two liquids and consequent solution of the zinc which would take place ; in such cases, Thomson's, Meidinger's, Marié-Davy's, or sometimes Leclanché's batteries might be used. In other cases—as, for instance, for the electro-deposition of metals, or whenever a strong current is to be maintained for a considerable time—it is essential that the capacity of the cells should be large compared with the size of the plates, in order that the amount of chemical action which takes place may not affect any very great proportion of the liquid or liquids with which the battery is charged. It must also be remarked further, in reference to the characters commonly ascribed to particular kinds of batteries, that the term 'constant battery' is frequently used in two very different senses. On the one hand, batteries are often called constant if they give a current of sensibly the same strength when their terminals are repeatedly joined for a short time by the same conductor at intervals of a few hours or days ; whereas the proper meaning of the term constant, as applied to a battery, means that, if the poles are kept joined by a given conductor, a current of sensibly constant strength will be maintained for a greater or less length of time, and that, if the resistance of the circuit is altered, the strength of the current will alter in the inverse ratio. For a battery to be constant in the former sense, it is sufficient that there should be no local action when the poles are disconnected, and no spontaneous alteration due to the mixing of the liquids employed or other similar cause ; these conditions are sufficiently fulfilled by Leclanché's and various other batteries, which are far from being constant in the true sense. Real constancy requires in addition that there should be no polarisation (ii. 429, 424), or, in other words, that the electromotive force should not vary with the strength of the current. Probably, properly constructed Grove's or Daniell's cells, of sufficient capacity, with well-amalgamated zinc plates, and with porous partitions sufficiently thick to prevent rapid mixing of the liquids, come nearer to possessing this kind of constancy of action than any other combinations that have been proposed hitherto. A table giving the comparative electromotive forces of several kinds of cells will be found at p. 579.

Thomson's Galvanometer. In the ordinary double-needle galvanometer (ii. 443, 444), the moment of inertia of the needles is usually considerable as compared with the moment of the deflecting couple due to a very weak current, and consequently the instrument is sluggish in its indications, and, if a current passes through it for only a very short time, may not even show any appreciable deflection ; and again, when the astatic system has been deflected, its inertia prevents it from coming to rest again until after a considerable number of oscillations, and thus renders it impossible to make a series of observations in rapid succession with this instrument. If we try to remedy these defects by reducing the length of the needles, we run the risk of making the change of position due to a small angular displacement imperceptible. In these respects the galvanometer devised by Sir William Thomson is a very great improvement on the instruments previously in use. This is represented in its most complete form in fig. 14. A and B in this figure are two rather flat metallic bobbins filled with coils of fine copper wire, well insulated throughout its length, and wound in opposite directions upon each. The back and front of the bobbins are made in separate pieces, which when put together leave a small free space between them, as is shown in fig. 15, which represents a section of the bobbins and coils by a vertical plane passing through their axes. In this space is suspended by a silk fibre the astatic

system of magnets *M* and *N*, each formed of a bit of fine watch-spring about $\frac{3}{4}$ inch long, and connected by a thin strip of aluminium of such a length that one of the magnets is at the middle of each coil. In order to render the deflections of the

FIG. 14.

FIG. 15.

FIG. 16.

magnets perceptible, a small concave mirror of very thin silvered glass is fixed to the magnet inside the coil *A* (fig. 14), and reflects the light of a paraffin-lamp, which falls upon it through a narrow slit, *c*, so as to form an image of the slit upon the

divided scale *nm*, at a distance of about three feet. This mirror, together with the two magnets and the connecting strip of aluminium, is shown in fig. 16 in its real size. All these parts are made so light that all together they weigh only about three grains. When no current is passing through the instrument, the axes of the suspended magnets ought to be perpendicular to the axes of the coils, and the image of the slit ought to be formed at the centre of the divided scale. In order to ensure the fulfilment of these conditions, the scale should be set at right angles to the vertical plane passing through the axes of the coils, and with its middle point, which ought to be directly over the slit, in this plane, and then the position of the large adjusting magnet *r* should be changed until the image appears in the required position. This adjustment can be made very accurately by means of the tangent-screw *g*.

Another form of the same instrument, specially intended for use on board ship, is represented in fig. 17. In this instrument there is only one coil and one magnet,

FIG. 17.

and in order to counteract the effects of the ship's motion, the magnet and mirror are fixed to the middle of a silk fibre, which passes exactly through their common centre of gravity and is stretched from end to end of a brass slide (represented apart at *d*). This slide fits into a groove in the centre of the coil *n*, and the magnet is kept in an invariable position relatively to the coil, when no current is passing, by a broad steel horse-shoe magnet, *x*. The adjustment of the image of the slit to the zero-point of the scale is made in this instrument by means of a pair of straight magnets placed together with their like poles in opposite directions and contained in a brass tube at *c*: by means of a rack-and-pinion motion these magnets can be slid over each other in opposite directions, and thus can be made to neutralise each other entirely as to their action on the suspended magnet, or by making one of them project beyond the other the action of either can be made to preponderate to any required extent. Lastly, in order to counteract the local attractions due to the iron of the ship or of its freight, the instrument is enclosed in a thick casing of wrought iron, *a*.

It is easy to see that, with the scale at three feet from the mirror, the motion of the spot of light corresponding to any given angular deflection of the magnet will be equal to the tangent of twice the angle of deflection referred to a circle of three feet radius. This circumstance not only implies that very weak currents will produce sensible movements of the spot of light, but justifies us in concluding that currents which are not so strong as to send the spot of light beyond the end of the scale are proportional to the displacements they produce. Hence, for very weak currents a Thomson's galvanometer is an accurate measuring instrument. It can also be used for the comparison of stronger currents if, instead of allowing the whole current to traverse the instrument, some known proportion of it only, not too great to let the spot remain on the scale, be allowed to pass through it. For this purpose, a set of coils, technically called 'shunts,' generally adjusted so as to have respectively $\frac{1}{10}$, $\frac{1}{20}$, $\frac{1}{50}$, . . . of the resistance of the galvanometer-wire, are usually supplied with it by the makers. When one of these coils is put into the circuit, in multiple arc with the galvanometer, $\frac{1}{10}$, $\frac{1}{20}$, or $\frac{1}{50}$. . . of the current passes through the shunt, and only $\frac{1}{10}$, $\frac{1}{20}$, or $\frac{1}{50}$ respectively through the galvanometer (see p. 565).

Magneto-electric Induction Machines. When a coil of wire surrounds an iron core, any alteration in the magnetic condition of the core produces an electromotive force in the wire; and if the coil forms part of a closed circuit, a current is produced in it the strength of which is proportional to the electromotive force, but inversely proportional to the resistance of the circuit. The magnitude of the electromotive force at any instant is proportional to the number of times the wire passes round the core, and to the rate at which the magnetic moment of the core is varying at that instant; consequently, the average electromotive force which acts in the wire during any given interval of time can be increased either by increasing the number of turns of wire forming the coil, or by increasing the magnetic change taking place in the core during the interval in question. If, however, we endeavour to increase the strength of the current, by augmenting the electromotive force in the former of these ways, a point is reached sooner or later beyond which any further addition to the length of the coil makes the current weaker instead of stronger; for, with a core of finite length, only a limited number of turns of wire can be placed in immediate proximity with it, and, if more wire is to be wound round it, the additional length must be arranged in one or more layers outside the first, and therefore of greater diameter, so that, after the first layer, the resistance of the circuit increases more rapidly than the electromotive force.

Applying these considerations to the construction of magneto-electric machines, we see that, other conditions being the same, that machine will give the strongest current in which the greatest length of wire is within a given distance from the core, and in which the changes in the magnetisation of the core are the most considerable.

These conditions are fulfilled much more perfectly in the form of magneto-electric machine devised by Siemens (*Pogg. Ann.* ci. 271 [1857]) than in the machines previously constructed, such as those described in vol. ii. pp. 455-457. The principal peculiarities of this arrangement are: first, that the soft iron keeper or armature, to the reversal of whose magnetism the induced currents are due, is magnetised transversely instead of longitudinally; secondly, that the action of the permanent steel magnets, instead of being concentrated upon the ends of the armature, is distributed over its whole length. Consequently, at each reversal of the magnetic polarity of the armature a much smaller coercive force has to be overcome than would be the case if the magnetisation were longitudinal; and the permanent magnets, being separated a short distance from each other, instead of being combined into one large magnet, retain their magnetism more completely.

A perspective view of a Siemens's armature is given in fig. 18, and a transverse section in fig. 20 (p. 560); a complete magneto-electric machine provided with one of these

FIG. 18.

armatures is represented in the upper part of fig. 19, the Π -shaped bodies r being the permanent steel magnets between whose poles the armature rotates. The armature itself is made by cutting two deep rectangular or semicircular grooves along the whole length of a cylinder of wrought iron, so as to leave the remainder with a transverse section approaching in shape to that of a dumb-bell, as shown in fig. 20. The wire forming the coil is wrapped longitudinally round the piece of soft iron, so as completely to fill the grooves, as represented in figs. 18, 20. a and b , in the former figure, are the surfaces of the iron core, which assume alternately north and south magnetic polarity, as it revolves between the poles of the fixed magnets; at c there is a commutator consisting of two pieces of steel, insulated from each other, each of which is connected with one end of the coil; n and z are brass collars which serve to keep the coil of wire in its place; and p is a pulley round which the driving belt works.

A very important improvement in the construction of magneto-electric machines, whereby they were made to produce effects greatly surpassing anything that had been previously obtained, and were in fact converted into the most powerful generators of dynamic electricity hitherto constructed, was made by Mr. Henry Wilde, of Manchester, in 1863 (*Patent* No. 3006, December 1, 1863; *Proc. Roy. Soc.* xv. 109 [1866]; *Phil. Mag.* [4] xxxii. 148). Without entering into details of

FIG. 19.

FIG. 20.

mechanical construction in connection with Wilde's machines, we may state the general principle of his invention to consist in the employment of the current produced by a magneto-electric machine, with an armature such as has been described, to excite an electro-magnet, and in using this electro-magnet to induce electric currents in the coil of a second armature of similar construction but larger size. Mr. Wilde was led to this mode of employing the current of the magneto-electric machine by the observation which he made that this current was capable, when used to magnetise soft iron, of producing electro-magnets of far greater power than the permanent magnets by which it was generated. Fig. 19 is a representation of a Wilde's magneto-electric machine: the upper part consists of a simple magneto-electric machine, and the lower part of a similar machine on a larger scale, with the substitution of the electro-magnets *in situ*, excited by the current of the smaller machine on the top, for permanent magnets. The extremities of the magnets, in both the upper and the lower machine, rest upon two pieces of soft iron (c.c. figs. 19, 20) of the same length as the armatures; these are hollowed out on the sides which are turned towards each other, so that, with the pieces of brass, *o o*, by which they are kept apart, they form two complete cylinders, within which the armatures revolve.

When once it had been ascertained that the current of a magneto-electric machine could be multiplied by causing it to excite an electro-magnet in a second machine, the further step of carrying the multiplication to a higher degree, by combining together three or more machines, was obvious. This step was made by Wilde, who used the current from a machine having six permanent magnets, each weighing 1 lb. and capable together of lifting about 60 lb., and an armature $1\frac{1}{2}$ inch in diameter, to excite the electro-magnet of a second machine, having an armature 6 inches in diameter, while at the same time the current of the latter was made to traverse the electro-magnetic coils of a third machine, with an armature 10 inches in diameter. When the armatures of this triple machine were kept in rapid rotation by a powerful steam-engine, a current of enormous power was obtained from the third armature. When this armature was coiled with an insulated copper conductor 67 feet long and weighing 344 lb., and was driven at a uniform speed of 1,500 revolutions per minute, the current was sufficient to melt pieces of a cylindrical iron rod 15 inches long and $\frac{1}{2}$ inch in diameter, or an equal length of copper wire $\frac{1}{4}$ inch in diameter. When the coil upon the armature consisted of a bundle of thirteen copper wires 376 feet long and weighing 232 lb., the same speed of revolution furnished a current which, when allowed to pass between rods of gas-carbon half an inch square, cast shadows of the flames of street lamps at a distance of a quarter of a mile, and produced upon ordinary photographic paper in 20 seconds a blackening effect equal to that produced by the full sunshine of a very clear March day in one minute.

The next step in the improvement of magneto-electric machines was made almost simultaneously by Drs. Werner and C. W. Siemens (*Proc. Roy. Soc.* xv. 367 [February 4, 1867]) and by Sir Charles Wheatstone (*Proc. Roy. Soc. ibid.* p. 369 [February 14, 1867]). The general principle involved in their improvements may be thus stated: If two pieces of soft iron, each of them slightly magnetised and surrounded by a coil of wire, both coils being connected so as to form parts of a single closed circuit, have their like poles moved towards each other or their unlike poles separated, a current will be induced in the coils in such a direction as to strengthen the magnetisation of the pieces of iron. And since this current will be proportional, other things being equal, to the strength of the magnetic forces which oppose the movement, and since these forces are themselves increased by the existence of the current itself, it is obvious that a continuous movement, under the conditions that have been indicated, must produce a current in the coils of continually increasing strength, even if the initial magnetism of the soft iron were indefinitely weak. In order to put this principle in practice, a magneto-electric machine was employed provided with soft iron electro-magnets and a Siemens's armature. If no current passed through the coils of the electro-magnet, and if the iron were quite unmagnetic, no current was produced by the rotation of the armature; but if a galvanic current be sent for a short time through the coils of the electro-magnet, the residual magnetism retained by the soft iron after the cessation of the current sufficed to produce a weak current, alternately in opposite directions, when the armature was made to revolve and the ends of the wire surrounding it were joined together. If now this current, after being reduced to a constant direction by a commutator, was made to traverse the coils of the electro-magnet in such a direction as to increase the slight magnetisation already existing, it was itself strengthened by the result of its own effect on the magnet, and in its turn increased still further the power of the magnet, and thus again its own strength. By the mutual action and reaction of armature and electro-magnet, the mechanical resistance is found to increase rapidly, to such an extent that either the driving-strap

begins to slip or the insulated wires constituting the coils are heated to the extent of igniting their insulating silk covering' (Siemens).

But although currents of almost any degree of intensity can be produced by the arrangement that has been indicated, a magneto-electric machine constructed on this principle has the important practical defect that, in proportion as the current is

FIG. 21.

FIG. 22.

employed in producing external effects, so the power of the machine to generate a current is lessened. A remedy for this was devised by Mr. Ladd (*Proc. Roy. Soc. xv. 404*), who adopted the simple expedient of putting two armatures into the same machine, and employing the current of one solely in maintaining the magnetism of the electro-magnets, while that of the other could be used for any other purpose. In machines of the largest size he places the armatures at opposite ends of a pair of broad electro-magnets (*nn*), as shown at *m* and *n*, fig. 21; in the smaller machines the armatures

are connected together with their axes of rotation in the same straight line, and the coils are wound upon them at right angles to each other. A machine of this construction, intended to be driven by one or two men, is shown in fig. 22, and the double armature is represented separately at A. B. (For a sketch of the mathematical theory of magneto-electric machines, see Maxwell, *Proc. Roy. Soc.* xv. 397. A good account of the construction and general principles of those above described is given by Bertin, *Ann. Chim. Phys.* [4] xv. 169.)

Electric Resistance of Conductors. The relations between the dimensions and the resistances of cylindrical electric conductors, such as metallic wires, stated at p. 466 of vol. ii., may be expressed mathematically as follows:

$$\rho = R \frac{l}{a},$$

where ρ denotes the resistance of the particular conductor under consideration, l its length, a the area of its cross-section, and R a coefficient, called the 'specific resistance' of the material of the conductor. This coefficient expresses the resistance of a portion of the conductor having *unit length and unit section*, and has a constant value for the same material under the same conditions. It is frequently easier to determine by direct experiments the weight and specific gravity of a conductor, than the area of its cross-section, but the latter number can be easily calculated from the two former; thus, let w be the weight of the conductor, and s its specific gravity, or the weight of a portion of unit length and of uniform cross-section equal to the unit of area, then $a = \frac{w}{ls}$. Substituting this value of a in the last equation, we get

$$\rho = R s \frac{l^2}{w},$$

which shows that the resistances of conductors of the same material are proportional to the squares of their lengths and inversely proportional to their weights.

In the case of a conductor having a circular section, such as a well-drawn wire, the area of the section may be calculated from a measurement of the diameter, which may be made either under a microscope or by means of a micrometer. Then, since, if d be the diameter, $a = \frac{\pi d^2}{4}$, the resistance of the conductor may be expressed in reference to its length and diameter thus:

$$\rho = R \frac{l}{\frac{\pi d^2}{4}} = 1.27324 R \frac{l}{d^2}.$$

The following table (p. 564), calculated from Matthiessen's determinations by F. Jenkin (*Journ. Soc. Arts*, February 23, 1866), gives the values of the products Ra and $1.2732 R$ for wires of several of the most important metals, expressed in terms both of the British and the metrical standards of length and weight, and referred to the unit of electrical resistance adopted by the Committee of the British Association on Electrical Standards.

An example will show the mode of using this table. For instance, let it be required to know the resistance at 0° C. of 240 feet of hard-drawn copper wire weighing 16½ lb. The first column of figures gives, for the resistance of 1 foot of wire weighing 1 grain, the number 0.2106; hence the resistance of 240 feet weighing 16½ lb., or 116,500 grains, is

$$0.2106 \times \frac{240 \times 240}{116500} = 0.105.$$

If the length and weight of the wire whose resistance is required be given in metres and grammes, the calculation must of course be made in the same way, using the number given in the second column of figures. Again, to find the resistance of 10,000 metres of hard-drawn copper wire having a diameter of 2.5 millimetres, we must use the fourth column of figures; in this case the calculation would be

$$0.02104 \times \frac{10000}{2.5 \times 2.5} = 33.664.$$

For short ranges of temperature within ordinary limits, the resistance of metallic conductors increases very nearly proportionally to the temperature, and, as Matthiessen has shown (*Phil. Trans.* 1862, p. 23)—with the exception of iron, the resistance of which varies between 0° and 100° C., in the ratio of 1.0 to 1.62—the resistance of the most important metals in a state of purity varies almost exactly at the same rate. The numbers in the last column of the table give the approximate percentage variation

	Resistance at 0° C. of Wires				Approximate percentage variation of resistance per 1° at 20° C.

of resistance for 1° centigrade, for moderate intervals of temperature above or below 20° C. The general effect of changes of temperature between 0° and 100° C. may be expressed, according to Matthiessen's experiments, by the following formula :

$$p_t = p_0 (1 + at + bt^2),$$

where p_t is the resistance of a conductor at the temperature t° C., p_0 its resistance at 0°, and a and b are coefficients depending on the material of which it is composed. The following table gives the values of these coefficients for several cases :

	a	b
Pure metals	+ 0·003894	+ 0·00000252
Mercury	+ 0·0007485	— 0·000000398
German silver	+ 0·0004433	+ 0·000000152
Platinum-silver alloy	+ 0·00031	—
Gold-silver alloy	+ 0·0006999	— 0·000000062

The following table gives the results of F. Kohlrausch and Nippoldt's experiments (*Pogg. Ann.* cxxxviii. 385) on the resistance of dilute sulphuric acid of various degrees of concentration. The numbers in the third and fourth columns give the resistance and conducting power at 22° C. of a column of acid of given length and section as compared with the resistance and conducting power of a similar column of mercury at 0° C. taken as unity. The last column gives the percentage increase of conducting power for a rise of temperature of 1° C. :

Resistance and Conducting Power of Sulphuric Acid.

Specific gravity at 18·5° C.	Hydric sulphate per cent.	Specific resistance (Mercury = 1)	Specific conducting power (Mercury = 1)	Percentage variation of conducting power per degree centigrade
1·0504	8·3	34465	0·000029015	0·653
1·0989	14·2	18910	52881	0·646
1·1431	20·2	14962	66837	0·799
1·2045	28·2	13108	76290	1·317
1·2631	35·2	13107	76293	1·259
1·3163	41·5	14259	70130	1·410
1·3597	46·0	157·2	63505	1·674
1·3994	50·4	17692	56523	1·682
1·4482	55·2	20756	48182	1·417
1·5026	60·3	25525	39176	1·794

From these determinations, it appears that the mixture of hydric sulphate and water which possesses the greatest conducting power has the sp. gr. 1.233 at 18.5°, and therefore contains 31.5 per cent. of hydric sulphate, and that the conducting power of this acid at 22° is 0.000077274, that of a similar column of mercury at 0° being taken as unity. The last column of the table shows that the variation of conducting power for a change of temperature of 1° is sensibly proportional to the percentage of hydric sulphate in the solution. Calling the percentage variation for 1° δ , and the percentage of hydric sulphate p , the experimental numbers give, when compared by the method of least squares:

$$\delta = 0.4680 + 0.0219 p.$$

And by help of the coefficient thus calculated, the conducting power k_t at any temperature t° may be deduced from the conducting power k_{22} at 22°, by the formula:

$$k_t = k_{22} \left[1 + \frac{\delta}{100} (t - 22) \right].$$

Resistance of Conductors variously combined.—If any two points, p and q , are connected together by two or more conductors, a, b, c, \dots , having separately the respective resistances $\rho_1, \rho_2, \rho_3, \dots$, and combined together *in series*, as in fig. 23, the resistance r of the whole combination is evidently equal to the sum of the resistances of the separate conductors, or

$$r = \rho_1 + \rho_2 + \rho_3 + \dots$$

FIG. 23.

If, on the other hand, the conductors are connected *in multiple arc*, as in fig. 24, the total resistance between the two given points is represented by

FIG. 24.

$$r' = \frac{\rho_1 \rho_2 \rho_3}{\rho_2 \rho_3 + \rho_1 \rho_3 + \rho_1 \rho_2}.$$

This relation may be easily proved as follows: Let $\kappa_1, \kappa_2, \kappa_3, \dots, \kappa'$ be the respective conducting powers of the several conductors a, b, c , and of the combination of them represented in fig. 24; then, by the definition of resistance and conducting power, we have:

$$\kappa_1 = \frac{1}{\rho_1} \quad \kappa_2 = \frac{1}{\rho_2} \quad \kappa_3 = \frac{1}{\rho_3} \quad r' = \frac{1}{\kappa'}.$$

Further, it is evident that the conducting power of the combination fig. 24 must be equal to the sum of the conducting powers of the separate conductors, or

$$\kappa' = \kappa_1 + \kappa_2 + \kappa_3;$$

whence

$$r' = \frac{1}{\kappa_1 + \kappa_2 + \kappa_3} = \frac{1}{\frac{1}{\rho_1} + \frac{1}{\rho_2} + \frac{1}{\rho_3}} = \frac{\rho_1 \rho_2 \rho_3}{\rho_2 \rho_3 + \rho_1 \rho_3 + \rho_1 \rho_2}.$$

To find the strength of the current in the several branches of a compound conducting system, such as that indicated in fig. 24, we have to consider that the strength of the current in the undivided part of the circuit is equal to the sum of the currents in the

branches, and also that the same electromotive force acts in each of the branch-conductors. The former relation is expressed by the equation

$$C = c_1 + c_2 + c_3 \dots (1),$$

where C represents the strength of the current in the undivided part of the circuit, and c_1 , c_2 , and c_3 the currents in the branches A , B , and C respectively. The latter relation gives rise, by Ohm's law, to the equations

$$e = c_1 \rho_1 = c_2 \rho_2 = c_3 \rho_3 \dots (2),$$

in which e stands for the electromotive force between the points p and q . Substituting for c_2 and c_3 in (1) their values in terms of c_1 given by (2), we get, for the strength of the current in the conductor A , the value

$$c_1 = C \frac{\rho_2 \rho_3}{\rho_2 \rho_3 + \rho_1 \rho_3 + \rho_1 \rho_2};$$

and, by proceeding in a similar way, we obtain the values of c_2 and c_3 , namely—

$$c_2 = C \frac{\rho_1 \rho_3}{\rho_2 \rho_3 + \rho_1 \rho_3 + \rho_1 \rho_2},$$

and

$$c_3 = C \frac{\rho_1 \rho_2}{\rho_2 \rho_3 + \rho_1 \rho_3 + \rho_1 \rho_2}.$$

The corresponding expressions for the strength of the current in any one of any number of conductors connecting the same two points is easily obtained from the above, if it is remembered that the numerator in each case is the product of all the resistances *except* that of the branch in question, and that the denominator is the sum of a series of terms formed by multiplying together all the resistances except the first, then all but the second, and so on. A case of very frequent occurrence is a combination of *two* conductors in multiple arc: the expressions for the strength of the currents in the two branches are then

$$c_1 = C \frac{\rho_2}{\rho_1 + \rho_2}, \text{ and } c_2 = C \frac{\rho_1}{\rho_1 + \rho_2}.$$

Method of Comparing Resistances.—The method of measuring the resistance of conductors by comparing them with a rheostat, as described at p. 467, vol. ii., is not capable of giving very accurate results. Of the various more exact methods that have been devised, those which are most generally applicable are modifications of that introduced by Sir Charles Wheatstone in 1843, and known as *Wheatstone's Electrical Bridge or Balance* (*Phil. Trans.* 1843, p. 323). The general principle of this

FIG. 25.

method may be explained by help of the diagram, fig. 25, where B represents a galvanic battery, connected by wires, a and b , with the thick copper conductors cd and gh ; G is a delicate galvanometer; and M , N , P , and Q are resistances. One of them, for instance Q , is the resistance to be measured; its neighbour P consists of a rheostat or a graduated set of resistance-coils, so that it can be increased or diminished at will to any required amount; and M and N are adjusted so as to be equal, or to bear some other simple known ratio to each other. M and N are connected by the thick copper conductor e , and P and Q by the similar conductor f , and each of these conductors is connected by a branch-wire with one terminal of the

galvanometer. The process of measurement consists simply in altering the value of the resistance P , until, when the battery-circuit is completed, no current passes through the galvanometer, and the needle consequently remains at rest. When this is the case, it can be shown, by the laws of divided currents which have just been stated, that the resistance P is to the resistance Q in the same ratio as the resistance M to the resistance N , and consequently the value of Q is given by the equation :

$$Q = P \frac{N}{M}.$$

To prove this, let C denote the strength of the current in the undivided part, $a n h$, of the circuit. The current in $c m e$ is of the same strength as the current in $e n g$, and that in $d r f$ is equal to that in $f q h$, for, since no current passes through the galvanometer, the currents in $c g$ and $d h$ are not modified by the presence of the cross connection $e o f$. Accordingly, let the strength of the current in $c m e n g$ be denoted by C_1 , and the strength of the current in $d r f q h$ by C_2 . Then, since the resistance of the former branch of the circuit may be represented by $M + N$, and that of the latter by $P + Q$ —the resistances of the connections c, d, e, f, g, h being negligible in comparison—we have

$$\frac{C_1}{C_2} = \frac{P + Q}{M + N} \dots (a).$$

Further, let C_1' represent the part of the current C_1 which would flow from e to f if the current C_2 did not exist; and let C_2' represent the part of the current C_2 which would flow from f to e if the current C_1 did not exist; we have then

$$C_1' = C_1 \frac{N}{P + N + Q},$$

and

$$C_2' = C_2 \frac{Q}{P + N + Q}.$$

These currents, C_1' and C_2' , would traverse the galvanometer in opposite directions; but, since, in the actual experiment, the galvanometer remains at rest, it is obvious that C_1' and C_2' must be equal to each other, whence

$$C_1 N = C_2 Q$$

or

$$\frac{C_1}{C_2} = \frac{Q}{N} \dots (b).$$

Equating the values of $\frac{C_1}{C_2}$ given by equations (a) and (b) and transposing, we get

$$\frac{P + Q}{Q} = \frac{M + N}{N},$$

whence

$$\frac{P}{Q} = \frac{M}{N} \text{ or } Q = P \frac{N}{M}.$$

(For further details relating to the electrical balance and the mode of using it, see Jenkin, *Brit. Assoc. Rep.* 1862, p. 159; Matthiessen and Hockin, *Brit. Assoc. Rep.* 1864, p. 352; also *The Laboratory*, 1867, pp. 343, 391, 423.)

In certain cases the comparison of resistances by means of the electrical balance requires special precautions or corrections. If, for instance, one of the conductors to be compared consists of alternate pieces of two different metals connected together end to end, as in the thermo-electric pile, the passage of a current through it will cause the points of junction of the metals to be alternately heated and cooled, and will thus generate an electromotive force, opposed to that of the battery, which, in the comparison of resistances, produces the same effect as an increase of resistance. This inverse electromotive force is proportional to the difference of temperature at the alternate metallic joints, and therefore does not acquire a sensible value if the current is allowed to pass for only a very short time; if however the current is maintained, the inverse electromotive force finally attains a constant maximum value proportional to the strength of the current. The effect of this is, as has been shown by Beets (*Pogg. Ann.* cxix. 520), equivalent to a constant additional resistance, independent of the strength of the current. Analogous phenomena, causing a complication in the measurement of resistance, arise in the case of electrolytic conductors, in which an inverse electromotive force is caused by the polarisation of the electrodes already described (ii. 429).

In this case also the inverse force gradually increases from zero to a constant maximum when the current is kept up continuously; it is probable therefore that, by employing comparatively large electrodes and currents of very short duration, it would be possible to prevent its producing very serious results. But the only generally applicable method yet devised, by which its effects can be entirely got rid of, consists in the employment of a rapid succession of currents of short duration alternately in opposite directions. By the employment of a process founded upon this principle, F. Kohlrausch and Nippoldt have proved conclusively that, when the disturbing effects of polarisation are got rid of, Ohm's law (ii. 459) applies to electrolytic as fully as to metallic conductors (*Pogg. Ann.* cxxxviii. 280, 370).

Standards of Electrical Resistance. In order that the results obtained by comparing the resistances of various conductors may be comparable among themselves, it is needful that one term of the comparison should either be identically the same in every case, or else that it should bear a known relation to some one invariable standard. Accordingly, various propositions have been made from time to time with a view to induce different experimenters to use the same standard or *unit* of resistance, and so to make the results of their experiments mutually comparable. Hitherto, however, no one standard has come to be universally employed; and the comparison of measurements made by reference to the different units which are in partial use presents difficulties of the same kind as, but greater in degree than, the comparison of measurements of length or mass expressed in terms of the standards employed in different countries. The following table gives the approximate relative values of the standards of electrical resistance most commonly referred to in scientific writings:

Standards of Resistance.

Name of Standard	Definition	Relative Values		
		B. A. unit, or Ohm ^a	Weber's unit × 10 ¹⁰	Mercury unit

In this table, the numbers in each vertical column express the resistance of the standard named at the head of it in terms of the other standards, while the numbers in each horizontal line give the relative resistances of the several standards. These

numbers, however, cannot lay claim to any high degree of accuracy, as exact inter-comparisons of the various units are wanting. The nature of the units adopted by Weber and by the Committee of the British Association, and the meaning of the definitions of them given in the table, will become more apparent from what follows.

If electrical resistance were an independent magnitude, it would be, comparatively speaking, a matter of indifference what unit was adopted for measuring it, so long as the unit itself had an accurately defined value; but, seeing that electrical resistance can only be defined by reference to the correlative magnitudes *electromotive force* and *electric current*, it is obviously desirable that the units adopted for the measurement of resistance, electromotive force, and electric current should be chosen so as to express the mutual relations of these magnitudes in the simplest and most direct way possible. When the same electromotive force acts in circuits of various lengths, or composed of various materials, it produces in general electric currents having different degrees of strength; and the 'resistance' of each circuit is simply the name given to that quality of it which determines the strength of the current produced by a given electromotive force. According to Ohm's law, the resistance R of a circuit in which the electromotive force E produces the current C is expressed by the formula

$$R = a \frac{E}{C},$$

where a is an arbitrary constant depending upon the units of measurement adopted for R , E , and C . The physical meaning of a becomes apparent if we suppose that E and C each = 1: the above expression then becomes

$$R = a,$$

which shows that a is (1) the resistance of a circuit in which unit electromotive force would produce a current of unit strength. Again, if we make $E = R = 1$, we get $C = a$; or, by making $C = R = 1$, we find $\frac{1}{E} = a$; whence we see that a may also

be defined (2) as the strength of the current produced by unit electromotive force in a circuit of unit resistance, or (3) as the reciprocal of the electromotive force required to produce the unit current in a circuit of unit resistance. Now it is obvious from those relations, that whatever be the units adopted for measuring two of the magnitudes R , E , and C , it is always possible to choose such a unit for the measurement of the third as will make the coefficient $a = 1$. In this case the formula expressing Ohm's law assume their simplest possible form, namely,

$$R = \frac{E}{C}, \quad C = \frac{E}{R}, \quad E = CR,$$

and the unit of resistance would then be defined as the *resistance of a circuit in which unit electromotive force produces the current of unit strength*. Ohm's law then determines the relation which the units of resistance, current, and electromotive force must bear to each other in order that they may form a coherent system; but it leaves us free to choose any two of them quite arbitrarily.

A further condition, however, which a satisfactory system of electrical measures must fulfil, is that of expressing conveniently the relations of electrical to other physical magnitudes. The most fundamental of these relations are determined by Joule's discoveries of the laws according to which mechanical energy and the energy of current electricity are respectively converted into heat. These laws are expressed by the equations

$$W = JH$$

and

$$H = b.C^2Rt,$$

where J stands for the mechanical equivalent of heat, W for the number of units of work which must be expended to produce the same quantity of heat, H , as would be produced in the time t by a current of the strength C in a conductor of the resistance R , and b for a constant depending on the units of measurement for heat, current, and resistance. Combining the two equations, we get

$$W = Jb.C^2Rt = Jb.ECt = Jb\frac{E^2}{R}t.$$

If we suppose C to denote a current of unit strength, R a unit of resistance, and t a unit of time, the value of W becomes

$$W = Jb.$$

But, in a natural system of measures, the unit current circulating for unit of time in a conductor of unit resistance would perform unit of work or its equivalent. In order that this condition may be fulfilled, the units adopted for the measurement of work and for the electrical magnitudes E , C , and R must be so chosen as to make the factor $Jb = 1$. We then get, for the work done by an electric current in unit of time, the expressions

$$W = C^2R = EC = \frac{E^2}{R},$$

establishing a relation between the unit of work and the electrical units. But the unit of work is defined, independently of electrical phenomena, as the work done by the unit force when it acts through unit of distance; and the unit force is itself defined as the force required to impart unit velocity to unit mass in the unit of time; consequently, the measurement of work involves reference only to the fundamental physical units of space, time, and mass. If then we can define either the unit of electromotive force, of current, or of resistance, without reference to anything beyond the same fundamental units, two of the four magnitudes occurring in the above equations are determined, and the equations themselves suffice for determining the other two. Now the phenomena of the mutual action of electric currents and magnets afford the means of measuring both electric currents and electromotive force in terms of the units of space, time, and mass, and therefore of obtaining an independent definition of the natural unit of each. From the units thus determined, the unit of resistance can be deduced by Ohm's law. Hence a system of electrical measures can be based, either upon the phenomena of electromagnetism alone, or upon these phenomena taken in connection with the laws of the production of work by electric currents; and if the experimental data required in each case were perfectly accurate, the measures obtained by the two methods would be identical. Hitherto, however, it is probable that the measures derived solely from electromagnetic phenomena are the most trustworthy, and it is upon them that both Weber's unit of resistance and the British Association unit are founded. By definition, these two units would be identical (except that, as a matter of practical convenience, the B. A. unit is taken 10,000,000,000 times as great as Weber's), were it not for experimental errors.

Standards of measure which, like those we have been discussing, are derived from the units of space, time, and mass, are often called *absolute standards*, not as implying any special accuracy in the measurements made by means of them, but in contradistinction to *comparative measures*, which merely enable us to express the relation between the magnitude to be measured and some other magnitude of its own kind. Thus, the cubic foot, or the cubic inch, may be called an absolute unit of capacity, while the gallon, or the pint, is merely a relative unit.

We shall now try to explain the general principles of the methods by which electric currents, electromotive force, and resistance can be measured in absolute units.

Absolute Measurement of Electric Currents.—The force exerted by an element of the length s of a current of the strength C upon a magnetic pole of intensity M , at a distance r in a direction making an angle θ with the tangent to the current at the position of the element in question, is directly proportional to the length of the element of the current, to the strength of the current, to the intensity of the magnetic pole, and to the sine of the angle θ , and inversely proportional to the square of the distance; and its direction is perpendicular to the plane passing through the element of the current and the pole. The force may therefore be represented in magnitude by the formula

$$f = \frac{sCM \sin \theta}{r^2}.$$

If the current is carried round the circumference of a circle with the magnetic pole at the centre, each element of it is at the same distance from the pole, and $\sin \theta$ is throughout equal to unity, and the plane containing the whole current also contains the pole; hence the resultant force F exerted by the entire current is the product of the force f exerted by each element into the number of elements $\frac{2\pi r}{s}$ in the whole circumference, or

$$F = \frac{2\pi CM}{r}.$$

If, instead of a single magnetic pole at the centre of the circle round which the current passes, there is a complete magnet with poles of the intensity M and $-M$

but with the distance between them, L , so short, in comparison to the radius of the circle, that each pole may, without sensible error, be regarded as at the centre, the two poles are subject to equal parallel forces in opposite directions; and the perpendicular distance between the lines of action of these forces is $L \cos \alpha$, if α be the angle which the axis of the magnet makes with the plane of the current. Consequently, the magnet is subject to a statical couple, tending to set its axis perpendicular to the plane of the current, the moment of which is

$$G = FL \cos \alpha = \frac{2\pi C\mu}{r} \cos \alpha,$$

where $\mu = ML$ stands for the magnetic moment of the magnet. If the plane of the current be vertical and coincide with the plane of the magnetic meridian, the magnet is also subject to a couple, tending to set its axis parallel to the plane of the current, of which the moment is

$$E = H\mu \sin \alpha,$$

where H is the horizontal component of the earth's magnetic force. The magnet therefore, under the action of these two opposing couples, comes to rest in such a position that their moments are equal, that is so as to make

$$\frac{2\pi C\mu}{r} \cos \alpha = H\mu \sin \alpha.$$

This equation gives, for the strength of the current in terms of the radius of the circle, the deflection of the magnet from the meridian, and the horizontal component of the earth's force, the expression

$$C = \frac{Hr}{2\pi} \tan \alpha.$$

The conditions that have been supposed in deducing this formula are approximately fulfilled in the simplest form of tangent-galvanometer (ii. 460); the observation of the deflection which a given current produces on a tangent-galvanometer of known radius affords a measure of the strength of the current in absolute units, when the horizontal component of the earth's magnetic force, at the time and place of the experiment, is known in absolute measure. (See iii. 781, 782.) The definition of the unit current which results from this mode of measurement is as follows:

A current of unit strength is a current of which the unit length placed along the circumference of a circle of unit radius (the current therefore occupying an arc of $57^{\circ}29'578''$), the plane of which is parallel to the lines of force of a magnetic field of unit intensity, would cause a short magnet suspended at the centre of the circle to be deflected through an angle ($= 45^{\circ}$); whose tangent is unity.

Or the same definition may be put into a form in which it is more directly applicable to the tangent-galvanometer, thus:

A current of unit strength placed once round the circumference of a vertical circle of unit radius, in the plane of the magnetic meridian, will cause a short magnet suspended at the centre of the circle to be deflected through an angle whose tangent is $6.2832 (= 2\pi)$ divided by the absolute horizontal intensity of the earth's magnetic force at the time and place of observation.

It will be seen that, in order to determine the strength of a current in absolute measure, by means of the tangent-galvanometer, the absolute intensity of the earth's horizontal magnetic force must have been ascertained by independent observations. But if the current be made to traverse a coil of wire, suspended so that its axis is horizontal and perpendicular to the magnetic meridian when no current is passing, as well as a tangent-galvanometer, the observation of the deflection of the coil combined with that of the tangent-galvanometer gives, as has been shown by Kohlrausch, the data for determining simultaneously the absolute horizontal force of the earth and the absolute strength of the current. The general principle of this method may be stated as follows: When a current of the strength C traverses the coil, it develops a statical couple tending to set the axis of the coil parallel to the magnetic meridian, the moment of which is obtained by multiplying the strength of the current by the horizontal magnetic force of the earth H , by the total area A enclosed by the coil (that is, the mean area enclosed by a single turn of the wire multiplied by the number of turns), and by the sine of the angle β which the axis of the coil makes with the magnetic meridian; but the coil is also subject to another couple, tending to set its axis perpendicular to the meridian, the moment of which is the coefficient of torsion-elasticity of

the suspending wires T , multiplied by the angle of deflection of the coil. Hence the position of equilibrium of the coil, when the current is passing, is determined by the equation

$$CH.A \sin \beta = T(90^\circ - \beta)$$

or

$$CH = \frac{T(90^\circ - \beta)}{A \cdot \sin \beta} \dots (a).$$

And the simultaneous observation with the tangent-galvanometer gives

$$\frac{C}{H} = \frac{r}{2\pi} \tan \alpha \dots (b).$$

The combination of these two equations, (a) and (b), gives both C and H in absolute measure. (For further details, see F. Kohlrausch, *Pogg. Ann.* [1869] cxxxviii. 1.)

Absolute Measurement of Electromotive Force.—The electromotive force of a galvanic battery, or other equivalent apparatus, may be defined as the quality in virtue of which it tends to do work by the transference of electricity from one point to another; and it may be expressed numerically by the amount of work done during the transfer of the unit quantity of electricity. Thus if W be the work done by the chemical or other forces of the battery, during the transfer of the quantity of electricity Q through the circuit, the electromotive force of the battery may be represented by

$$E = \frac{W}{Q} = \frac{W}{Ct}$$

the last expression being applicable when the electricity is transferred in the form of a current of uniform strength C lasting for the time t . Hence the electromotive force of a battery may also be said to be the work done when a current of unit strength is maintained for unit of time. The work may of course be of various kinds, as, for example, production of heat; work against gravity, as when weights are raised by an electromagnetic engine; work of acceleration against inertia; chemical work, as in a voltameter; magnetic and electrical work, as in an induction coil; but in the above formula it is supposed to be always expressed in absolute mechanical units.

But, just as electromotive force does work in a conducting circuit through the agency of the current which it produces, so, conversely, work done upon a conductor may give rise to electromotive force, and therefore to a current, if the conductor forms part of a closed circuit. This fact, coupled with the condition that the electromotive force developed when unit of work is expended per unit of time is to be taken as the unit of electromotive force, serves as the basis for the absolute measurement of electromotive force. The principles of the measurement will be easily understood from the following considerations.

If a current of the strength C circulate in a rectilinear conductor of length l placed at right angles to the lines of force in a uniform magnetic field of intensity H , every element dl of the current is subject to a force equal to

$$HC'dl$$

in a direction perpendicular to the current and to the lines of force. The resultant force acting upon the whole length l is therefore the sum of the forces acting upon the several elements of it, or

$$F = HC'l;$$

and if the conductor be displaced through the distance D perpendicularly to itself and to the lines of force, and in opposition to the force F , a quantity of work w will have been expended in producing the displacement which is expressed by

$$w = FD = HC'lD,$$

or, if the displacement take place with the constant velocity v and occupy unit of time, we may write

$$w = HC'lv.$$

If E be the electromotive force acting in the conductor when at rest, the work (in this case simply evolution of heat) done in unit of time by the electrical forces when the strength of the current is C' , will be

$$W = EC'.$$

But the principle of the Conservation of Energy requires that, when an amount of work w is done upon the conductor by external forces, the equivalent of this work shall

make its appearance in the conductor: hence, during the displacement, for the whole quantity of work developed in the conductor per unit of time we have

$$W' = W + w.$$

But in order that a quantity of work W' may be done in a conductor in a unit of time by a current of strength C' , the electromotive force must be E' , such that

$$W' = E'C'.$$

And this expression, taken in connection with the last three, gives

$$E' = E + H/v.$$

Hence we see that by displacing the conductor in opposition to the electromagnetic forces, the electromotive force acting in it has been increased by an amount H/v ; or, in other words, that the movement of the conductor has developed an additional electromotive force proportional to the length of the conductor, the intensity of the magnetic field, and the velocity of the motion. And in order that the relation between the expenditure of work and production of electrical effects may be expressed in the simplest way possible, the electromotive force developed under conditions such as we have been considering must be measured numerically by the product H/v , which is equivalent to adopting as the unit of electromotive force *the electromotive force developed when a rectilinear conductor of unit length is moved with unit velocity at right angles to its own length and to the lines of force of a magnetic field of unit intensity.*

Although the preceding considerations suffice to afford a perfectly definite conception of the mechanical unit of electromotive force, it would be exceedingly difficult, in practice, so to arrange matters as to cause electromotive force to be continuously developed under the precise conditions which, for the sake of simplicity, we have taken as the basis of the above discussion. But the principle would remain exactly the same if, instead of a conductor of which every point moved with the same velocity, we had one of which the different points moved with different velocities, and if, instead of moving at right angles to the lines of magnetic force, the conductor cut them at any angle. In such a case, however, instead of being able to represent the electromotive force due to the movement by the simple formula

$$e = H/v,$$

where v is the velocity of displacement of any point of the conductor, it would be represented by

$$e = H\lambda u,$$

where λ stands for the length of the projection of the straight lines joining the ends of the conductor upon a plane perpendicular to the line of force, and u for the mean velocity of displacement of this projection perpendicularly to itself and to the lines of force.

The conditions here supposed are most easily realised practically by means of a circular metallic disc rotating in its own plane about an axis through its centre. An electromotive force is developed, due to the movement across the direction of the earth's magnetic force of the several radii of the disc; and if one terminal of a galvanometer be connected with a metal spring pressing against the edge of the disc, and the other terminal be connected with the centre, the galvanometer will indicate the passage of a current as long as the rotation of the disc continues (Faraday, *Experimental Researches*, vol. i. pp. 44, 45; Series ii. par. 149-152). In this case, the conductor by whose movement the current is produced is the radius of the disc which at any instant completes the galvanometer circuit; and, since in the case of a straight line rotating about one end the average velocity of the whole line is the same as that of its middle point, it is easy to see that, if r be the radius of the disc, ω its angular velocity (or the velocity of a point at unit distance from the centre), H the absolute magnetic force of the earth at the time and place of the experiment, and α the angle between the axis of rotation and the direction of the earth's force, the electromotive force causing the current through the galvanometer may be represented by

$$e = H \frac{r}{2} \omega \cos \alpha.$$

Hence the arrangement that has been indicated affords one means of developing an electromotive force which can be measured in absolute units, under conditions in which it can produce a continuous current; and, consequently, all that we require further in order to be able to measure electromotive forces, produced in any way whatever, in absolute units, is a method of comparing one electromotive force with

another. But before discussing the processes for the comparative measurement of electromotive forces, it will be most convenient to discuss the principles involved in the absolute measurement of electric resistance.

Absolute Measurement of Electric Resistance. We have already seen that the strength of electric currents and the intensity of electromotive forces can be expressed in terms of the fundamental mechanical units. Consequently, if we express thus the intensity of the electromotive force acting in a given circuit, and also the strength of the current produced by it, the ratio of the numbers expressing these magnitudes will express similarly the absolute resistance of the circuit. In this way the absolute resistance of a particular conductor may be ascertained, and from this the absolute resistances of other conductors can be deduced by comparative methods. For the purpose of accurate measurements, the current produced by a revolving disc, as in the experiment above described, could not be satisfactorily employed, as it is practically impossible to keep the resistance at the point of contact between the moving edge of the disc and the spring connected with the galvanometer constant; but the principle that has been indicated has been put in practice in various ways by W. Weber (*Elektrodynamische Maassbestimmungen*, 2te Abhandlung [1850]. *Zur Galvanometrie* [1862]; in abstract, *Fortschr. d. Phys.* xviii. 417), and by Maxwell, Stewart, Jenkin, and Hockin, acting as a sub-committee of the British Association for the Advancement of Science (*Rep. Brit. Assoc.* 1863, p. 163; *ibid.* 1864, p. 350). Two methods were employed by Weber, the general nature of which may be described as follows: In the first, a momentary current was produced by causing a flat annular coil of insulated wire to make rapidly a half-turn about either its horizontal or its vertical diameter, and the strength of the current was deduced from the throw of a magnetic needle, suspended either inside the movable coil itself, or within a galvanometer coil which made part of the same circuit with the movable coil. The electromotive force was in this case known from the dimensions of the coil, the rapidity of its motion, and the absolute intensity of the earth's magnetic force. In Weber's second method, a magnetic needle suspended inside a galvanometer-coil, the terminals of which were connected together, was displaced from the magnetic meridian and then left to itself, and the amplitude of the gradually diminishing oscillations about its position of equilibrium was observed for a considerable number of oscillations. In this experiment, an electromotive force was produced, the intensity of which depended upon the magnetic moment of the magnet, the velocity of its motion, and the dimensions of the coil; and this caused a current in the coil, always in such a direction as to oppose the motion possessed by the magnet at any given instant, the strength of which was indicated by the rate at which the amplitude of the oscillations of the magnet diminished (allowance being of course made for the retarding effect of the air and the viscosity of the suspending fibre). The method employed by the sub-committee of the British Association consisted in causing the coil of a tangent-galvanometer of known dimensions to revolve at a known speed about its vertical diameter, and in observing the deflection of the galvanometer-needle caused by the currents induced in the revolving coil by the earth's magnetism. In these experiments, the tangent of the angle of deflection was directly proportional to the strength of the induced current, and inversely proportional to the horizontal component of the earth's magnetic force. The strength of the current however was directly proportional to the earth's horizontal magnetic force, and depended also upon the velocity of rotation and the resistance of the coil. Hence the tangent of the deflection was both directly and inversely proportional to the earth's horizontal magnetic force, or, in other words, was independent of this force altogether, and therefore the only data required for determining the resistance of the coil, in addition to the number of convolutions of the wire and its mean distance from the magnet, were the velocity of revolution of the coil and the deflection of the magnet.

All these processes, being dependent upon the fundamental relation expressed by the equation,

$$R = \frac{E}{C}$$

give the value of R expressed in the same terms as those adopted for the measurement of E and C . But, as we have seen (p. 571), the absolute strength of a current may be expressed in electro-magnetic measure by the formula

$$C = H r \frac{\tan \alpha}{2\pi},$$

in which r stands for a length, and the factor written in the form of a fraction is a pure number. Further (p. 573), electromotive force is expressed in absolute electromagnetic measure by the formula

$$E = Hlv,$$

where l again represents a length. Consequently, it follows that the resistance of any conductor, or the quotient of the electromotive force acting in it by the strength of the current produced, must be expressed by a velocity. *The absolute unit of resistance is therefore identical with the unit of velocity*; and this same result would be arrived at, whatever were the experimental process adopted for the actual measurement of electromotive force and current-strength. In all cases it will be found that the expression for electromotive force, if written out in terms of its ultimate physical factors, the units of space, time, and mass, represents the square root of a force multiplied by a velocity; and that the expression for the strength of a current represents the square root of a force, and therefore that their quotient represents a velocity.

Hence the magnitude of the absolute unit of resistance depends only upon the magnitudes of the units of length and time, and Weber, adopting 1 millimetre as the unit of length and 1 second as the unit of time, necessarily defined the absolute unit of resistance as a velocity of 1 millimetre per second. This however represents a resistance so very much smaller than those which have most frequently to be dealt with in practice, that the adoption of Weber's unit would lead to inconveniently high numbers for expressing ordinary resistances; consequently, as a matter of practical convenience, the Committee of the British Association upon Electrical Standards (see *Rep. Brit. Assoc.* 1862, p. 125) adopted a unit which, by definition, represents a resistance ten thousand million times as great as Weber's, namely a velocity of 10 million metres per second. This standard is variously referred to as the '10⁷ × metre second

unit,' the 'B. A. unit,' or the 'Ohm^{al}.'

The absolute unit of resistance may also be deduced from the relation expressed by the equation

$$R = \frac{W}{C^2 t},$$

where W represents the work done in the time t by a current of the strength C in a conductor of resistance R . The numerator of this expression represents a force multiplied by a length, and the denominator represents a force multiplied by a time (since C is equivalent to the square root of a force); hence we find here again that resistance is measured by the ratio of a length to a time, that is, by a velocity. Determinations upon the principle here indicated have been made by H. Weber (*Fortschr. d. Phys.* 1863, xix. 417). The strength of the current employed was measured by a tangent-galvanometer, and the work done by it in the conductor was calculated from the quantity of heat evolved. Experiments of a similar kind have also been made by Joule (*Rep. Brit. Assoc.* 1867, p. 612), but with a converse purpose; Joule's object having been to deduce the value of the mechanical equivalent of heat, from the quantity of heat developed in a given time, by a current of known strength, in a conductor of which the absolute resistance was known from independent experiments.

[For a further account of the British Association unit of resistance, and a comparison of the various units that are or have been in use, see Fleeming Jenkin, *Proc. Roy. Soc.* (1866) xiv. 164; *Phil. Mag.* [4] xxix. 477].

Comparison of Electromotive Forces. The method given at p. 465 of vol. ii. is not capable of giving trustworthy results in the case of batteries whose electromotive force varies with the strength of the current which passes through them, as is the case, for example, with a battery of Smee's construction, and with most other batteries containing only a single liquid. Such batteries have a definite electromotive force only when the current has a determinate value, and the only condition in which we can be sure that two or more are truly comparable is when they are not traversed by any current at all. This condition may be realised, either by interposing an infinite resistance between the poles (that is, by leaving them disconnected), or by balancing their electromotive force by an equal and opposite force. In the former case the measurement of electromotive force comes to be simply a measurement of the difference of statical tension upon the poles, and may be effected by means of a Thomson's electrometer (p. 553). Several methods, founded upon the second general principle mentioned above, have been devised; but they may all of

them be regarded as modifications of one which was introduced many years ago by Poggendorff (*Pogg. Ann.* liv. 161 [1841]), and is known as his *method of compensation*. The general nature of this method will be understood from the following description. Let \mathfrak{D} and \mathfrak{G} (fig. 26) represent the two cells whose electromotive forces are to be compared, the electromotive force of \mathfrak{G} being greater than that of \mathfrak{D} (for instance, \mathfrak{G} being a Grove's, and \mathfrak{D} a Daniell's cell). The cells are to be united, by wires connecting their similar poles, so as to form parts of the same circuit, at some part of which a galvanometer Λ is to be inserted. Then a point a , in the conductor which connects one pole of \mathfrak{D} with the like pole of \mathfrak{G} , is to be connected, by a conductor ab , of known resistance which can be varied at pleasure (such as a rheostat or set of resistance-coils), with a point b in the conductor which connects the galvanometer with the other

FIG. 26.

pole of \mathfrak{G} ; and, lastly, the resistance at b is to be increased or diminished until no current circulates in the branch ab , and consequently the galvanometer Λ shows no deflection. Calling E_D and E_G the electromotive forces of the two cells, and R and R_G the resistances of the branches ab and aGb respectively, we have for the ratio of the electromotive forces:

$$\frac{E_D}{E_G} = \frac{R}{R + R_G}.$$

This formula is easily established from the following considerations. Since there is no current in the part of the circuit containing the cell \mathfrak{D} and the galvanometer Λ , the strength of the current in \mathfrak{G} and the condition in all respects of the circuit aGb would be unchanged if the branch aDb were removed. Then, putting C for the strength of the current in \mathfrak{G} , we have

$$E_G = C(R + R_G);$$

and, since the strength of the current through \mathfrak{D} is the same as that through \mathfrak{G} , we have also

$$E = CR,$$

if E represents the electromotive force acting between a and b . Hence

$$\frac{E}{E_G} = \frac{R}{R + R_G}.$$

But, since there is no current through \mathfrak{D} and Λ , the electromotive force between a and b must be equal to that of the cell \mathfrak{D} , and must tend to produce a current through \mathfrak{D} in the opposite direction to that which the electromotive force of this cell would produce if it acted alone in the circuit. That is

$$E = E_D \quad \text{or} \quad \frac{E_D}{E_G} = \frac{R}{R + R_G}.$$

The same relation is also easily deduced from the principles discussed at p. 565, as applying to the strength of currents in divided circuits. It is only needful to write

down the strength of the current in the branch $a \Delta b$ due to the cell n , and the strength of the current in the same branch due to the cell a , and to make their sum $= 0$, in order to arrive at the above equation.

It will be seen that this method gives the ratio of the electromotive forces to be compared in terms of the resistances R and R_G . Of these, R , which is the resistance of a metallic conductor, can always be ascertained within a very small fraction of its whole amount; but R_G , which includes the resistance of the cell a , cannot in general be measured with equal accuracy. If, however, a great metallic resistance—say 2,000 or 3,000 units—be introduced into the branch $a \Delta b$, any uncertainty in the determination of the resistance of a becomes of small consequence in comparison with the total resistance R_G , and indeed, in such a case, the resistance of the cell may be generally entirely disregarded. Even if it is inconvenient to introduce into the branch $a \Delta b$ a metallic resistance so great that the resistance of the cell is negligible in comparison, the necessity of knowing what the resistance of the cell is may be avoided by the following artifice, due to Bosscha (*Pogg. Ann.* xciv. 172 [1855]). The connections are made exactly in the way that has been described, and the resistance at n is adjusted so as to cause no current to traverse the galvanometer Δ . Then the resistance R_G is increased or diminished by a known amount r_G , whereby a current is produced either in one direction or the other through Δ , and lastly the resistance at n is increased or diminished so as again to destroy the current in Δ : let τ be the alteration required for this purpose; then the first experiment gives, as before,

$$\frac{E_D}{E_G} = \frac{R}{R + R_G},$$

and the second experiment gives

$$\frac{E_D}{E_G} = \frac{R + \tau}{(R + \tau) + (R_G + r_G)};$$

and therefore, from the two together we get

$$\frac{E_D}{E_G} = \frac{r}{r + r_G}.$$

Another modification of Poggendorff's method, which presents the advantage of making the conditions of the two cells to be compared exactly similar, by simply allowing neither of them to be traversed by a current, has been devised by Mr. Latimer Clark (*Elementary Treatise on Electrical Measurement* [London, 1868] p. 106). In this method, the poles of a battery of considerably greater electromotive force than

FIG. 27.

either of the cells to be compared are connected by a metallic conductor of great resistance; the similar poles of both the cells to be tested, the positive poles for instance, are then connected with the same point of this conductor, and the points are found by trial with which the other pole of each cell must be connected in order that neither of them may be traversed by a current. The above diagram (fig. 27), in which A and A'

denote the cells to be compared, B a battery of greater electromotive force, and a and a' galvanometers which show whether or not any current is passing through A or A' , will help to explain the mode of arranging the apparatus. It is plain that, when the indicated connections have been made, and both the galvanometers remain at zero, the electromotive force of the cell A is to that of the cell A' in the same ratio as the resistance of the portion of the conductor of the battery B included between the points a and b is to that of the portion included between the points a and b' . A special apparatus constructed by Mr. Clark for conveniently measuring electromotive forces by this method will be found described in the work referred to above.

Another simple modification of Poggendorff's arrangement enables us to ascertain whether the electromotive force of a cell when producing a current varies with the resistance of the circuit, and if so to what extent. This will be readily understood from the following diagram (fig. 28), where A and B represent, one of them a standard cell,

FIG. 28.

and the other a cell to be compared with it, and a a galvanometer one terminal of which is connected with the point a in the circuit of the cell A , and the other with the point b in the circuit of the cell B . Then, if the points c and d are also connected by a conductor, and the resistances in the various parts of the two circuits are so adjusted that no current traverses the galvanometer, it will be easily seen that the electromotive force acting between the points a and c must be equal to that acting between the points b and d ; and since the former is the same fraction of the total electromotive force of the cell A that the resistance between a and c is of the resistance of its whole circuit, and the latter is to the total electromotive force of the cell B as the resistance between b and d is to the whole resistance of this circuit, we get for the ratio of the electromotive forces of the two cells the expression

$$\frac{E}{E'} = \frac{Rr'}{R'r}$$

in which E stands for the electromotive force of the cell A , R for the total resistance of the circuit aac , and r for the resistance between a and c , while E' , R' , and r' denote the corresponding magnitudes in the case of the cell B .

The electromotive force of cells of professedly the same construction is not always identical, but varies within small limits in consequence of causes which have not been thoroughly investigated, but of which the most important are probably the greater or less purity of the metals and solutions employed, and the degree of concentration of the latter. The following table gives the average electromotive forces of several of the best known cells compared with that of a Daniell's cell taken as unity:

Electromotive Forces of Galvanic Cells.

Construction of Cell	Electromotive Force	Authority
Daniell's	1	
Grove's	1·67 } to 1·81 }	Poggendorff.
"	1·75	Buff.
"	1·79	Latimer Clark.
Bunsen's	1·75	L. Clark ; J. Müller.
"	1·70 } to 1·87 }	Buff.
Snee's (when not in action) .	1·02	Clark.
" " (when in action) .	1·05	Poggendorff.
" "	about 0·45	Clark.
" "	0·65	Joule.
" "	0·44	Bosscha (by calculation).

Zinc and binocide of manganese in saturated solution of ammonium chloride (Leclanché) }	1·382 0·896	Leclanché. Müller.

The absolute electromotive force of a Daniell's cell is estimated by Bouscha at 10·258, by Thomson at 10·79, and by von Waltenhofen (*Pogg. Ann.* cxxxiii. 478) at 10·8; that is to say, a Daniell's cell would produce, in a circuit whose total resistance was 1 B. A. unit, a current of a little more than *ten* times the unit current as defined at p. 571.

The following determinations are given by Kohlrausch (*Pogg. Ann.* cxli. 456): they are expressed in terms of Siemens's mercury-unit of resistance and of the absolute unit of current:

Electromotive force of a Grove's cell (platinum, concentrated nitric acid, sulphuric acid of sp. gr. 1.06, freshly amalgamated zinc) = 1.98.

Electromotive force of a Daniell's cell (copper, saturated solution of cupric sulphate, sulphuric acid, and zinc, as above) = 11.71.

Electromotive force of a cell formed of copper, sulphuric acid, and zinc (as above) = 10.82.

Electromotive forces of thermo-electric couples, one joint being at about 16° C., and the other t° higher :

1. German-silver and copper—

$$e = 0.0001549t + 0.000000291t^2.$$

- ## 2. Copper and iron—

$$\delta = 0.0000989t - 0.000000149t^2.$$

- ### 3. German-silver and iron—

$$= 0.0002476t + 0.000000196t^2.$$

[A very instructive exposition of the general relations of electrical magnitudes, by Prof. J. Clerk Maxwell and F. Jenkin, will be found in Appendix C to the second Report of the Committee of the British Association on Standards of Electrical Resistance (*Brit. Assoc. Rep.* 1863, p. 130); and a clear and concise statement of the general principles of the most important electrical measurements has been given by M. Bertin in the *Annales de Chimie et de Physique* for December 1869 and April 1870 (vol. xviii. pp. 446-461; vol. xix. pp. 483-501).]

G. C. F.

ELIC ACID. An acid existing, according to Chevreul (*Compt. rend.* lxii. 1015), in the sweat of sheeps' wool. It is a colourless liquid, somewhat heavier than water, nearly insoluble therein, but soluble, with acid reaction, in alcohol and ether. The barium salt, which is likewise soluble in alcohol, decomposes in dilute aqueous solution, with separation of a varnish-like acid salt.

EMETINE. $C^{20}H^{44}N^2O^8$ (J. Lefort, *J. Pharm.* [4] ix. 241).—This alkaloid, discovered by Pelletier and Magendie in 1807 (ii. 485), is best prepared as follows: Powdered ipecacuanha is exhausted, first with alcohol of 86 p. c., then with alcohol of 56 p. c.; the united extracts are evaporated to a syrup over the water-bath, and the residue is treated in a flask with very strong potash-solution (2 pts. potassium hydrate dissolved in a small quantity of water to 100 pts. of the powder), and with a quantity of chloroform equal in bulk to the mixture. The flask must be completely filled with the mixture and closely corked; the whole well agitated and left to stand for several days, till the chloroform has separated; the chloroform then removed with a pipette; and the residue treated with a fresh quantity of chloroform. On distilling off the chloroform, there remains a brown mixture of emetine with a resin, from which the emetine may be extracted by a weak acid, and reprecipitated by ammonia not in excess. A bulky greyish powder is thus obtained, which must be washed, first with water and then with ether, to remove the last traces of resin.

Pure emetine is a very light, whitish, amorphous powder, becoming slightly brown on exposure to the air; it is inodorous, but has a bitter taste; melts at 70° to a dark brown liquid. Water at 15° dissolves only $\frac{1}{1000}$ of its weight of emetine, but acquires thereby an alkaline reaction; alcohol and chloroform dissolve it in all proportions; ether and fixed oils very sparingly. It dissolves very easily in caustic fixed alkalis, less easily in ammonia. With hydrochloric, sulphuric, phosphoric, and acetic acids it forms uncrystallisable salts very soluble in water. It is precipitated by tannic acid, and by a solution of iodine in potassium iodide. With mercuric chloride and potassio-mercuric iodide, it forms compounds sparingly soluble in water; with platinum chloride, a light yellow salt, easily soluble in water, sparingly in alcohol. It is also precipitated from its saline solutions by phosphomolybdic acid and by basic lead acetate.

EPACRIS. The alcoholic extract of the leaves of a species of *Epacris* from Australia, examined by Rochleder and Tonner (*Jahresb.* 1861, p. 773; 1866, p. 694), has been found to contain ursone (v. 969), together with fat, wax, and chlorophyll. The leaves also contain a tannin which agrees in all its properties with that of the horse-chestnut, and when treated with hydrochloric acid, yields a red compound exhibiting the composition $C^{28}H^{22}O^{11} \cdot 2C^{13}H^{12}O^4$. The same tannin appears also to occur in *Ledum palustre*.

EPICHLORHYDRIN. See CHLORHYDRINS (p. 433).

EPICYANHYDRIN. $C^8H^8NO = (C^3H^3)^n \begin{Bmatrix} O \\ CN \end{Bmatrix}$.—Produced by gently warming epichlorhydrin with aqueous potassium cyanide. A violent action takes place, which may be moderated by cooling, and ultimately epicyanhydrin is deposited in slender laminae, which are easily purified by washing with water and alcohol, and recrystallisation. The crystals are colourless, soluble in water and alcohol, slightly soluble in ether, and give off large quantities of ammonia when boiled with potash (Pazschke, *Zeitschr. f. Chem.* [2] v. 612).

ERBIUM. See TERBIUM (v. 720).

ERGOTINE. This substance, the active principle of ergot of rye, may be prepared by precipitating the aqueous extract of the ergot with neutral lead acetate, treating the filtrate (free from lead) with mercuric chloride, and precipitating the filtered liquid with phosphomolybdic acid. The ergotine separated from the resulting precipitate by digestion with barium carbonate and water, is a varnish-like brown powder, insoluble in ether and chloroform, and forming amorphous deliquescent salts with acids. Its analysis leads to the formula $C^{20}H^{24}N^2O^8$ (Manassewitz, *Zeitschr. f. Chem.* [2] iv. 154).

ERICINONE. Zwenger & Himmelmanna (*Ann. Ch. Pharm.* cxxix. 203) have shown that this substance is identical with hydroquinone, as originally suggested by Hesse (ii. 500).

ERICIC ACID. $C^{22}H^{42}O^2$ (ii. 501).—This acid, homologous with acrylic acid, was discovered by Darby (*Ann. Ch. Pharm.* lxi. 1), and has been further examined by Otto (*ibid.* cxxvii. 182; cxxxv. 226) and by Haussknecht (*ibid.* cxliii. 40). It unites directly with bromine, when that substance is added to it under water, forming erucic acid dibromide, $C^{22}H^{42}Br^2O^2$, which crystallises by cooling from solution in absolute alcohol, in small white nodular groups of crystals melting between 42° and 43° . Its barium salt, $(C^{22}H^{41}Br^2O^2)^2Ba$, and its lead salt, $(C^{22}H^{41}Br^2O^2)^2Pb$, are white, viscid, easily decomposable precipitates. Sodium-amalgam in alcoholic solution reconverts erucic acid dibromide into erucic acid (Otto).

Erucic acid dibromide heated in sealed tubes to about 145° for seven or eight hours with 4 or 5 mol. potassium hydrate in alcoholic solution, yields the potassium salt of benolic acid, $C^{22}H^{40}O^2$ ($= C^{22}H^{40}Br^2O^2 - 2HBr$) (p. 257). But when an alcoholic solution of the dibromide is mixed with alcoholic potash-solution at ordinary temperatures, only 1 mol. hydrobromic acid is abstracted, and monobromerucic acid, $C^{22}H^{41}BrO^2$, is formed, with rise of temperature and separation of potassium chloride. On diluting the solution with water and adding hydrochloric acid, monobromerucic acid is separated in the form of an oil, which soon solidifies. It melts at 33° – 34° , and remains liquid for a long time. It is heavier than water and insoluble therein, but dissolves easily in alcohol and ether. It unites with 1 mol. bromine, forming the acid dibromide, $C^{22}H^{41}Br^2O^2$ or $C^{22}H^{41}BrO^2 \cdot Br^2$, which melts at 31° to 32° , and forms amorphous viscid salts. This dibromide treated with alcoholic potash gives up hydrobromic acid, but it has not been decidedly made out whether dibromerucic acid is then reproduced by elimination of 1 mol. HBr , or monobromobenolic acid, $C^{22}H^{41}BrO^2$, by elimination of $2HBr$.

When erucic acid dibromide is triturated with water and a large excess of silver oxide, and the mass, which soon becomes warm and granular, is heated for several hours, till it turns brown, hydrobromic acid is eliminated, and on boiling the mass with water, a yellow oil separates, which is a mixture of liquid oxyerucic acid, $C^{22}H^{42}O^3$, and dioxybenic acid, $C^{22}H^{40}O^4$, the latter of which crystallises out partially after long standing. For complete separation, the oil, after being well washed, is saponified with baryta-water; the precipitate is exhausted with ether; the dissolved barium oxyerucate is decomposed by hydrochloric acid; and the oxyerucic acid, which separates as a yellowish oil, is purified by solution in alcohol. It is viscid, lighter than water, insoluble therein, but miscible in all proportions with alcohol and ether. Its salts, $C^{22}H^{42}O^3M$, are amorphous, and are all insoluble in water, excepting those of the alkali-metals and of barium. The formation of oxyerucic acid is represented by the equations:

This acid may therefore also be formed, though less easily, by treating monobromerucic acid with silver oxide. When boiled with potash-ley, it is converted into dioxybenic acid, $C^{22}H^{40}O^4$, according to the equation, $C^{22}H^{42}O^3 + KOH = C^{22}H^{40}O^4$ (Haussknecht).

ERYTHRERIC ACID. An acid contained in the blood-red juice of the dragon's blood tree of Brazil (*Croton erythraea*, p. 547).

ERYTHRIN or **ERYTHRIC ACID.** $C^{20}H^{32}O^{10}$ (ii. 502).—The following method of preparing this substance from *Rochella fuciformis* is given by Stenhou (*Chem. Soc. J.* [2] v. 222): Three pounds of the lichen are macerated for twenty minutes in a milk of lime made by slaking $\frac{1}{2}$ lb. of lime in 3 gallons of water, and the partially exhausted weed is then treated with a fresh quantity of milk of lime; third maceration is found to exhaust the lichen completely. These weak lime-liquors are employed instead of milk of lime for exhausting fresh quantities of the lichen whilst the first and strongest liquor is filtered rapidly through bag-filters about 6 inches wide and 6 feet long; and the clear liquor, as it passes through, is immediately precipitated by hydrochloric acid, as prolonged contact with the lime decomposes a portion of the erythrin. The precipitated erythrin is collected in bag-filters, and when the greater part of the mother-liquor has been thus removed, it is freed from

adhering hydrochloric acid and calcium chloride by stirring it up once or twice with a considerable quantity of water.

The recent experiments of De Luynes (*Ann. Ch. Phys.* [4] ii. 555), Marchand (*Bull. Soc. Chim.* [2] ii. 424), and Hesse (*Ann. Ch. Pharm.* cxxxix. 22) have confirmed the view originally put forward by Berthelot, that erythrin is the diorsellinic ether, and picroerythrin the mono-orsellinic ether of erythrite:

Erythrite.

Picroerythrin.

Erythrin.

Grimaux (*Bull. Soc. Chim.* [2] iii. 410), regarding orsellinic acid, $\text{C}^2\text{H}^5\text{O}^1$, as a triatomic and monobasic acid, $\left(\begin{array}{c} \text{C}^2\text{H}^5\text{O}^1 \\ \text{H}^2 \end{array} \right) \text{O}^2$, represents erythrin and picroerythrin by the following formulæ:

Picroerythrin.

Erythrin.

According to Hesse (*Jahresb.* 1866, p. 658), erythrin in the air-dried state retains 6 p. c. water = $2\text{C}^2\text{H}^5\text{O}^1 \cdot 3\text{H}^2\text{O}$, which is given off partly over sulphuric acid, completely at 100° . The lead salt contains $(\text{C}^2\text{H}^5\text{O}^1)^2\text{Pb}^2 \cdot 3\text{H}^2\text{O}$; bromerythrin is $2\text{C}^2\text{H}^5\text{O}^1\text{Br}^2 \cdot 3\text{H}^2\text{O}$.

Erythrin boiled with absolute alcohol yields picroerythrin and ethyl orsellinate (ii. 502); with hydrated alcohol the same products are obtained, but the proportion of ethyl orsellinate is smaller, because part of the erythrin is decomposed by the water of the alcohol, in such a manner as to yield orcin and carbon dioxide:

With ether, erythrin behaves indifferently, dissolving in 328 pts. at 20° . Boiled with amyl alcohol, it yields amyl orsellinate and picroerythrin, both of which crystallise. This reaction affords an easy method of obtaining perfectly pure picroerythrin. When the decomposition is complete, the remaining amyl alcohol is distilled off, whereupon the amyl orsellinate gradually separates as a colourless oil, while the picroerythrin separates from the liquid filtered at about 40° in white silky efflorescent needles containing $\text{C}^2\text{H}^5\text{O}^1 \cdot 3\text{H}^2\text{O}$ (Hesse, *loc. cit.*).

BETA-ERYTHRIN. $\text{C}^2\text{H}^5\text{O}^1$.—This body, homologous with erythrin, was discovered by Menschutkin (*Bull. Soc. Chim.* [2] ii. 424; *Jahresb.* 1864, p. 548), not by Lamparter, as stated in vol. iv. p. 641. It is prepared from certain varieties of *Rochella fuciformis* (the South American varieties, according to Lamparter) by digestion with lukewarm dilute lime-water (Menschutkin), cold milk of lime (Lamparter), precipitation with sulphuric or hydrochloric acid, and crystallisation from alcohol. It separates as a white crystalline powder containing $\text{C}^2\text{H}^5\text{O}^1 \cdot \text{H}^2\text{O}$, soluble in alcohol and ether, nearly insoluble in water, and decomposed by alcohol or water at the boiling heat, yielding β picroerythrin, $\text{C}^2\text{H}^5\text{O}^1$, and orsellinic acid or orsellinic ether (ii. 611). β erythrin is coloured transiently red by chloride of lime; its solution in ammonia forms with silver nitrate a reddish, easily reducible precipitate; with basic lead acetate, a gelatinous precipitate having nearly the composition $\text{C}^2\text{H}^5\text{Pb}^2\text{O}^1$ (Menschutkin).

β picroerythrin boiled with saturated baryta-water is resolved into carbon dioxide, erythrite, and β orcin (Menschutkin):

ERYTHROMANNITE. $\text{C}^2\text{H}^5\text{O}^1 = \left(\begin{array}{c} \text{C}^1\text{H}^6 \\ \text{H}^1 \end{array} \right) \text{O}^1$. Erythromannite, Erythroglucin, Phycite

(ii. 504).—To prepare this substance from erythrin, Stenhouse (*loc. cit.*) dissolves the latter in a slight excess of milk of lime, and boils it for half an hour in a vessel furnished with a long condensing tube, so as to exclude the air, and thereby prevent,

in a glass, as observed by De Luynes (*Jahres*, 1863, p. 502), the formation of a colourless, resinous substance. The solution, now containing orcin and erythrite, is heated, the excess of lime removed by a stream of carbonic acid—or more conveniently, on the large scale, by exact neutralisation with dilute sulphuric acid—and evaporated to dryness, first over a sand-bath, finally over a water-bath. The orcin is dissolved out of the residue by repeated digestion with benzol (boiling between 110° and 150°) in a metallic vessel connected with a condenser and heated in a paraffin-bath; and the undissolved portion treated with boiling water gives up the erythrite, which may be purified by washing with cold alcohol and recrystallisation from water.

Erythrite exhibits in a high degree the phenomenon of surfusion. When heated nearly to its boiling point, it forms a mobile liquid, viscid after cooling, which sometimes crystallises spontaneously at ordinary temperatures, but mostly not till it is agitated, the solidification being then attended with considerable rise of temperature. Its concentrated aqueous solution in contact with platinum-black absorbs oxygen so rapidly that the mass becomes red hot; with a dilute solution the oxidation is more gradual and an acid is formed (*infra*). Lime dissolves in an aqueous solution of erythrite more abundantly than in pure water; the solution conglutinates when heated, and alcohol throws down from it a compound of erythrite and lime. Erythrite heated to 240° with potassium hydrate forms oxalic and acetic acids, with evolution of hydrogen. With fuming hydriodic acid it yields secondary butyl iodide, or butylene hydriodide, C^4H^8HI (ii. 505; v. 736). With phosphorus pentachloride or chlorine in sunshine, it yields hydrochloric acid and a viscid uncrystallisable substance.

The chlorhydrin of erythrite, $(C^4H^8)^2 \begin{Bmatrix} Cl^2 \\ (OH)^2 \end{Bmatrix}$, is produced by heating erythrite to 100° for about a hundred hours with 12 to 15 pts. concentrated hydrochloric acid in very strong tubes, and evaporating the product over potash-lime. The crystals are purified by recrystallisation from ether, with addition of a little animal charcoal; they dissolve easily in water, alcohol, and ether; melt at 145° ; and volatilise in white vapours which condense to crystals (De Luynes, *Ann. Ch. Phys.* [4] ii. 385; *Jahres*, 1864, p. 497).

ERYTHRITIC or ERYTHROGLUCIC ACID. $C^4H^3O^5 = (C^4H^3O^4)^2 \begin{Bmatrix} H \\ O^1 \end{Bmatrix}$.—

This acid, related to erythrite in the same manner as glyceric acid to glycerin, is produced by the oxidation of erythrite in contact with platinum-black, or by the action of nitric acid. It was first observed by De Luynes (*supra*), and has been further examined by Sell (*Bull. Soc. Chim.* [2] v. 384), and by Lamparter (*Ann. Ch. Pharm.* cxxiv. 243), whose descriptions of its lead salts do not however quite agree.

Sell prepares the acid by leaving a solution of 30 grms. erythrite in 250 to 300 grms. water in contact with 15 to 20 grms. platinum-black previously mixed with pumice, renewing the water from time to time as it evaporates. The liquid then acquires a strong acid reaction, and if filtered after all the erythrite has disappeared, then evaporated to one-half, and mixed with basic lead acetate, yields a yellowish-white precipitate, which must be purified by decomposing it with hydrogen sulphide, reprecipitating with basic lead acetate, and repeating this treatment several times till the lead precipitate becomes perfectly white. It then yields a colourless solution of the acid, which, however, when evaporated over the water-bath, turns yellow and then brown, giving off the odour of caramel. The syrupy acid when left in a vacuum, partly solidifies to a crystalline mass which deliquesces on exposure to the air. The lead salt obtained as above is, according to Sell, a basic salt containing $C^4H^3Pb^2O^{12}$ or $4C^4H^3O^4 \cdot Pb^2H^2O^2$. The other salts of erythritic acid are easily soluble. Silver nitrate produces in the aqueous solution of the acid a white precipitate which is reduced in a few minutes, with deposition of a silver speculum; lime-water produces a slight turbidity which disappears on the addition of a drop of acetic acid.

Lamparter prepares erythritic acid by oxidising erythrite in warm concentrated solution with fuming nitric acid (with dilute nitric the chief product is oxalic acid). The product is a gummy acid whose barium salt is precipitated from its aqueous solution by alcohol, in the form of a powder having the composition $C^4H^3O^4Ba + H^2O$. The lead salt obtained by precipitation with basic lead acetate is, according to Lamparter, a normal salt, having when dried at 160° the composition $C^4H^3O^4Pb$.

ERYTHROBENZENE. A red colouring matter prepared from nitrobenzene by leaving 1½ pts. of that substance in contact with 24 pts. of fine iron- filings and 8 pts. strong hydrochloric acid, for 24 hours at ordinary temperatures. The solid

mass is then pulverised, and exhausted with water, and the solution is precipitated with common salt. The colouring matter thus obtained is purified by again dissolving and precipitating it (F. Laurent & J. Coudane, *Recherches de Patent Inventions*, Oct. 1862, p. 339; *Dingl. pol. J.* clvi. 239).

ERYTHROCENTAURIN. $C^{18}H^{14}O^8$ (C. Mehu, *J. Pharm.* [4] iii. 265).—A substance allied to santonin, obtained from the common centaury (*Erythraea Centaurium*, Gentianaceæ). To prepare it, the aqueous extract of the flower-heads, or of the entire plant, is treated with 4 or 5 times its weight of alcohol; the syrupy residue of the alcoholic extract is repeatedly agitated with 4 vol. ether; and the ethereal solution is evaporated, whereby a yellowish-brown semifluid residue is obtained, which after a while yields crystals of impure erythrocentaurin. These, after being pressed and once recrystallised from water, are decolorised in ethereal solution by animal charcoal. On leaving the ether to evaporate, large colourless crystals are obtained, amounting to scarcely $\frac{1}{4}$ per thousand of the weight of the dried plant.

Pure erythrocentaurin is tasteless and inodorous, neutral and not hygroscopic, not volatile; melts at 136° , and solidifies again in the crystalline form. Its solution in chloroform neither acts on polarised light nor fluoresces. It dissolves in 1630 pts. water at 16° , in about 13.5 pts. at 100° , in 48 pts. of 86 p. c. alcohol at 15° , in 13.5 pts. chloroform, and 245 pts. ether; easily also in oils both fixed and volatile, in benzol, and in carbon bisulphide. Acids increase its solubility in water, but do not unite with it; from its colourless solution in strong sulphuric acid it is precipitated by water without alteration. It is not acted upon by nitric, hydrochloric, or chromic acid, bromine, iodine, or alkalis; when fused in chlorine gas, it is converted into a glutinous substance recrystallisable only from ether. Erythrocentaurin is decomposed by potassium permanganate, even at ordinary temperatures. When exposed to sunshine, it quickly acquires a bright red colour, but without alteration of weight or of its relations to solvents. This coloured erythrocentaurin yields colourless solutions which in the dark deposit colourless crystals. The red colour likewise disappears on heating the substance to about 130° . The coloration of erythrocentaurin (like that of santonin) is produced only by the most refrangible (blue or violet) rays of the spectrum; but santonin which has been turned yellow by light is not decolorised by heat.

ERYTHROGLUCIC ACID. Syn. with ERYTHRITIC ACID (p. 583).

ETHANE. $C^2H^4 = \begin{array}{c} CH^3 \\ | \\ C^2H^4 \\ | \\ CH^3 \end{array} = C \begin{Bmatrix} CH^3 \\ H^3 \end{Bmatrix}$. Ethyl Hydride, Methyl, Dimethyl (ii. 533;

iii. 984).—This gas is evolved, together with carbon dioxide, by heating barium dioxide with acetic anhydride, barium acetate being produced at the same time (Schützenberger, *Bull. Soc. Chim.* [2] v. 278):

Darling (*Chem. Soc. J.* [2] vi. 426) finds that this reaction is apt to give rise to violent explosion [arising from the formation of acetyl peroxide, i. 35], which, however, may be prevented by mixing the barium dioxide with dry sand. The gas then evolved consists, after removal of carbon dioxide, chiefly of methane (marsh gas) with a little carbon monoxide and about 17 p. c. ethane. Frankland's mode of preparation by heating methyl iodide with zinc, yields perfectly pure ethane; but is not well adapted for the preparation of large quantities. The best process is the electrolysis of potassium acetate. Darling's experiments fully confirm the results obtained by Schorlemmer (iii. 984) respecting the identity of the gas obtained by this process with that obtained from mercuric ethide. When treated with chlorine in diffused daylight, it is converted into a mixture of ethyl chloride, C^2H^5Cl , and chorethyl chloride, $C^2H^4Cl^2$. The ethyl chloride thus obtained was converted into acetate, which by saponification with potash yielded pure ethyl alcohol.

Pentachlorethane. C^2HCl^5 (Paterno, *Compt. rend.* lxxiii. 450).—Produced by the action of phosphorus pentachloride on anhydrous chloral:

A small quantity of the pentachloride is added to chloral contained in a retort fitted with an upright condenser; the mixture is warmed; another portion of pentachloride added as soon as the first action is over, the process being repeated till 1 mol. $POCl^3$ has been added to 1 mol. chloral; and the reaction is completed by heating the mixture for some hours to the boiling point. Water is then added,

and the separate pentachlorethane is dried over calcium chloride and rectified. It is a colourless oil, like chloroform, boiling without decomposition at 158°, having d_4^{20} sp. gr. of 1.69 at 0°, 1.69 at 13°, soluble in alcohol and ether. It remains liquid at -11°, but is easily solidified by the cold produced by evaporation of sulphurous anhydride. Heated in sealed tubes to 250° with phosphorus pentachloride, it is converted into hexachlorethane or carbon trichloride, C^2Cl^3 :

It is also converted into carbon trichloride by exposure to sunshine.

Pentachlorethane obtained as above is most probably identical with Regnault's tetrachlorinated ethyl chloride (ii. 530) and trichlorethylene chloride (ii. 573), the former of which is described as boiling at 148°, the latter at 154°, the differences being probably due to the admixture of Regnault's compounds with other substitution-products formed at the same time. The compound boiling at 180°-181°, and said to contain C^2HCl^3 , which Hübner obtained among the products of the action of phosphorus pentachloride or acetyl chloride, was probably carbon trichloride.

The action of the pentachloride on chloral yields also a small quantity of a scaly crystalline compound, not yet analysed, which does not volatilise with vapour of water (Paterno).

ETHENE. Syn. with ETHYLENE.

ETHENYL. C^2H^3 .—The triatomic radicle derived from ethane by abstraction of 3 at. hydrogen.

ETHENYL-DIAMINE. $\left\{ \begin{smallmatrix} C^2H^3 \\ H^3 \end{smallmatrix} \right\} N^2$.—This is the composition of acediamine (i. 2).

Ethenyl-diphenyl-diamine. $C^2H^3N^2 = \left\{ \begin{smallmatrix} C^2H^3 \\ C^6H^5 \end{smallmatrix} \right\} N^2$ (Hofmann, *Compt. rend.* lxii. 729; *Bull. Soc. Chim.* [2] vi. 162).—This base, homologous with methenyl-[formyl-] diphenyl-diamine (iv. 459), is produced by the action of phosphorus trichloride on aniline mixed with phenyl-acetamide, or better with acetyl chloride, or better still with acetic acid:

A cooled mixture of 3 pts. aniline and 2 pts. acetic acid is gradually mixed with 2 pts. phosphorus trichloride, and the viscid liquid is heated for some hours to 160°. The resulting light-brown friable resinous mass is dissolved in boiling water, and the cooled filtrate is mixed with caustic soda, which throws down the base as a white crystalline precipitate, to be purified by recrystallisation from alcohol. It forms white laminae melting at 137°, volatilising without decomposition at a very high temperature, nearly insoluble in water, sparingly soluble in cold, easily in hot alcohol, in ether and in acids. Its *platinochloride*, $2(C^2H^3H^3N^2.HCl).PtCl^4$, is sparingly soluble and crystalline; the *nitrate*, $C^2H^3H^3N^2.HNO^3$, separates at first as an oil, which afterwards becomes crystalline. The base is attacked by strong sulphuric acid, which eliminates acetic acid and forms phenylsulphamic or sulphanilic acid:

Ethenyl-ethyl-diphenyl-diamine. $C^2H^3N^2 + \left\{ \begin{smallmatrix} C^2H^3 \\ C^6H^5 \end{smallmatrix} \right\} N^2$.—Ethenyl-diphenyl-diamine heated with ethyl iodide for several hours, forms a crystalline iodide, which may be converted into a chloride by treatment with chloride of silver; and this chloride treated with soda-ley yields ethenyl-ethyl-diphenyl-diamine, as a light oil insoluble in water and destitute of alkaline reaction. This oil is attacked by

methyl-iodide at 100° , and the iodide thus produced is converted by silver oxide into a

strongly alkaline liquid containing the ammonium-base,

$$\left. \begin{array}{l} (C^2H^3)^{''''} \\ (C^6H^5)^2 \\ C^2H^3 \\ CH_3 \\ OH \end{array} \right\} N^+$$

Methyl-aniline treated with phosphorus trichloride and acetic acid yields a chloride, which is converted by silver oxide into an alkaline ammonium-base homologous with

the preceding and represented by the formula,

$$\left. \begin{array}{l} (C^2H^3)^{''''} \\ (C^6H^5)^2 \\ (CH_3)^2 \\ OH \end{array} \right\} N^2.$$

Ethenyl-dinaphthyl-diamine, $C^{22}H^{18}N^2 = \left. \begin{array}{l} (C^2H^3)^{''''} \\ (C^{10}H^7)^2 \\ H \end{array} \right\} N^2$, is produced from naphthylamine in the same manner as ethenyl-diphenyl-diamine from aniline. This base is a tough resinous mass, yielding a platinochloride whose analysis leads to the formula just given.

Ethenyl-ditolyl-diamine, $C^{16}H^{18}N^2 = \left. \begin{array}{l} C^2H^3 \\ (C^7H^7)^2 \\ H \end{array} \right\} N^2$, obtained by the action of PCl^5 on toluidine and acetic acid, is scarcely distinguishable from the diphenylated base.

Ethenyl-triphenyl-diamine, $C^{20}H^{18}N^3 = \left. \begin{array}{l} (C^2H^3)^{''''} \\ (C^6H^5)^3 \end{array} \right\} N^2$, is produced by the action of phosphorus trichloride on a mixture of 1 mol. diphenylamine and 1 mol. phenylacetamide:

ETHERS. *Formation of Compound Ethers by the mutual action of Acids and Alcohols.*—The first part of the researches of Berthelot a. Péan de St. Gilles on this subject was noticed in vol. ii. p. 210 of this Dictionary. In a continuation of this research (*Bull. Soc. Chim.* v. 182, and [2] i. 336; in detail, *Ann. Ch. Phys.* [3] lxxviii. 225), the authors direct attention especially to the limit of combination between different acids and alcohols; the variations of this limit resulting from excess of acid, alcohol, neutral ether, or water; the action of acids on very dilute alcohols; and the result of the simultaneous action of several acids on several alcohols.

1. In a homogeneous mixture of acid, alcohol, compound ether, and water, the limit of combination is reached when the ether-forming affinity of the acid for the alcohol, and the ether-decomposing power of the water, are equal to one another. The existence of such a limit is proved by causing alcohol and acid on the one hand, and the corresponding compound ether with an equivalent quantity of water on the other (this mixture being exactly similar to the former in ultimate composition), to act upon one another for different times and at different temperatures. It is then found that if, in the first case, two-thirds of the whole quantity of acid has entered into combination, then in the second, one third of the neutral ether will be resolved into acid and alcohol.

That this limit of combination is almost independent of the particular nature of the acid and alcohol, and depends essentially on the equivalent proportions of the mixture, had been shown by the authors in the first part of their research, as far as regards particular systems (ii. 510); and this result is now shown to be universally true, not only with respect to the action of mono-acid or poly-acid alcohols on monobasic or polybasic acids, when these bodies act upon one another without the presence of water, but likewise for the most various mixtures, whether they contain excess of acid, or of alcohol, or of compound ether, or of water. The particular nature of the alcohol and of the acid does however exert a slight influence, at least in the case of monatomic compounds, inasmuch as metameric mixtures (e.g. amyl alcohol and acetic acid, ethyl alcohol and valeric acid) always exhibit slightly different limits; with polyatomic alcohols and acids, however, no such differences are observed.

A considerable difference is observed between the behaviour of polybasic acids and monobasic acids, inasmuch as a molecule of a bibasic acid etherifies the same quantity of alcohol as 2 molecules of a monobasic acid, and a molecule of a

tribasic acid etherifies the same quantity of alcohol as 3 molecules of a monobasic acid, whereas a molecule of a biacid or triacid alcohol—at least, if no great excess of acid is present—unites with only the same quantity of acid as a molecule of a monoacid alcohol. The cause of this difference of behaviour—which seems to show that the functions of the acid and of the alcohol in etherification are not exactly alike—is to be found in the fact that a polybasic acid forms only one neutral compound with a monoacid base, whereas the several compounds which may be formed from a polyacid alcohol and a monobasic acid (mono-, di-, and tri-aetin for example) are all destitute of acid properties.

2. When an excess of alcohol acts upon a molecule of acid, the quantity of compound ether formed increases regularly (not by sudden increments) with the augmentation in the quantity of alcohol, and tends towards the complete fixation of the acid; the quantity of acid which in presence of an excess of alcohol does not enter into combination, is nearly in inverse proportion to the total quantity of the latter, and directly proportional to the total quantity of the acid. In this case, also, monoacid and polyacid alcohols react nearly in the same manner with one and the same monobasic acid. The following table shows the quantities per cent. of various acids which entered into combination when 1 mol. of the acid was acted upon by n molecules of an alcohol:

Methyl alcohol	Acid	Ethyl alcohol	Acid	Amyl alcohol	Acid	Glycerin	Acid
$n = 1$	67.5	$n = 1$	66.5	$n = 1$	68.2	$n = 1$	68.7
1.5	75.9	1.5	77.9	—	—	1.5	72.0
2	84.0	2	82.8	2	86.9	—	—
—	—	3	88.2	3	89.4	—	—
—	—	—	—	—	—	6.1	89.3
19	95.0	—	—	—	—	—	—
500	100.0*	—	—	—	—	—	—

In like manner, the quantity of an alcohol etherified under the influence of an excess of one monobasic or polybasic acid, increases with the amount of this excess, and appears, when more than two molecules of acid act upon one molecule of alcohol, to be directly proportional to the total quantity of the acid. Traces of alcohol are taken up by excess of acid with nearly the same degree of completeness as traces of acid by an alcohol. Polyacid alcohols appear, moreover, in presence of excess of acid, to take up a larger quantity of the acid in proportion to their atomicity.

3. Etherification is retarded by addition either of a neutral ether or of water. But just as compound ethers are not completely decomposed, even by large quantities of water, so likewise is their formation not entirely prevented by the presence of large quantities of water, the amount of ether produced sinks to a minimum when the acid and alcohol are present in equivalent quantities, and is increased by the presence of an excess either of acid or of alcohol. In mixtures containing 8 mol. water (H_2O) to 1 mol. alcohol, and containing excess of alcohol, the quantity of ether formed is nearly proportional to the quantity of acid present; an almost exact proportionality is observed in mixtures diluted to the extent which is found in fermented liquors (23 to 48 mol. water to 1 mol. alcohol).

The phenomena exhibited in the action of water on compound neutral ethers are the converse of those which take place in their formation. A trace of water decomposes a nearly equivalent quantity of an ether into acid and alcohol; the decomposition of the ether increases with the quantity of water in the mixture, and becomes nearly perfect when only traces of ether are present.

4. In the simultaneous action of several alcohols on an acid, or of several acids on an alcohol, or finally of several monoacid or polyacid alcohols on several monobasic or polybasic acids, the sum of the compound ethers formed is equivalent to that produced by the corresponding quantity of a single alcohol on a single acid.

Formation of Ethers by Oxidation of Fatty Acids.—Strecker observed some years ago that butyric acid oxidised with manganese dioxide and sulphuric acid yields an ethereal product. This reaction has lately been further investigated by Veil (Ann. Ch. Pharm. cxlviii. 160), who finds that when pure butyric acid is gradually added upon a mixture of pulverised manganese dioxide and sulphuric acid diluted with an equal volume of water, and the mixture is distilled, an ethereal liquid is

* The mixture did not remain liquid.

which, after purification in the usual way, boils between 116° and 145° , has a composition expressed approximately by the formula $C^4H^{12}O^2$, and when decomposed by potash yields only butyric acid and alcohols; hence Vieil infers that it consists mainly of propyl butyrate, $C^3H^{10}O^2$, mixed with lower homologues. Valeric acid treated in a similar manner yielded an ether having the composition of methyl valerate, $C^5H^{12}O^2$, and yielding valeric acid by saponification. No non-volatile products were obtained.

Action of Bromine on Ethers (Ladenberg a. Wichelhaus, *Ann. Ch. Pharm.* clii. 163).—Oxygen-ethers in which the alcohol-radicle is immediately associated with a carboxyl group, such as ethyl acetate, $CH^3-COOC^2H^3$, ethyl oxalate, $COOH-COOC^2H^3$, &c., are not attacked by bromine; but those in which the alcohol-radicle does not enter in this manner, such as ethyl-orthocarbonate, $C(OC^2H^3)^4$, yield ethyl bromide when thus treated. *Orthoformic ether*, $CH(OC^2H^3)^3$, produced by the action of chloroform on sodium ethylate (p. 621), is attacked by bromine in the cold, and the product when distilled yields ethyl bromide, ethyl metacarbonate (ordinary carbonic ether), ordinary ethyl formate, and alcohol; thus:

Ethyl orthocarbonate heated with bromine yields ethyl bromide, ethyl metacarbonate, and a small quantity of bromal, resulting from the further action of the bromine on the ethyl oxide likewise produced in the first instance:

Ethyl metacarbonate heated with bromine also yields ethyl bromide and bromal, with evolution of carbon dioxide:

Ethyl-glycollic acid, $\begin{array}{c} CH^3(OC^2H^3) \\ | \\ COOH \end{array}$, heated with bromine yields ethyl bromide, and probably also glyoxylic and glycollic acids. *Ethyl-lactic ether* is attacked by bromine at 100° , yielding ethyl bromide, hydrogen bromide, and a liquid which distils between 120° and 250° , probably pyracemic ether:

Action of Alcohols upon Ethers.—Oxygen-acid ethers and haloform ethers are decomposed by heating with alcohols, the two alcohol-radicles changing places. Thus when ethyl silicate is heated to 160° – 180° with amyl alcohol, amyl silicate is formed, together with ethyl alcohol. A mixture of amyl iodide with rather more than 2 mol. ethyl alcohol heated for 24 hours to 160° – 180° , yields water, ethyl-amyl oxide, and ethyl iodide:

A similar reaction takes place between ethyl iodide and amyl alcohol. In like manner ethyl acetate and amyl alcohol yield water, amyl acetate, and ethyl-amyl oxide. Ethyl benzoate, and especially ethyl chloride, are but slowly decomposed. Ethyl oxalate heated to 220° – 250° for 36 hours with 1 mol. amyl alcohol is partially decomposed, yielding carbon dioxide, carbon monoxide, ethyl oxide, ethyl alcohol, amyl oxalate, and probably also ethyl-amyl oxide. Those ethers which are easily decomposable by water are also decomposed with more or less facility by alcohols, but apparently only by an action of masses, and not on account of the greater affinity of the alcohol to the acid (Friedel a. Crafts, *Ann. Ch. Pharm.* cxxx. 198).

A mixture of ethyl iodide and amyl alcohol, or of amyl iodide and ethyl alcohol, in equivalent quantities, yields hydriodic acid and ethyl-amyl oxide, according to the equation:

The hydriodic acid thus formed acts upon the amyl or ethyl alcohol in such a manner as to form ethylic or amyllic iodide and water, and, on the other hand, this

water may act upon the ethylic or amylic iodide so as to reproduce the alcohols, the reaction taking place one way or the other till an equilibrium is established. In this manner a small quantity of an alcoholic iodide may, by successive and alternating transformations, etherify a considerable quantity of alcohol, without any essential diminution of the quantity of the iodide (Friedel & Crafts, *Ann. Ch. Pharm.* cxxxi. 56).

According to H. Gal (*Compt. rend.* lix. 1049), the methylic and ethylic ethers of the formic, benzoic, or oxalic series saturated with dry *hydrogen bromide* and heated to 100°, are completely resolved into free acid and the bromide of the alcohol-radicle. Ethyl carbonate is resolved under these circumstances into ethyl bromide, carbon dioxide, and water; ethyl nitrate yields ethyl bromide and a considerable quantity of red vapours.

Action of Alkali-metals.—The action of alkali-metals on oxygen-ethers has given rise to considerable discussion. Löwig & Weidmann (*Pogg. Ann.* l. 98), by heating ethyl acetate with potassium, obtained potassium ethylate and a liquid which reduced silver salts: they did not observe any evolution of hydrogen. L. Gmelin (*Handbook*, viii. 499) explained their results by the following equation:

Geuther (*Arch. Pharm.* [2] cxvi. 97; *Jahresb.* 1863, p. 323) found that when ethyl acetate purified from alcohol by repeated rectification over sodium was heated with sodium, the metal dissolved, with evolution of hydrogen and formation of sodium ethylate, and the sodium salt of an acid, $\text{C}^2\text{H}^3\text{O}^2$, which he regards as *ethyl-diacetic acid*, $\text{C}^2\text{H}^3(\text{C}^2\text{H}^3)\text{O}^2$:

Frankland & Dupré (*Chem. Soc. J.* [2] iv. 396; v. 102; *Jahresb.* 1865, p. 304) have also examined the action of sodium on ethyl acetate and other compound ethers of the fatty series, with results partly agreeing with those of Geuther. They find that when acetic ether is heated with sodium to 130° in a flask provided with an inverted condensing apparatus, two reactions go on simultaneously, both being attended with evolution of hydrogen. (1) The sodium acts in such a manner as to produce alcohol, together with the monosodic and disodic salts of Geuther's ethyl-diacetic acid (to which salts, however, they assign different names and rational formulæ, p. 691); thus:

and

(2) The sodium simply displaces an equivalent quantity of hydrogen in one or in two molecules of acetic ether, producing the ethylic ethers of sodacetic and disodacetic acids:

and

These several sodium-compounds when heated with ethyl-iodide are converted into ethers in which the sodium is replaced by an equivalent quantity of ethyl. The sodium compounds, in fact, were not separated and analysed, but their composition was inferred from that of the several ethylic compounds, $\text{C}^2\text{H}^5(\text{C}^2\text{H}^3)\text{O}^2$, C^2H^3 , &c., obtained by treating the crude product of the action of sodium with ethylic iodide, and fractionating the resulting distillate.

The action of sodium on ethyl acetate and other compound ethers has also been studied by Wanklyn (*Chem. News*, 1868, pp. 121, 143; *Zeitschr. f. Chem.* [2] iv. 673 further, *Chem. News*, 1870, p. 7), who obtains the same products as Geuther, with exception of the free hydrogen. Wanklyn finds indeed, in accordance with Löwig & Weidmann, that when sodium acts upon perfectly pure ethyl-acetate, no hydrogen is evolved as a direct result of the reaction, the only products being sodium ethylate and sodium triacetyl, $(\text{C}^2\text{H}^3\text{O})^3\text{Na}$, identical with Geuther's sodium-ethyl-diacetate:

A secondary reaction, however, takes place at the same time between the sodium

ethylate and the excess of ethyl acetate, resulting in the formation of ethylene-sodium acetate and alcohol :

and the sodium acting on the alcohol thus produced converts it into sodium ethylate, with elimination of hydrogen; but the quantity of hydrogen thus evolved is always much less than the equivalent of the quantity of sodium dissolved. When only a slight excess of pure ethyl acetate is used, no hydrogen is evolved. If the ethyl acetate originally contains alcohol, the quantity of hydrogen evolved is of course greater. (See further, ACETIC ETHERS, p. 15.) Wanklyn also finds that amyl acetate, ethyl butyrate, ethyl valerate, and ethyl benzoate when acted upon by sodium do not yield a trace of gas.

Frankland & Duppa, in a recent communication to the Royal Society (*Proc. Roy. Soc.* xviii. 228), attribute the difference between their own results and those of Wanklyn to the fact that their experiments were made in open vessels, whereas Wanklyn operated in sealed tubes. They however confirm Wanklyn's observation that sodium dissolves in valeric ether under ordinary pressure without evolution of gas, and suggest that in the case of acetic ether, the two reactions—viz. the one observed by themselves, attended with elimination of hydrogen, the other observed by Wanklyn, unattended by evolution of gas—may go on together, the one or the other predominating according as the experiment is made under the ordinary pressure or in sealed tubes. In corroboration of these views, they point to the recent observation of Caillaetet, to the effect that the evolution of hydrogen from zinc and hydrochloric acid, or from water and sodium-amalgam, is gradually diminished and finally stopped under increasing pressure. (See CHEMICAL ACTION, p. 428.) Lastly, they point out that, even in most of Wanklyn's experiments with perfectly pure acetic ether, a certain amount, and sometimes a considerable amount, of hydrogen was evolved. In reply to these observations, Wanklyn (*Chem. News*, 1870, xxi. 113) refers to the explanation which he had previously given of the elimination of hydrogen in this process—namely, that it is due to the action of the sodium on alcohol resulting from a secondary decomposition; he regards the conditions under which Frankland and Duppa's experiments were made—namely, the high temperature (130°) and the great length of time (several days) occupied in the process—as peculiarly favourable to the occurrence of this secondary action. Finally, he observes that potassium dissolves without effervescence in pure acetic ether contained in an open vessel at ordinary atmospheric pressure.

ETHYL in the free state, or **DIETHYL**, $\text{C}^4\text{H}^{10} = \begin{array}{c} \text{CH}^2(\text{CH}^2) \\ \text{CH}^2(\text{CH}^2) \end{array}$ or $\text{C} \begin{array}{c} \text{CH}^2\text{CH}^2 \\ \text{CH}^2 \\ \text{H}^2 \end{array}$, is

identical with butane, butyl hydride, or tetryl hydride (v. 735), and isomeric with trimethyl-methane or trimethylformene, $\text{C} \begin{array}{c} (\text{CH}^3)^3 \\ \text{H} \end{array}$, produced by the action of zinc and water on tertiary butyl iodide (p. 374). These are in fact the only two possible modifications of the saturated hydrocarbon C^4H^{10} , the one having an atom of carbon directly united with three other carbon-atoms, whereas in the other no carbon-atom is associated with more than two others :

According to Schöyen (*Ann. Ch. Pharm.* cxxx. 233), pure ethyl or diethyl is easily obtained by heating a mixture of ethyl iodide and an equal volume of anhydrous ether with thin strips of zinc, in sealed tubes filled to about three-fourths, first to 100°, afterwards to 130°–140°, for several hours. On cooling the tubes in iced water and opening them, the ethyl gas is evolved and may be collected in a gas-holder.

A mixture of ethyl gas and chlorine exposed to diffused daylight yields an oily strong-smelling liquid, consisting chiefly of chlorodiethyl or butyl chloride,

$\text{C}^4\text{H}^8\text{Cl} = \begin{array}{c} \text{C}^2\text{H}^2 \\ \text{C}^2\text{H}^2\text{Cl} \end{array}$, which may be converted by saponification into primary butyl alcohol (Schöyen, p. 372).

Ethyl gas heated to 100° with excess of bromine in sealed tubes is converted into butylene bromide and hydrobromic acid: $C^4H^{10} + 2Br^2 = C^4H^8Br^2 + 2HBr$ (Carius, *Ann. Ch. Pharm.* cxxvi. 195).

ETHYL, ACETYLATED, SALTS OF. Acetylated ethyl, or *Acetethyl*, as its name implies, is ethyl with some of its hydrogen replaced by acetyl, C^2H^3O . Wanklyn attributes such a structure to some compounds derived from acetic ether. Thus the oily liquid obtained by acting on acetic ether with metallic sodium, and subsequently treating the solid product with any dilute acid, is acetate of acetylated ethyl. Treatment of the same solid product with methyl iodide gives propionate of acetylated ethyl; similarly, treatment with ethyl iodide gives butyrate of acetylated ethyl. Another method of obtaining the salts of acetylated ethyl is by the successive action of acetic ether and an iodide of an alcohol-radicle on ethylate of sodium: thus by acting on ethylate of sodium, first with acetic ether, and then with ethyl iodide, there is produced isocaproate of acetylated ethyl.

These compounds, which Wanklyn regards as salts of acetylated ethyl, were originally discovered by Geuther and by Frankland and Duppi, by whom they were looked upon in a totally different light (p. 589).

The following table exhibits the several formulæ assigned to these compounds, together with their specific gravities and boiling points:

Formulæ according to:

Wanklyn.	Frankland and Duppi.	Boiling point.	Specific gravity.
$\left. \begin{array}{c} C^2H^4(C^2H^3O) \\ C^2H^3O \end{array} \right\} O = H(C^2H^3O)^2$ Acetate. Hydrogen-triacetyl.	$C^2H^3O \cdot CO^2C^2H^3$ Ethyl Acetone carbonate.	181°	1.030 at 5°
$\left. \begin{array}{c} C^2H^4(C^2H^3O) \\ C^2H^3O \end{array} \right\} O = CH^3(C^2H^3O)^2$ Propionate. Methyl-triacetyl.	$C^2H^4(CH^3)O \cdot CO^2C^2H^3$ Ethyl Methacetone carbonate.	187°	1.009 at 6°
$\left. \begin{array}{c} C^2H^4(C^2H^3O) \\ C^2H^3O \end{array} \right\} O = C^2H^4(C^2H^3O)^2$ Butyrate. Ethyl-triacetyl.	$C^2H^4(C^2H^3)O \cdot CO^2C^2H^3$ Ethyl Ethacetone carbonate.	195°	0.998 at 12°
$\left. \begin{array}{c} C^2H^4(C^2H^3O) \\ \beta C^2H^3O \end{array} \right\} O$ Isobutyrate.	$C^2H^4(CH^3)^2O \cdot CO^2C^2H^3$ Ethyl Dimethacetone carbonate.	184°	0.991 at 16°
$\left. \begin{array}{c} C^2H^4(C^2H^3O) \\ C^2H^3O \end{array} \right\} O = C^2H^4(C^2H^3O)^2$ Isovalerate. Isopropyl-triacetyl.	$C^2H^4(C^2H^3)O \cdot CO^2C^2H^3$ Ethyl Isopropacetone carbonate.	201°	0.9805 at 0°
$\left. \begin{array}{c} C^2H^4(C^2H^3O) \\ C^2H^{11}O \end{array} \right\} O$ Isocaproate.	$C^2H^4(C^2H^3)^2O \cdot CO^2C^2H^3$ Ethyl Diethacetone carbonate.	210°	0.974 at 20°

Geuther's ethyl-diacetic acid is identical with the acetate of acetethyl, and his ethyl-divaleric acid, $C^4H^{12}O^4$, with the caprylate, $C^2H^4(C^2H^3O) \cdot OC^2H^{11}O$.

The formulæ in the first column afford perhaps the most intelligible explanation of the formation and principal reactions of these compounds. The reactions in question are:

1. Exchange of acetyl for hydrogen by treatment with sodium ethylate, resulting in the formation of a compound ether and a salt of ethylene-sodium: *eg.*,

2. Exchange of the two acid-forming radicles for 2 at. hydrogen under the influence of an alkali: *eg.*,

A salt of acetylated ethyl may obviously be regarded as ethylene half saturated with acetyl and half with acetyl-oxygen; as a sort of half ketone and half acetic ether of ethylene. J. A. W.

meyer a. Tachepe (*Zeitschr. f. Chem.* [2] iv. 343) have obtained alcohol from ether by heating the latter to 150°–180° with water slightly acidulated with sulphuric acid:

Linnemann (*Ann. Ch. Pharm.* cxlviii. 249) has produced the same alcohol by reduction of *acetic anhydride* with sodium-amalgam. Acetic anhydride is gradually poured upon an amalgam containing 4 p. c. sodium, the vessel being kept cool, and care being taken that the mass does not harden. When the mixture no longer becomes hot on agitation, but appears dry and dusty, it is agitated with snow, which melts, with considerable reduction of temperature, the amalgam at the same time deliquescing, almost without evolution of gas. Water is then added, together with a little fresh amalgam; the mixture is left to itself for a while, then freed from an oily substance by filtration, and neutralised with potassium carbonate; and the decanted liquid is dehydrated with solid potassium carbonate. The liquid thus obtained is ordinary alcohol. Its formation may be represented by the following equations:

and

Reactions.—1. By oxidation with *chromic acid mixture* (p. 150), alcohol is completely converted into acetic acid: $C^2H^4O + O^2 = C^2H^3O^2 + H^2O$ (Chapman a. Thorp). With *potassium permanganate* and dilute sulphuric acid it yields acetic acid and aldehyde; with the permanganate alone, oxalic acid and other products, including only small quantities of aldehyde and acetic acid; with the permanganate in alkaline solution, neither aldehyde nor acetic acid, but either oxalic acid (at ordinary temperatures) or various other acids (at higher temperatures) (Chapman a. Smith, *Chem. Soc. J.* [2] v. 301).

2. Absolute alcohol mixed in a well-cooled retort with 1 mol. *phosphorus trichloride*, is strongly attacked, yielding liquid ethyl-phosphorous chloride, $PCl_2(OC^2H^3)$, which distils at 90°–125°:

Similar reactions take place with butylic and amylalcohols (Menschutkin, *Ann. Ch. Pharm.* cxxxix. 343).

3. *Phosphorus sulphochloride* likewise acts very strongly upon alcohol, producing ethyl chloride and ethyl-sulphoxyphosphoric acid, $(C^2H^3)^2H^2PSO^4$, an oily, fetid, non-distillable liquid, heavier than water and insoluble therein:

A small quantity of ethylphosphoric acid is however formed at the same time, with separation of sulphur (Chevier, *Zeit-schr. f. Chem.* [2] v. 413).

4. *Sulphuric chlorhydrate*, $(SO^2)^2Cl(OH)$, forms with 1 mol. absolute alcohol, a black tarry mass which in contact with water becomes hot and gives off an irritating gas. With 1 mol. sulphuric chlorhydrate and 2 mol. alcohol, the residue consists of a thick brownish liquid, resolved by water into oily neutral ethyl sulphate, $S(C^2H^3)^2O^4$, and soluble ethyl-sulphuric acid, $S(C^2H^3)HO^4$ (Baumstark, *Ann. Ch. Pharm.* cxl. 75).

5. *Stannic chloride* etherifies alcohol even more readily than sulphuric acid, and may be advantageously substituted for the latter in the preparation of compound ethers. It first unites with the alcohol, forming the compound $2C^2H^4O.SnCl^4$ [or, according to Lewy, $2(C^2H^3Cl.HCl).SnO^2$], which, when in presence of an acid, forms the compound ether; thus with benzoic acid:

The compound $2C^2H^4O \cdot SnCl^4$ is resolved by alkalis into alcohol and stannic oxide; by ethyl alcohol into ethylic ether and hydrated stannic chloride; with methyl or amyl alcohol in like manner it yields mixed ethers:

(Girard a. Chapoteaut, *Bull. Soc. Chim.* [2] viii. 349).

6. Dilute alcohol fermented with *syntonin*, or washed meat and chalk from Sens (which contains a peculiar ferment, *Microzyna creta*), is converted into caproic acid and hexyl alcohol, with evolution of marsh gas and hydrogen:

and

these two reactions appearing to go on together (Béchamp, *Compt. rend.* lxxvii. 568, 569; *Zeitschr. f. Chem.* [2] iv. 702).

Lieben (*Ann. Chim. med.* September 1869, p. 136) has discovered a new and very delicate test for the presence of alcohol, depending upon its conversion into iodoform. The liquid under examination is heated in a test-tube, into which are then introduced a few grains of iodine and a few drops of potash-solution, whereupon, if alcohol is present, a yellow crystalline precipitate of iodoform is produced, immediately or after some time, according to the degree of solution of the liquid. This test is said to be capable of detecting 1 part of alcohol in 12,000 parts of water. For greater certainty, it is best to examine the precipitate with the microscope, iodoform exhibiting the appearance of hexagonal plates or six-rayed stars. The test just described has been successfully applied to the detection of alcohol in urine.

Sodium Alcohol.—Wanklyn finds that the crystalline compound obtained by saturating absolute alcohol with sodium has the composition C^2H^5NaO or $C^2H^5NaO \cdot 3C^2H^4O$, and bears a temperature of 100° without giving off alcohol. It melts completely at 100° , and remains perfectly colourless so long as it is kept from contact with the air; but the slightest access of air turns it brown. The crystals dissolve with some difficulty in ether, more easily in a mixture of ethyl oxide and acetate. When heated above 100° they give off alcohol, and when kept for some time at 200° , give off the whole of their 3 mol. alcohol, leaving absolute sodium ethylate, C^2H^5NaO , as a white amorphous mass, infusible and very light, so that it floats on ether. It is insoluble in ether, turns brown in the air, like the crystals, and may be heated to 275° or even higher, without alteration. Heated to 100° – 200° with ethyl acetate, it yields alcohol and ethylene-sodium acetate, isomeric with sodium butyrate. In like manner, with ethyl valerate it yields alcohol and ethylene-sodium valerate, isomeric with sodium cenantylate (p. 588).

Sodium ethylate unites with *hydrogen sulphide*, forming the body $C^2H^5NaO \cdot SH^2$, which has considerable stability, but breaks up slowly at 100° into alcohol C^2H^4O , and sodium sulphhydrate $NaHS$; and in like manner with 1 mol. *hydrogen chloride*, *acetyl chloride*, *ethyl acetate*, *ethyl valerate*, and *ethyl benzoate*. All these compounds have considerable stability, but when heated to 100° or 150° they decompose, the second for example into sodium chloride and ethyl acetate:

(*Chem. Soc. J.* [2] vii. 199). For Wanklyn's views of the constitution of these bodies, see ATOMICITY (p. 244); also SODIUM.

Geuther a. Scheitz (*Zeitschr. f. Chem.* [2] iv. 378), by dissolving 1 pt. of sodium in 8 pts. of absolute alcohol, then sealing the tube, quickly separating the mother-liquor from the crystals when cold, and drying these crystals with filter-paper, either immediately or after washing with ether (which however dissolves them in considerable quantity), have obtained crystals containing $C^2H^5NaO \cdot 2C^2H^4O$. They dissolve in absolute alcohol even more freely than in ether, and when left over sulphuric acid in a vacuum, give off the whole of the 2 mol. alcohol (57-2 p. c.).

Dry chlorine acts slowly on sodium ethylate mixed to a pulp with absolute alcohol, producing ethyl chloride, sodium chloride, and oxygen, which oxidises a portion of the alcohol to aldehyde and acetic acid:

Bromine acts in the same manner, but more quickly. *Iodine* and sodium ethylate yield iodoform (Maly, *Zeitschr. f. Chem.* [2] v. 345).

Sup.

Q Q

ETHYL BROMIDE. C^2H^5Br .—Personne (*Compt. rend.* lii. 468) recommends for the preparation of this compound the use of amorphous instead of ordinary phosphorus: 40 grms. amorphous phosphorus are mixed in a retort with 150–160 grms. absolute alcohol, and 100 grms. bromine are slowly poured in through a narrow tube passing through a cork fitted into the neck, the retort being kept cool. The mixture is then distilled into a cooled receiver; the distillate is treated with water; and the ethyl bromide thereby separated is dried over calcium chloride and rectified. Ethyl bromide is also produced by heating amyl bromide with ethyl alcohol; and this reaction, as well as the corresponding one with methyl alcohol, may be made available for obtaining the bromides of ethyl and methyl for the preparation of aniline-green (Hofmann a. Girard, p. 163).

Brominated derivatives of Ethyl bromide are produced by heating ethyl bromide with bromine to 170° in sealed tubes. The product submitted to fractional distillation yields monobromomethyl bromide, $C^2H^4Br.Br$, which boils at 110° – 112° , has a sp. gr. of 2.135 at 0° , and is isomeric with ethylene bromide, $C^2H^4Br^2$; and dibromomethyl bromide, $C^2H^3Br^3.Br$, boiling at 187° , having a sp. gr. of 2.659 at 0° , and identical with monobromomethylene bromide, $C^2H^3Br.Br^2$ (Caventou, *Compt. rend.* lii. 1330).

Monobromomethyl bromide is probably identical with ethylidene bromide, produced by the action of phosphorus pentachloride on aldehyde (ii. 599); its relation to ethylene bromide is represented by the following formulæ:

Reboul has observed that monobromomethylene heated in sealed tubes with hydrobromic acid yields the latter compound, instead of reproducing ethylene bromide, a result easily accounted for if we suppose that, in the formation of bromomethylene from ethylene bromide, the elements of hydrobromic acid are abstracted from both of the semimolecules CH^2Br , and that in the conversion of the bromomethylene into bromethyl bromide or ethylidene bromide, the same elements are added on in the reverse order; thus:

According to Caventou, bromethyl bromide treated with alcoholic solution of potassium acetate, yields a small quantity of ethylene diacetate, a result most probably due to the previous conversion of a portion of the bromethyl bromide into the isomeric compound ethylene bromide (*Dictionnaire de Chimie*, i. 1314).

ETHYL CHLORIDE. C^2H^5Cl , is formed: *a.* By the action of chlorine on ethane, C^2H^6 (whether produced from a methyl-compound, *e.g.* by the electrolysis of acetic acid, or from an ethyl-compound, *e.g.* by the action of sulphuric acid on mercuric ethide), the two gases being mixed in the shade and at the temperature of 5° (Schorlemmer, *Compt. rend.* lvi. 703; *Ann. Ch. Pharm.* cxxiv. 234; *Jahresb.* 1864, p. 467).

b. By the action of phosphorus pentachloride on potassium ethylsulphate, sulphuryl chloride being formed at the same time (Naquet, *Dictionnaire de Chimie*, i. 1315):

Ethyl chloride heated in sealed tubes for five hours to 130° with three or four times its weight of aqueous *hydriodic acid*, sp. gr. 1.9, is for the most part converted into ethyl iodide (Lieben, *see* p. 437).

Ethyl chloride is absorbed by *sulphuric anhydride*, forming chlorethyl-sulphuric acid, $SO_2 \begin{Bmatrix} OC^2H^5 \\ Cl \end{Bmatrix}$ (R. Williamson, ii. 529; v. 576). This compound has lately been

further investigated by Purgold (*Zeitschr. f. Chem.* [2] iv. 669), who, however, makes no reference to Williamson's results. He finds that it boils in a vacuum at 80° – 82° , has a sp. gr. of 1.379 at 0° ; 1.3556 at 27° ; 1.324 at 61° . It is insoluble in water, and when heated with water in sealed tubes, yields ethyl oxide, ethyl chloride, hydrochloric acid, and sulphuric acid; alcohol decomposes it in a similar manner. When ethyl chloride is agitated in a sealed tube with a large excess of sulphuric anhydride, a yellowish acid liquid is formed, which dissolves completely in water and yields a potassium salt having the composition $C^2H^5(OH)\left\{\begin{smallmatrix} SO^2OK \\ SO^2OK \end{smallmatrix}\right.$. The same acid is formed in small quantity in the preparation of chlorethylsulphuric acid (Purgold).

Monochlorinated Ethyl Chloride, $C^2H^4Cl.Cl$, is identical with ethylidene chloride, $CH^2=CHCl^2$, having very nearly the same boiling point and specific gravity (ii. 531, 599), and being converted by sodium ethylate and by alcoholic potash under pressure, into vinyl chloride, C^2H^3Cl (Beilstein, *Ann. Ch. Pharm.* cxiii. 110).

(Chlorethyl chloride heated to 140° in sealed tubes with a solution of neutral sodium sulphite is converted into sodium chlorethylsulphate:

(Kind, *Zeitschr. f. Chem.* [2] v. 165). On the other hand, Städel (*ibid.* iv. 272), by heating ethylidene chloride with solution of neutral potassium sulphite in a retort with upright condensing tube, has obtained two acids free from chlorine, viz. ethylidene-sulphuric acid, $CH^2CH\left\{\begin{smallmatrix} SO^2H \\ OH \end{smallmatrix}\right.$, and ethylidene-disulphuric acid, $CH^2CH\left\{\begin{smallmatrix} SO^2H \\ SO^2H \end{smallmatrix}\right.$.

ETHYL IODIDE, C^2H^5I , is produced by heating the chloride with hydriodic acid in sealed tubes (p. 437). In preparing it by the action of iodine and phosphorus upon alcohol, Personne (*Compt. rend.* iii. 468) recommends the use of amorphous phosphorus: 30 grms. of pulverised amorphous phosphorus and 120 grms. absolute alcohol are introduced into a tubulated retort; 100 grms. of iodine are added in two portions, with an interval of a few minutes, and the mixture is distilled till water no longer separates anything from the liquid which passes over. The product is decolorised with a few drops of potash solution, and washed with water. Rieth a. Beilstein (*Ann. Ch. Pharm.* cxxvi. 250) recommend 10 pts. amorphous phosphorus, 50 pts. alcohol of 90 p. c. (sp. gr. 0.83), and 100 pts. dry iodine, added by small portions, these proportions being founded on the equation:

They also recommend that the mixture be left to itself for 24 hours before distillation.

Reactions.—1. Ethyl iodide oxidised with *chromic acid mixture* (p. 150) yields acetic acid, water, and free iodine, $2C^2H^5I + O^2 = 2C^2H^3O^2 + H^2O + I^2$ (Chapman a. Thorp).—2. Heated with *silver powder* to 120° , it yields a combustible gas consisting chiefly of diethyl or butane, C^4H^{10} (Wislicenus, *Zeitschr. f. Chem.* [2] iv. 681).—3. *Bromine* converts it completely in ethyl bromide, without formation of hydrobromic acid (Friedel, *Jahresb.* 1865, p. 491).—4. *Iodine monochloride* gradually added in equivalent quantity converts it into ethyl chloride, with separation of iodine: $C^2H^5I + ICl = I^2 + C^2H^5Cl$ (Gauthier, *Ann. Ch. Pharm.* cxxiii. 123).—5. Heated for several hours to 150° with concentrated *hydriodic acid*, it is partly converted into ethane (ethyl hydride), with separation of hydrogen [? iodine: $C^2H^5I + HI = C^2H^6 + I^2$] (Butlerow, *Ann. Ch. Pharm.* cxliv. 36).—6. Heated with *mercuric chloride*, it yields ethyl chloride and mercuric iodide (Oppenheim, *Compt. rend.* lxii. 1085).—7. When ethyl iodide, phosphorus trichloride, and zinc are heated together to 100° for eight or nine hours, the zinc becomes covered with a brown film, and the liquid on cooling deposits crystals of phosphorus di-iodide. The liquid product mixed with water gives off ethane, and deposits a brown substance which contains zinc and gives off hydrogen phosphide when boiled with potash (Chapman a. Smith, *Laboratory*, p. 22).—8. Heated with neutral *potassium sulphite*, it yields ethylsulphite and iodide of potassium:

(Strecker, *Zeitschr. f. Chem.* [2] iv. 213).—9. It is strongly attacked by *sulphuric chlorhydrate*, SO^2HCl , yielding ethylsulphuric acid (Wroblevsky, *Zeitschr. f. Chem.* [2] v. 280).—10. Heated with *amyl alcohol*, it yields hydriodic acid and ethyl-amyl oxide:

(Friedel a. Crafts, p. 587).

ETHYL OXIDE. $C^2H^4O = (C^2H^3)^2O$.—The presence of small quantities of water in common ether may be detected by means of *potassium phosphate*, which is insoluble in anhydrous ether, but dissolves partially in ether containing water, a brown residue being left (Romei, *Zeitschr. anal. Chem.* 1869, p. 390).

Ethyl oxide unites with certain metallic *bromides* and *chlorides*, forming crystallisable compounds, which are decomposed by water and by heat, and decompose carbonates with effervescence (Nicklès, *Compt. rend.* lii. 396; lviii. 537; lx. 479, 800).

Bromo-aluminic Ether, $Al^2Br^3 \cdot 2C^2H^4O$, is obtained by treating ethyl oxide with bromine and aluminium-filings, whereby two layers of liquid are formed, the lower containing the bromo-aluminic ether. This compound is volatile without decomposition, and forms a yellow, very fusible, and deliquescent sublimate, imperfectly soluble in water. An *iodo-aluminic ether* may be obtained in the same manner.

Bromo-antimonious Ether, $SbBr^3 \cdot C^2H^4O$, formed by the action of bromine on pulverised antimony in contact with ether, is an oily deep yellow liquid, which begins to boil at 91° , giving off bromine, ether, and hydrobromic acid, and leaving a residue of antimonious bromide; part of it however distils without decomposition. Ethyl oxide combines in like manner with *antimonious chloride*, but not with the *iodide*.

Bromo-arsenious Ether, $AsBr^3 \cdot C^2H^4O$, prepared like the preceding, is more volatile, but decomposes even at ordinary temperatures. Evaporated over sulphuric acid, it leaves a residue of arsenious bromide crystallised in long shining prisms. Volatilises when heated, but is in great part decomposed; is not attacked by zinc. *Arsenious chloride* forms a similar compound.

Bromobismuthic Ether is obtained by direct combination of bismuth bromide with ether under pressure, or by the action of bromine on pulverised bismuth in presence of ether. Over sulphuric acid in a vacuum it crystallises in very deliquescent rhombic prisms containing $BiBr^3 \cdot C^2H^4O + 2H^2O$. A similar compound is formed with *bismuth chloride*, but not with the *iodide*.

With the *bromides of cadmium and zinc*, ethyl oxide forms unstable compounds which fume in the air and dissolve in water, apparently decomposing at the same time; with *ferric bromide* it forms a compound of a deep red colour, decomposable by heat.

Bromomercuric Ether, $HgBr^2 \cdot 3C^2H^4O$, is produced by the action of bromine on mercury under ether; the lower layer of liquid then formed deposits mercuric bromide, and the mother-liquor consists of the ethereal compound.

Chloroboric Ether, $2BCl^3 \cdot 5C^2H^4O + 9aq(?)$, is a volatile liquid obtained by heating an alcoholic solution of boric acid saturated with hydrochloric acid.

Chloromanganic Ether.—By passing hydrochloric acid gas into a mixture of ether and manganese dioxide in a vessel cooled with ice, Nicklès has obtained a compound to which he assigns the formula $MnCl^4 \cdot 12C^2H^4O + 2aq$. It is a green, very unstable substance, soluble in ether, insoluble in carbon bisulphide, easily reduced by metals, metallic sulphides, &c., yielding manganous chloride.

Chlorothallic Ether, $TlCl^3 \cdot C^2H^4O \cdot HCl + aq$. (v. 748). *Chlorostannic Ether*, $SnCl^4 \cdot 2C^2H^4O$ (v. 809).

Substitution-derivatives of Ethyl Oxide.

Dichlorinated Ethyl Oxide, $C^2H^2Cl^2O = \frac{C^2H^2Cl^2}{C^2H_3}O$ (formerly called *Monochlorinated ether*, ii. 540).—Lieben a. Bauer (*Ann. Ch. Pharm.* cxxiv. 130. Lieben, *ibid.* cxxiii. 287; cxli. 236; cxlvi. 180; cl. 87; *Jahresb.* 1864, p. 471; 1866, p. 485; 1867, p. 544).—This compound is best prepared by passing washed and dried chlorine into anhydrous ether cooled to 0° in a flask with upright condensing tube, and after some time (about 10 hours when a kilogram of ether is used) distilling the product in the water-bath, whereby a colourless distillate and a brown residue are obtained. The distillate is again treated in the same manner with chlorine, the product redistilled from the water-bath, and this treatment repeated till the portion volatile at 100° has disappeared. The united dark-coloured residues are then heated in an oil-bath till a thermometer immersed in the vapour rises to 136° ; the portion which has passed over is again treated with chlorine; and finally, after another repetition of this treatment, the brown-black residues not volatile at 136° are subjected to fractional distillation. The portion which then distils between 140° and 147° consists for the most part of dichlorinated ethyl oxide. It is a limpid colourless liquid, having an acrid taste, and burning with a green-edged flame; sp. gr. 1.174 at 23° . It dissolves for the most part in water at ordinary temperatures, with evolution of heat and formation of hydrochloric acid, alcohol, and a body which exhibits the reactions of aldehyde.

From the following reactions it appears most probable that the two chlorine-atoms in the molecule of this ether are situated unsymmetrically, as represented by the formula $\begin{smallmatrix} \text{C}^2\text{H}^3\text{Cl}^2 \\ \text{C}^2\text{H}^3 \end{smallmatrix} \text{O}$, not symmetrically as in the formula $\begin{smallmatrix} \text{C}^2\text{H}^3\text{Cl} \\ \text{C}^2\text{H}^3\text{Cl} \end{smallmatrix} \text{O}$.

The dichlorinated ether added by drops to an ethereal solution of *zinc-ethyl* cooled to -15° , is converted into ethylchlorinated ethyl oxide, $\text{C}^2\text{H}^3\text{ClO}$:

This compound is a liquid having a pleasant ethereal odour, and boiling at 137° . Sp. gr. of 0.9735 at 0° . Vapour-density = 69.3, referred to hydrogen as unity (calc. 68.25). It is insoluble in water, but mixes in all proportions with alcohol and ether.

By heating ethylchlorinated ethyl oxide with zinc-ethyl, the remaining atom of chlorine is removed, and diethylated ethyl oxide, $\text{C}^2\text{H}^3\text{O} = \begin{smallmatrix} \text{C}^2\text{H}^3 \cdot \text{C}^2\text{H}^3 \cdot \text{C}^2\text{H}^3 \\ \text{C}^2\text{H}^3 \end{smallmatrix} \text{O}$, isomeric with butyl oxide, $(\text{C}^2\text{H}^3)^2\text{O}$, is produced. Dichlorinated ethyl oxide treated with *zinc-methyl* yields methylchlorinated ethyl oxide, $\begin{smallmatrix} \text{C}^2\text{H}^3 \cdot \text{Cl} \cdot \text{CH}^3 \\ \text{C}^2\text{H}^3 \end{smallmatrix} \text{O}$, a colourless aromatic liquid miscible with alcohol and ether, having a sp. gr. of 0.9812 at 0° , and vapour-density = 63 (calc. = 62.25).

Ethylchlorinated ethyl oxide treated with fuming *hydriodic acid* yields, as principal products, ethylated ethyl iodide (or butyl iodide), ethyl iodide, hydrochloric acid, and free iodine, together with butyl chloride and secondary products. The reaction appears to take place as shown by the following equations:

This butyl iodide has the constitution of ethyl-methyl carbinyl iodide, $\text{C} \begin{Bmatrix} \text{C}^2\text{H}^3 \\ \text{CH}^3 \\ \text{H} \\ \text{I} \end{Bmatrix}$, and

when heated with silver acetate yields the corresponding acetic ether, which, when saponified by potash, yields secondary butyl alcohol or ethyl-methyl carbinol,

Diethylated ethyl oxide treated with *hydriodic acid* yields in like manner diethylated ethyl iodide, $\text{C}^2\text{H}^3(\text{C}^2\text{H}^3)^2\text{I} = \text{C}^4\text{H}^{11}\text{I}$, from which, by saponification, a secondary or tertiary hexyl alcohol might probably be obtained.

Action of Sodium Alcohol and Alcoholic Potash on Dichlorinated Ethyl Oxide, &c.—Dichlorinated ethyl oxide treated with alcoholic potash, or better with sodium ethylate, is converted into oxethylchlorinated ethyl oxide, $\text{C}^2\text{H}^3\text{ClO}$:

a limpid colourless liquid having an agreeable refreshing odour, boiling at 167° – 158° , heavier than water, and not attacked by aqueous potash, even at the boiling heat.

When 1 mol. dichlorinated ethyl oxide is treated with 2 mol. sodium ethylate, the second atom of chlorine is also, though slowly, replaced by oxethyl, $\text{C}^2\text{H}^3\text{O}$, yielding dioxethylated ethyl oxide, $\begin{array}{c} \text{C}^2\text{H}^3(\text{C}^2\text{H}^3\text{O})^2 \\ \text{C}^2\text{H}^3 \end{array} \text{O}$. This compound is best prepared by heating oxethylchlorinated ethyl oxide with a slight excess of sodium ethylate to 140° – 150° for 30 hours, separating the product by water, submitting it to fractional distillation, and heating the portion which goes over between 162° and 171° with sodium. It is a colourless fragrant liquid, not miscible with water, having a sp. gr. of 0.8924 at 21° , and boiling at 168° . Heated with concentrated *hydriodic acid* to 130° , it yields ethyl iodide, alcohol, charcoal, and a small quantity of another iodised compound:

Ethylchlorinated ethyl oxide heated to 140° for twenty or thirty hours with sodium ethylate or with pasty alcoholic potash, is converted into ethyloxethylated ethyl oxide, $\text{C}^2\text{H}^{10}\text{O}^2 = \text{C}^2\text{H}^3 \cdot \text{C}^2\text{H}^4 \cdot \text{C}^2\text{H}^3\text{O}\left\{\begin{matrix} \text{O} \\ \text{C}^2\text{H}^3 \end{matrix}\right\}$, a liquid having a pleasant ethereal odour, floating on water, and boiling at 147° .

Oxymethyl chlorinated Ethyl oxide, $\text{C}^2\text{H}^{11}\text{ClO}^2 = \text{C}^2\text{H}^3\text{Cl} \cdot \text{CH}^3\text{O}\left\{\begin{matrix} \text{O} \\ \text{C}^2\text{H}^3 \end{matrix}\right\}$, produced, like the corresponding ethyl compound, by the action of sodium methylate on dichlorinated ethyl oxide, boils at 137° , and has a sp. gr. of 1.056 at 13.5° .

Action of the Chlorides and Bromides of Phosphorus on Dichlorinated Ethyl Oxide, &c.—Phosphorus tribromide acts upon dichlorinated ethyl oxide at 200° in the manner shown by the equation:

On ethylchlorinated ethyl oxide, phosphorus tribromide acts at 180° , forming phosphorous acid, ethyl bromide, and a chlorobromide, probably consisting of $\text{C}^2\text{H}^3\text{ClBr}$ or $\text{C}^2\text{H}^3 \cdot \text{C}^2\text{H}^4 \cdot \text{ClBr}$, which however has not been obtained pure. Methylochlorinated ethyl oxide yields similar products.

Phosphorus pentachloride decomposes dichlorinated ethyl oxide, forming hydrochloric acid and a black liquid containing phosphorus trichloride, together with chlorinated substitution-products of dichlorinated ethyl oxide and their products of decomposition by heat. Ethylchlorinated ethyl oxide reacts with phosphorus pentachloride in a similar manner.

ETHYL SULPHIDE, $(\text{C}^2\text{H}^3)^2\text{S}$, is produced by passing the vapour of sulphurous chloride, SO^2Cl^2 , together with a current of carbon dioxide, over zinc-ethyl. On distilling the resulting viscid mass with water, zinc oxide separates, and ethyl sulphide boiling at 91° passes over (F. Gauhe, *Jahresb.* 1867, p. 542).

Ethyl sulphide dissolves in fuming nitric acid, with evolution of red vapours, and without formation of sulphuric acid. The acid solution when left to evaporate solidifies to diethylsulphone, $(\text{C}^2\text{H}^3)^2\text{SO}^2$, or sulphuric dioxydiethide, $\text{S}^4\left\{\begin{matrix} (\text{C}^2\text{H}^3)^2 \\ \text{O}^2 \end{matrix}\right\}$, which crystallises from hot water or alcohol in long thin tables, melts at 70° , boils at 248° , and is reduced by nascent hydrogen to ethyl sulphide.

Nitric acid of sp. gr. 1.2 dissolves ethyl sulphide without much evolution of gas, forming an acid uncrystallisable liquid, which is converted by potassium ferrieyanide and free alkali, by potassium chromate, and by ferric chloride, into several crystallisable compounds whose composition has not yet been determined (A. v. Oefele, *Ann. Ch. Pharm.* cxxvii. 370).

Ethyl sulphide unites directly with chloride, bromide, and iodide of ethyl, forming triethylsulphurous compounds (v. 881) in which the sulphur may be regarded as quadrivalent: *e.g.*,

This triethiodide is also formed by heating ethyl sulphide with acetyl iodide in sealed tubes. On dissolving the resulting crystals in water, removing the iodine with silver oxide, neutralising with hydrochloric acid, and adding platonic chloride to the filtrate, crystals of a platinum salt are obtained exhibiting the composition $2[\text{S}(\text{C}^2\text{H}^3)^3\text{Cl}] \cdot \text{PtCl}^4$ (Lukaschewicz, *Zeitschr. f. Chem.* [2] iv. 643).

Ethyl-methyl Sulphide. $\text{C}^2\text{H}^3\text{S} - \text{CH}^3\left\{\begin{matrix} \text{S} \\ \text{CH}^3 \end{matrix}\right\}$ (Carius, *Ann. Ch. Pharm.* cxix. 313; cxx. 61).—Produced by heating ethyl disulphophosphate with 2 vol. anhydrous methyl alcohol to 150° for an hour or two, and distilling the product:

Ethyl-methyl sulphide is a colourless liquid having a disagreeable odour, boiling at 58.8° – 59.6° (corr.) with the barometer at 757 mm., and having a vapour-density of

2.625 (calc. 2.5-2.6). By oxidation with nitric acid of sp. gr. 1.1, it yields ethylsulphurous acid. Mixed in alcoholic solution with *mercuric chloride*, it forms shining laminae of the compound $(C^2H^5)(CH^3)S.HgCl_2$. A compound with *mercuric iodide* containing $2(C^2H^5)(CH^3)S.HgI_2$ is produced by boiling a solution of mercuric sulphethylate (mercaptide) in absolute alcohol with methyl iodide. It is a sulphur-yellow crystalline powder, which melts under boiling alcohol, and solidifies on cooling to a mass having the aspect of porcelain. It is sparingly soluble in alcohol, and when boiled with a quantity of that liquid not sufficient to dissolve it, is decomposed, with separation of mercury and mercuric sulphide.

Ethyl-amyl Sulphide. $\begin{matrix} C^2H^5 \\ C^2H^{11} \end{matrix} S$ (Carius, *loc. cit.*; Saytzeff, *Ann. Ch. Pharm.*

exxxix. 354; further, *Zeitschr. f. Ch. m.* [2] vi. 104).—Carius prepares this compound, like the preceding, by the action of ethyl alcohol on ethyl disulphophosphate. Saytzeff prepares it by the action of ethyl iodide on sodium-amyl sulphide; also by the action of amyl iodide on a solution of potassium monosulphide in absolute alcohol (potassium-ethyl sulphide), or of amyl chloride on sodium-ethyl sulphide:

On heating the last-mentioned materials together in a sealed tube for 6 to 8 hours, washing the product with water, drying and rectifying, an oily body was obtained, distilling for the most part between 150° and 160° , and after repeated treatment with sodium passing over completely at 157° - 159° . It is a colourless liquid having an alliaceous odour, insoluble in water, boiling at 132° - 133.5° (corr.) under a pressure of 758 mm. (Carius); at 168° (Saytzeff). Sp. gr. = 0.852 at 0° (Saytzeff). Vapour-density referred to air = 4.4954 (Carius); calc. = 4.5606. By oxidation with nitric acid, it yields, according to Carius, nothing but ethyl-sulphurous acid; according to Saytzeff, on the other hand, the chief product of the oxidation is ethyl-amyl oxysulphide, with only a trace of ethyl-sulphurous acid. The compound of ethyl-amyl sulphide with *mercuric iodide*, $2(C^2H^5)(C^5H^{11})S.HgI_2$, prepared like the corresponding methyl compound, is more easily fusible and more soluble in alcohol than the latter. It is decomposed by heat.

Ethyl-amyl Oxysulphide, $(C^2H^5)(C^5H^{11})SO$, is a viscid liquid insoluble in water, soluble in alcohol and ether, solidifying to a crystalline mass at -16° , and decomposing when distilled. It is not susceptible of further oxidation. Nascent hydrogen reduces it to ethyl-amyl sulphide (Saytzeff).

Ethyl-benzyl Sulphide, $(C^2H^5)(C^7H^9)S$, prepared by the action of ethyl iodide on sodium benzyl-mercaptide, C^7H^9NaS , is a limpid, colourless, very pungent liquid distilling at 214° - 216° (Märker, *Ann. Ch. Pharm.* cxl. 86).

Ethyl Disulphide. $(C^2H^5)_2S^2$.—This compound heated in a sealed tube with 4 mol. ethyl iodide yields sulphurous triethiodide, with separation of iodine:

(Saytzeff, *Zeitschr. f. Chem.* [2] vi. 109).

Ethyl Bisulphoxide, $(C^2H^5)_2S^2O^2$, is produced by treating ethyl bisulphide with nitric acid of sp. gr. 1.2 diluted with an equal volume of water. After washing with water and drying over calcium chloride, it forms a colourless transparent liquid, having an alliaceous, somewhat biting odour; it is easily soluble in alcohol and ether, does not crystallise at low temperatures, and is decomposed by boiling even in a vacuum. Strong nitric acid dissolves it without alteration at ordinary temperatures, but oxidises it at the boiling heat to ethylsulphuric acid. By zinc and dilute sulphuric acid it is reduced to bisulphide and ultimately to mercaptan (Lukaschewicz, *Zeitschr. f. Chem.* [2] iv. 641). The same compound appears to have been obtained by Kopp and by Löwig a. Weidmann (*Ann. Ch. Pharm.* xxxv. 343) by the action of nitric acid on mercaptan.

ETHYLACETONE. See KETONES.

ETHYLAMINES. Wanklyn a. Chapman (*Proc. Roy. Soc.* xv. 218) prepare ethylamine by heating equal volumes of ethyl iodide, strong alcohol, and ammonia for half an hour and with constant agitation to a temperature somewhat below 100° . After the free ammonia has been removed by evaporation, the product is distilled with potash; the distillate is received in dilute sulphuric acid; the ammonium sulphate is separated by alcohol; and the alcoholic solution of the remaining sulphate is distilled with a quantity of potash sufficient to liberate about $\frac{1}{10}$ of the bases present. The distillate then contains no base except ethylamine, together with alcohol and water.

By oxidation with chromic acid mixture, ethylamine is converted into nitrogen, water, acetic acid, and aldehyde, without formation of ammonia (Wanklyn a. Chapman, *Chem. Soc. J.* [2] iv. 328).

Hydriodic acid converts ethylamine into ammonia and ethane (Berthelot).

On the conversion of ethylamine into alcohol by the action of nitrous acid, see ALCOHOLS (p. 63).

Ethylamine heated in sealed tubes with *ethyl orthoformate*, $\text{CH}(\text{OC}^2\text{H}^5)^3$, converts that ether into ordinary ethyl formate, $\text{CHO}(\text{OC}^2\text{H}^5)$ (Wichelhaus, *Zeitschr. f. Chem.* [2] v. 284).

Diethylamine. $(\text{C}^2\text{H}^5)^2\text{HN}$.—The hydrochloride of this base distilled with potassium nitrite yields nitrosoethylin or nitrosodiethylin, $(\text{C}^2\text{H}^5)^2(\text{NO})\text{N}$ (iv. 114). *Triethylamine hydrochloride* mixed with a moderately concentrated solution of potassium nitrite is not decomposed in the cold, but yields nitrosodiethylin on boiling the mixture till potassium chloride separates out (Geuther, *Zeitschr. f. Chem.* [2] ii. 513). According to Heintz (*ibid.* 571), the triethylamine salt is not decomposed, or but very slightly, in dilute aqueous solution, whereas with the diethylamine salt the decomposition takes place more easily; the reaction may therefore be applied to the separation of di- and tri-ethylamine.

Tetretethylammonium.—On the salts of this base with metallic acids, see vol. v. p. 731.

ETHYLATE OF SODIUM. See ETHYL ALCOHOL (p. 592).

ETHYL-BENZOIC ACID. $\text{C}^6\text{H}^5\text{O}^2 = \text{C}^6\text{H}^4(\text{C}^2\text{H}^5) \cdot \text{CO}^2\text{H}$ (Kekulé, *Ann. Ch. Pharm.* cxxvii. 178. Fittig a. König, *ibid.* cxliv. 277. Kekulé a. Thorpe, *Chem. Soc. J.* [2] vii. 366).—This acid, isomeric with xylic acid, was first obtained by Kekulé, by the action of sodium and carbon dioxide on bromethyl-benzene:

Fittig a. König produced it by oxidising diethyl-benzene with boiling dilute nitric acid:

and Kekulé a. Thorpe have further examined it and demonstrated the identity of the acids obtained by the two processes.

Ethylbenzoic acid crystallises from boiling water in small laminae, less soluble in water than benzoic acid; from alcohol in small prisms. It melts at 110° – 111° and solidifies on cooling to a radio-crystalline mass; melts also when heated with a small quantity of water not sufficient to dissolve it; sublimes without decomposition below its melting point. Easily soluble in ether and in alcohol.

Barium ethylbenzoate, $(\text{C}^6\text{H}^4\text{O}^2)\text{Ba} + \text{H}^2\text{O}$, crystallises in concentrically united efflorescent laminae, soluble in 45 pts. of cold water. The *calcium salt* $(\text{C}^6\text{H}^4\text{O}^2)^2\text{Ca} + 2\text{H}^2\text{O}$ crystallises in feathery tufts of needles. The *copper salt* $(\text{C}^6\text{H}^4\text{O}^2)^2\text{Cu}$ is a light blue precipitate quite insoluble in water. The *silver salt* $\text{C}^6\text{H}^4\text{O}^2\text{Ag}$ is a white precipitate crystallising in needles from hot water (Fittig a. König).

By further oxidation with nitric acid of greater concentration than that used in its preparation, ethylbenzoic acid is converted into terephthalic acid, $\text{C}^6\text{H}^4(\text{CO}^2\text{H})^2$ (Fittig a. König).

ETHYL-CROTONIC ACID. $\text{C}^6\text{H}^5\text{O}^2 = \text{C} \begin{Bmatrix} \text{C}^2\text{H}^5 \\ (\text{C}^2\text{H}^5)'' \\ \text{CO}^2\text{H} \end{Bmatrix}$.—This acid, isomeric

with pyroterebic acid, is produced by decomposition of diethoxalic acid (iv. 273). Frankland a. Duppa (*Chem. Soc. J.* [2] iii. 133) obtain the ethylic ether by treating ethylic diethoxalate with phosphorous chloride:

Geuther (*Bull. Soc. Chim.* [2] x. 34; *Jahresb.* 1867, p. 456) prepares the acid by heating ethylic diethoxalate with hydrochloric acid to 150° :

By treating diethoxalic acid with phosphorus pentachloride, and distilling the product, Geuther obtained an oily liquid which when treated with water yielded hydrochloric and ethylcrotonic acids, and therefore consisted of ethylcrotonic

chloride. The diethoxalic acid is first converted by the pentachloride into diethoxalic chloride:

and this chloride is resolved by distillation into water and ethylcrotonic chloride:

Ethylcrotonic acid crystallises very easily from fusion in large four-sided prisms having a peculiar odour, recalling those of pyrogallie and benzoic acids. It melts at 39.5° (Frankland a. Duppa); at 41.5° (Geuther); sublimes at ordinary temperatures; dissolves sparingly in water, very easily in alcohol and ether. The aqueous solution reddens litmus and neutralises the strongest bases. Its salts easily give up part of their acid when their solutions are evaporated; the *barium*, *potassium*, and *sodium salts* are soapy. The sparingly soluble *silver salt* $\text{C}^2\text{H}^{10}\text{O}^2\text{Ag}$ crystallises from water in scales which are not much affected by light; the *cupric salt* $(\text{C}^2\text{H}^{10}\text{O}^2)^2\text{Cu}$ is a greenish-blue precipitate; the *lead salt* $(\text{C}^2\text{H}^{10}\text{O}^2)^2\text{Pb}$ is a white precipitate quite insoluble in water. The *ethyl ether* $\text{C}^2\text{H}^{10}\text{O}^2 \cdot \text{C}^2\text{H}_5$ is a very mobile liquid having a burning taste and pungent odour, recalling that of peppermint oil and that of fungi; it is nearly insoluble in water, mixes in all proportions with alcohol and ether, boils without decomposition at 165° , and has a sp. gr. of 0.9203 at 13° . It does not oxidise in the air, and is not altered by contact with water, but is resolved by boiling with alcoholic potash into alcohol and ethylcrotonic acid (Frankland a. Duppa).

ETHYL-DIACETIC ACID. $\text{C}^2\text{H}^{10}\text{O}^3$.—This compound, the sodium salt of which is produced by the action of sodium on ethyl acetate, was regarded by Geuther, who discovered it, as diacetic acid, $\text{C}^2\text{H}^8\text{O}^3$ (i.e. acetic anhydride), having 1 at. hydrogen replaced by ethyl; and by Wanklyn at first as hydrogen triacetyl, $\text{H}(\text{C}^2\text{H}_3\text{O})^3$, afterwards as the acetate of acetethyl, $\text{C}^2\text{H}_5(\text{C}^2\text{H}_3\text{O}) \cdot \text{OC}^2\text{H}_3\text{O}$ (pp. 16, 588–590). Its methylic ether, $\text{C}^2\text{H}^{12}\text{O}^3$, is the propionate, and its ethylic ether, $\text{C}^2\text{H}^{14}\text{O}^3$, the butyrate of acetethyl. The latter treated with ammonia forms the amides $(\text{C}^2\text{H}^{11}\text{NO})^2$ or $\text{C}^2\text{H}^8(\text{NH}_2)\text{O}^3$, and $\text{C}^2\text{H}^{10}\text{NO}^3$ or $\text{C}^2\text{H}^8(\text{NH}_2)\text{O}^4$, the former soluble in water, alcohol, and ether, melting at 90° and subliming in long needles at 100° ; the latter forming monoclinic crystals, which melt at 59.5° , dissolve in alcohol and ether, but are insoluble in water (Geuther, *Jahresb.* 1863, p. 324).

ETHYL-DIVALERIC ACID, $\text{C}^{12}\text{H}^{22}\text{O}^3$, or *Cap. ylate of Acetethyl*, $\left. \begin{matrix} \text{C}^2\text{H}^4(\text{C}^2\text{H}_3\text{O}) \\ \text{C}^2\text{H}^{12}\text{O}^3 \end{matrix} \right\} \text{O}$ (p. 590) (Geuther a. Greiner, *Bull. Soc. Chim.* [2] vi. 218; *Jahresb.* 1865, p. 319. Greiner, *ibid.* viii. 504; *Jahresb.* 1866, p. 320).—This compound, homologous with the preceding, is formed by the action of sodium on ethyl-valerate, together with another body called *divalerylene-divaleric acid*. The crude product is a semifluid mass, which, when mixed with water, separates into an oily liquid, and the aqueous solution of sodium divalerylene-divalerate. On removing the oily liquid by agitation with ether, and mixing the aqueous solution with acetic acid, an oil separates which quickly solidifies, and by solution in ether, evaporation, and crystallisation of the residue from warm alcohol, yields crystallisable divalerylene-divaleric acid.

Ethyldivaleric acid is scarcely fluid at ordinary temperatures; it has a yellowish colour, a disagreeable odour of valeric acid, is insoluble in water, soluble in alcohol and ether. Its sodium salt is a yellow resinous mass soluble in alcohol.

Divalerylene-divaleric acid, $\text{C}^{12}\text{H}^{14}\text{O}^3$, crystallises in transparent rhomboidal plates melting between 125.5° and 128.5° and distilling at 295° . It is insoluble in water, sparingly soluble in cold alcohol, soluble in boiling alcohol and in ether; does not crystallise from fusion, but solidifies to an amorphous mass. Its *barium salt* is uncrystallisable; the *sodium salt* is soluble in water and in alcohol, and is decomposed by carbonic acid. The *ethyl ether*, obtained by the action of ethyl iodide at 180° on the sodium salt, boils between 250° and 280° .

The action of sodium on sodium valerate likewise gives rise to several other products. (See VALERIC ETHERS.)

ETHYLENE. C^2H^4 .—Formed: a. By electrolysis of a concentrated solution of sodium succinate (Kekulé, *Ann. Ch. Pharm.* cxxxi. 79):

b. Together with benzene, by heating cinnamene with hydrogen in sealed tubes (Berthelot, *Jahresb.* 1866, p. 544):

Reactions.—1. Ethylene heated in a glass tube is decomposed somewhat more easily than marsh gas, yielding chiefly ethane, together with small quantities of acetylene and tarry hydrocarbons: $2C^2H^4 = C^2H^6 + C^2H^2$ (Berthelot, *Jahresb.* 1866, p. 518). By passing it through a porcelain tube heated to not very bright redness, and condensing the liquefiable products in a U-tube cooled to a low temperature, Berthelot has obtained benzene, cinnamene, and crystallisable hydrocarbons distilling at and above 200° , probably naphthalene and naphthalene hydride (*ibid.* 1867, p. 332).—2. Heated in a glass tube to dull redness with an equal volume of acetylene, it yields several products, the chief of which is a very volatile liquid consisting of $C^4H^6 = C^2H^4 + C^2H^2$, isomeric or identical with crotonylene (Berthelot, *ibid.* 1866, p. 519).

3. It unites with *hydriodic acid* at ordinary temperatures, and more quickly at 100° , forming ethyl iodide, C^2H^5I (Berthelot, *ibid.* 1867, p. 344).

4. *Sulphuric chlorhydrate*, SO^2HCl , absorbs dry ethylene at ordinary temperatures, with great evolution of heat and formation of hydrochloric acid; and if the action be ultimately assisted by heating to 88° , there remains a brown oil containing isethionnic anhydride, $C^2H^4SO^2$, together with another anhydride, $C^2H^4SO^2$, and the corresponding acids. When ethylene is passed for some time into cooled sulphuric chlorhydrate, a pungent non-distillable oil is formed, which is decomposed by water into sulphuric acid, hydrochloric acid, ethyl chloride, and an oil, $C^2H^4SO^2Cl$, having an odour of mustard-oil, and boiling at 154° . This oil, when exposed to the air, forms two layers, the upper containing sulphuric acid and chlorine, the lower consisting of a viscous non-distillable oil, $C^2H^4SO^2$, which is converted by water at 100° into isethionnic acid. The oil $C^2H^4SO^2Cl$ is converted by dry ammonia into a solid mass of sul-ammoniac, mixed with large deliquescent tabular crystals of the compound $C^2H^4NSO^2$, which is decomposed by potash, yielding ammonia, ethylamine, and ethionic acid (Baumstark, *Zeitschr. f. Chem.* 1867, p. 566).

5. Ethylene oxidised with *chromic acid mixture* (p. 150) is converted into carbon dioxide and water: $C^2H^4 + O^2 = 2CO^2 + 2H^2O$ (Chapman & Thorp). Heated to 120° with a solution of crystallised *chromic acid* in a small quantity of water, it is oxidised to aldehyde (Berthelot, *Compt. rend.* lxxiii. 334).—6. When a solution of *potassium permanganate* is poured into a vessel containing ethylene gas (12 to 14 grms. of the crystallised salt to 1 litre of the gas) the solution becomes colourless, and the ethylene is oxidised to formic and carbonic acids (Truchot, *Compt. rend.* lxxiii. 274); but on agitating the gas with a strongly alkaline solution of the permanganate, added by small portions in a well-cooled vessel, oxalic acid is formed, as well as the two products just mentioned: $C^2H^4 + O^2 = C^2H^2O^4 + H^2O$ (Berthelot, *ibid.* lxiv. 35).

Compounds and Derivatives of Ethylene.

ETHYLENE BROMIDE, $C^2H^4Br^2$, heated with water, to 150° – 160° , in a sealed tube, is completely resolved into aldehyde (partly changing into aldehyde resin) and hydrobromic acid:

Heated for several hours with 2 or 3 vol. absolute alcohol to 150° – 170° , it forms two layers, the upper containing water, aldehyde, and traces of hydrobromic acid, while the lower is a mixture of ethyl bromide, aldehyde, ether, and alcohol. If a larger proportion of alcohol is used, part of the aldehyde is converted into acetal. Monobromethylene bromide heated with water or alcohol yields exactly the same products (Carius, *Ann. Ch. Pharm.* cxxxi. 172).

Ethylene bromide treated with fuming sulphuric acid or sulphuric anhydride, or heated to 100° with sulphuric chlorhydrate, is converted, with evolution of hydrobromic acid, into bromomethylsulphuric acid, $C^2H^4BrSO^4$, the barium salt of which, $(C^2H^4BrSO^4)^2Ba$, crystallises in anhydrous shining scales very soluble in water. The lead salt $(C^2H^4BrSO^4)^2Pb + 3H^2O$ crystallises in beautiful scales easily soluble in water; it is very unstable, its solution being decomposed by boiling, with formation of lead sulphide, and probably of glycol or of ethylene oxide; perhaps thus:

The calcium, magnesium, zinc, and copper salts also crystallise very beautifully, but are likewise decomposed on boiling (Wroblevsky, *Zeitschr. f. Chem.* [2] iv. 563; v. 281).

MONOBROMETHYLENE or VINYL BROMIDE, C^2H^3Br , heated for several hours with *mercuric acetate*, glacial acetic acid, and water, is decomposed, with formation of

mercuric bromide, partial reduction of the mercuric salt to mercurous salt or metallic mercury, and formation of aldehyde and acetic acid (Linnemann, *Ann. Ch. Pharm.* exliii. 347). According to Saytzeff a. Glinsky (*Zeitschr. f. Chem.* [2] iii. 675), the products of this reaction (at 100°) are acetic acid and a compound of aldehyde with mercurous bromide, which is deposited as a white amorphous precipitate, turning brown in the air, with separation of aldehyde:

Bromethylene dissolves in well-cooled *hypochlorous acid*, forming a product very soluble in water, and not volatile without decomposition, which appears to be a mixture of chlorinated and brominated aldehyde. *Chlorethylene* and hypochlorous acid form monochloraldehyde, $\text{C}^2\text{H}^3\text{ClO}$, a neutral, oily, easily decomposable liquid, converted by atmospheric oxidation into chloracetic acid (Saytzeff a. Glinsky).

Bromethylene Bromide. $\text{C}^2\text{H}^3\text{Br}^2 = \text{C}^2\text{H}^3\text{Br}.\text{Br}^2$ (Glöckner, *Ann. Ch. Pharm. Suppl.* vii. 107).—This compound is most readily prepared by passing vinyl bromide, $\text{C}^2\text{H}^3\text{Br}$, into bromine: 46 pts. ethylene bromide are added to a solution of 16 pts. potassium hydrate in 80 pts. alcohol cooled to 0°; the cooling mixture is then removed; and the gradually evolved vinyl bromide is passed into 30 pts. of bromine under water. The product, after washing with aqueous potash and distillation, consists of pure bromethylene bromide boiling at 188°.

This compound heated with water in sealed tubes is very slowly attacked; much more readily by alcohol under the same circumstances (at 160°–180°), yielding ethyl bromide, ethyl oxide, hydrogen bromide, and a liquid which boils at 27°, forms a crystalline compound with acid ammonium sulphite, and appears to consist of monobromaldehyde, $\text{C}^2\text{H}^3\text{BrO}$:

the ethyl oxide results from the action of the ethyl bromide on the excess of alcohol used:

Bromethylene bromide heated to 150° in a sealed tube with barium hydrate in the proportion of $2\text{C}^2\text{H}^3\text{Br}^2$ to BaH^2O^2 , yields a mixture of acetylene, C^2H^2 , and bromacetylene, C^2HBr . Mixed with potassium hydrate, $(\text{C}^2\text{H}^3\text{Br}^2:\text{KHO})$, dissolved in ten times its weight of alcohol in a flask filled with hydrogen, the mixture being cooled at first by a freezing mixture, but afterwards exposed to the ordinary atmospheric temperature, it gives off bromacetylene with a small quantity of acetylene; and if the flask be connected with two receivers, the first being empty and the second filled with absolute alcohol, the greater part of the bromacetylene dissolves in this liquid, and the first receiver becomes partly filled with a solution of bromacetylene, C^2HBr , and dibromethylene, $\text{C}^2\text{H}^3\text{Br}^2$. Part of the liquid dibromethylene is, however, converted into a solid body of the same composition, first noticed by Sawitsch: this body is not altered by heating with water to 180°.

If in the preceding reaction the air be not completely excluded, monobromacetic acid is formed, together with bromide of potassium or barium; hence it appears that the first product of the action of the alkaline hydrate on bromethylene bromide is monobromaldehyde:

this aldehyde being afterwards converted into bromacetic acid by oxidation. Bromacetic acid is also formed when a solution of bromacetylene in absolute alcohol is exposed to the air:

ETHYLENE CHLORIDE, $\text{C}^2\text{H}^2\text{Cl}^2$, is decomposed by *potassium*, forming potassium chloride and a mixture of ethylene, chlorethylene, and hydrogen gases:

If excess of ethylene chloride is used, the chlorethylene remains dissolved therein (Mauméné, *Compt. rend.* lxxviii. 931).

TRICHLORETHYLENE, C^2HCl^3 , is produced by treating carbon trichloride with zinc and sulphuric acid (as in Geuther's process for preparing carbon dichloride, i. 767). It is contained in the portion of the product which boils between 87° and 90°, and, after repeated rectification, is an oily substance smelling like carbon dichloride, and quickly decomposing in contact with the air, with formation of hydrochloric acid (E. Fischer, *Zeitschr. Chem. Pharm.* 1864, p. 268).

CHLOROBROMETHYLENE, $\text{C}^2\text{H}^2\text{ClBr}$, is formed, together with hydrocyanic acid, by distilling an alcoholic solution of chlorethylene bromide, $\text{C}^2\text{H}^3\text{Cl}.\text{Br}^2$, with

potassium cyanide. It is a heavy liquid, boiling in contact with water at 55°-58°; its vapour irritates the eyes and has a pungent odour, like that of benzoyl chloride. It is converted partially on standing, completely by repeated distillation with water, into a solid modification (H. Müller, *Chem. Soc. J.* [2] ii. 420).

ETHYLENE IODIDE, $C^2H^4I^2$, is easily obtained in large quantity by saturating a pasty mixture of iodine and absolute alcohol with ethylene gas, agitating, and repeatedly adding fresh portions of iodine; the iodine-solution decanted from the crystals first formed is again mixed with iodine and treated with ethylene. The ethylene iodide, after washing with cold alcohol, is quite pure (Semenoff, *Zeitschr. Ch. Pharm.* 1864, p. 673).

Ethylene iodide heated with water in an exhausted tube to 275° for fifteen hours, is decomposed into ethane, carbon dioxide, and free iodine:

The hydrogen liberated from the water by the carbon of the ethylene iodide, ($C^2H^4I^2 + 4H^2O = 6H^2 + 2CO^2 + I^2$), decomposes the ethylene iodide, according to the equation $C^2H^4I^2 + H^2 = C^2H^6 + I^2$ (Berthelot, *Ann. Ch. Phys.* [4] iii. 211).

Ethylene iodide is decomposed by mercuric chloride according to the following equations:

Decomposition according to equation 1, takes place at ordinary temperatures, the equation then becoming

In fact, when an intimate mixture of 1 mol. $C^2H^4I^2$ and 3 mol. $HgCl^2$ is left to itself for some days, it becomes saturated with a red oil consisting of ethylene chloriodide, C^2H^4ClI (ii. 574). The decomposition represented by the second equation takes place when the mixture of $16HgCl^2$ and $6C^2H^4I^2$ is heated to 100°. Ethylene chloride is then obtained, mixed with a certain quantity of the chloriodide, the quantity of which may be diminished by rapid heating, but is always considerable (Maumené, *Compt. rend.* lxxviii. 727; *Zeitschr. f. Chem.* [2] v. 366).

Iodethylene, C^2H^4I , heated in alcoholic solution to 100° with silver oxalate, yields silver iodide and a liquid decomposable by water, with formation of oxalic acid, probably an oxalic ether of vinyl alcohol, C^2H^3OII (Semenoff, *Zeitschr. Chem. Pharm.* 1864, p. 673).

ETHYLENE CHLORIODIDE, C^2H^4ClI , heated to 100°-200° in a sealed flask with 1 mol. moist silver oxide is converted in great part into ethylene alcohol, $C^2H^4(OH)^2$, both the chlorine and the iodine being replaced by hydroxyl. The same results are obtained with 2 mol. silver oxide. The chloriodide heated with water to 160°-220° is also converted into ethylene alcohol, hydrochloric acid, and hydriodic acid, which latter converts part of the ethylene alcohol into iodide. It appears from these results that the chlorine and iodine in the chloriodide are combined with the carbon in the same manner, and that it is not possible to replace one of them with hydroxyl without the other (Maxwell Simpson, *Phil. Mag.* [4] xxxv. 282).

ETHYLENE OXIDE, C^2H^4O , heated to 100° in a sealed tube with acid sodium sulphite is converted into the sodium salt of isethionic acid (Erlenmeyer, *Zeitschr. f. Chem.* [2] iv. 342):

ETHYLENE HYDROXYCHLORIDE, or GLYCOLIC CHLORHYDRIN, $C^2H^4 \begin{Bmatrix} OH \\ Cl \end{Bmatrix}$, is produced by direct combination of ethylene with hypochlorous acid, $ClOH$ (Carius, *Ann. Ch. Pharm.* cxxvi. 195). The following mode of preparation is recommended by Butlerow (*ibid.* cxliv. 40). Glass flasks of the capacity of 30 litres or more are filled over water with ethylene gas. To prepare the hypochlorous acid, moist recently precipitated mercuric oxide (10 pts., containing about 4 pts. of the dry oxide, being taken for every litre of ethylene) is mixed with so much ice and water that the mixture shall contain 1 pt. oxide to 16 pts. water, and into this mixture, in a vessel standing in ice-water and in the dark, chlorine gas is slowly passed till the mercuric oxide has nearly disappeared. Half the original quantity of oxide is then added, and the whole is quickly poured into the flasks containing the ethylene,

which must then be securely closed. The mixture, after standing for 70 or 80 hours in the dark, is diluted with water and filtered; a quantity of concentrated aqueous sodium hyposulphite is added sufficient to decompose the excess of hypochlorous acid; and the mixture is distilled as long as the distillate exhibits a sweet taste. By saturating this distillate with common salt, agitating with ether, decanting the ethereal solution, and evaporating the ether, the glycolic chlorhydrin is obtained pure.

Glycolic chlorhydrin unites directly with *trimethylamine*, forming the chloride of oxethyl-trimethylammonium, which is identical with the hydrochloride of choline or neurine (Wurtz, p. 448):

Glycolic chlorhydrin does not act upon *monosodic glycol* at ordinary temperatures; but on heating the mixture to 130°, ethylene oxide is given off, and on increasing the heat to 250°, a yellow oily liquid passes over, separable by fractional distillation into monoethylenic alcohol (glycol) passing over at 194°–196°, and a small quantity of diethylenic alcohol at 235°–245°. The reaction is:

the greater part of the diethylenic alcohol however splitting up into glycol and ethylene oxide (E. Scheiz, *Zeitschr. f. Chem.* [2] iv. 379). Ethylene monoacetate heated with monoethylenic alcohol (glycol) passing over at 130°–140° for twelve hours, yields chiefly diethylenic alcohol (R. Mohs, *ibid.* ii. 495; *Jahresb.* 1866, p. 606):

ETHYLENE HYDROXYIODIDE, or GLYCOLIC IODHYDRIN, $C^2H^4 \left\{ \begin{array}{c} OH \\ I \end{array} \right.$, was first obtained, though not in the pure state, by Maxwell Simpson (ii. 578) by passing hydriodic acid gas into glycol contained in a cooled vessel. According to Butlerow a. Ossokin (*Ann. Ch. Pharm.* cxlv. 257), it is more easily prepared by heating the chlorhydrin, C^2H^4ClOH , with a large excess of finely pulverised potassium iodide to 100° for 24 hours. On treating the resulting mass with the exact quantity of water required to dissolve the chloride and iodide of potassium, a heavy oil separates, coloured black by iodine, from which it may be freed by washing with an alkaline carbonate or sulphite, and if then dried over dehydrated Glauber salt, and distilled in a vacuum, gives off first water, then pure glycolic iodhydrin. This compound is a heavy liquid, not volatile without decomposition, moderately soluble in water, and separable for the most part from the solution by potassium carbonate; it has a peculiar odour, like that of methylene iodide, and a burning sweet taste. With *zinc methyl* (or zinc-ethyl) it reacts in the manner shown by the equations:

The reaction represented by the first equation is very violent, and is best performed under a layer of benzol. The solid white product treated with water gives off gas and reproduces the iodhydrin:

The product of the second reaction, formed under peculiar circumstances, yields when decomposed by water, an alcoholic liquid, which, when zinc-methyl has been used, consists of isopropyl alcohol, C^3H^7O , and in the case of zinc-ethyl, of secondary butyl alcohol or methyl-ethyl carbinol, $C^4H^{10}O$ (Butlerow a. Ossokin).

ETHYLENE NITRITE, $C^2H^4(NO^2)^2$.—Produced by passing dry ethylene gas through liquid nitrogen tetroxide, or by heating the gaseous mixture of the two bodies to 60° or 70°, an oily liquid being formed at the same time; more abundantly and in the pure state by passing ethylene into anhydrous ether, to which liquid nitrogen

tetroxide is at the same time added by drops, then cooling the liquid, pressing the crystals which separate between bibulous paper, and drying them over sulphuric acid. The compound is insoluble in water, easily soluble in alcohol or ether, and crystallises in white four-sided prisms or tables which melt at 37.5° , and sublime with partial decomposition at a higher temperature. In a stream of ethylene gas, the compound sublimes at a gentle heat. The fused compound, when cooled to 0° , remains liquid till it is touched with a solid body.

The heavy oily liquid formed, as above mentioned, together with ethylene nitrite, is also very volatile, has a pungent odour, and possesses poisonous properties (Semenoff, *Zeitschr. Ch. Pharm.* 1864, p. 129).

ETHYLENE NITROSO-NITRATE. $C^2H^4N^2O^4 = C^2H^4 \begin{Bmatrix} NO^1 \\ NO^2 \end{Bmatrix}$ —When ethylene gas is continually passed through a cooled mixture of nitric and sulphuric acids, an oil collects on the surface, which after washing with water and alkaline carbonate, distillation with aqueous vapour, and dehydration with calcium chloride, exhibits the composition above given. It is a colourless liquid, of sp. gr. 1.472, having an odour spirituous at first, afterwards pungent; its vapour attacks the eyes strongly and produces transient headache. In the dry state it does not volatilise without decomposition, but gives off red fumes even below its boiling point. When distilled with aqueous vapour, it decomposes in great part, with evolution of nitrogen dioxide and trioxide, and formation of oxalic, glycollic, and glyoxylic acids. It is decomposed in like manner by boiling with bases, excepting that the oxidation is less energetic and the proportion of glycollic acid formed is larger. Treated with caustic soda and sodium-amalgam, or with hydriodic acid, it is converted into ethylene alcohol, the whole of the nitrogen being evolved, in the first case as ammonia, in the second chiefly as nitrogen dioxide. The compound $C^2H^4N^2O^3$ is likewise formed by passing ethylene into fuming nitric acid; but a certain portion of the ethylene then undergoes oxidation (Kekulé, *Zeitschr. f. Chem.* [2] v. 601).

DIETHYLENE BISULPHIDE. $(C^2H^4)^2S^2$ (Husemann, *Ann. Ch. Pharm.* cxxvi. 269; *Jahresb.* 1862, p. 430).—Produced: 1. By heating ethylene trisulphocarbonate (v. 502) with ethylene bromide for a long time (finally to 150°) in a retort fitted with a long upright condenser:

It collects in the receiver and may be purified by recrystallisation from ether-alcohol.—2. By heating mercuric sulphethylenate (prepared by precipitating an alcoholic solution of ethylene-mercaptan with mercuric chloride) with ethylene bromide to 150° for about six hours, the diethylene bisulphide then subliming:

3. The white amorphous ethylene sulphide C^2H^4S (ii. 582), obtained by the action of potassium monosulphide on ethylene chloride (much more easily with the bromide) when heated to 160° – 170° for several days with carbon bisulphide, is almost wholly converted into diethylene bisulphide. The same compound heated by itself also yields diethylene bisulphide, together with a black residue and a yellow liquid having a disagreeable odour.

Diethylene bisulphide is slightly soluble in water, easily soluble in hot alcohol, ether, chloroform, benzol, and carbon bisulphide, and crystallises from alcohol in white needles and laminae grouped like fir-branches; from ether in thick hard monoclinic prisms, mostly combinations of $\infty P, oP, (P\infty)$; it sublimes undecomposed at 56° , melts at 111° , boils at 200° , and has a strong, not altogether unpleasant odour.

Its observed vapour-density 4.28 agrees very nearly with the number 4.155 calculated from the formula $(C^2H^4)^2S^2$, showing that this compound is polymeric with the non-volatile ethylene sulphide C^2H^4S , and is related to it in the same manner as diethylene dioxide $(C^2H^4)^2O^2$ to ethylene oxide C^2H^4O .

Diethylene bisulphide is not attacked by hydrochloric acid, ammonia, or alcoholic potash, and crystallises unaltered from its colourless solution in strong sulphuric acid. Fuming nitric acid dissolves it, forming a blood-red solution which solidifies to a crystalline mass of diethylene oxysulphide. It unites directly with chlorine, bromine, and iodine, but not with cyanogen. In alcoholic solution it forms with mercuric, auric, and platinum chlorides, crystalline compounds containing 1 mol. of the bisulphide to 1 mol. $HgCl^2$ and $PtCl^4$, and 2 mol. $AuCl^3$; these compounds are nearly insoluble in water, but dissolve in hot alcohol, and separate therefrom in microscopic crystals. With silver nitrate in like manner it forms the compound $3(C^2H^4)^2S^2.4AgNO^3$ (polymeric with the ethylidene-compound obtained by Weidenbusch, p. 607), which

crystallises in monoclinic prisms or tables, blackens on exposure to light, and decomposes at 140° .

Diethylene Sulphobromide, $(C^2H^4)^2S^2Br^4 = (S^2)^{III} \left\{ \begin{matrix} (C^2H^4)^+ \\ Br^- \end{matrix} \right\}$, is formed on adding dry

bromine to a solution of the bisulphide in anhydrous carbon bisulphide or ether, as a lemon-yellow amorphous precipitate, which decomposes in moist air, more quickly in contact with water or alcohol, into hydrobromic acid (or ethyl bromide) and diethylene oxysulphide. It gives off bromine at 70° , and melts at 96° with copious evolution of hydrobromic acid. This compound may be represented by the structural formula

Diethylene Sulphochloride, $(C^2H^4)^2S^2Cl^4$, analogous in structure to the preceding, is deposited on passing dry chlorine into a solution of the bisulphide in carbon bisulphide, as a white amorphous very unstable substance; it is polymeric with Guthrie's ethylene dichlorosulphide (ii. 584).

Diethylene Sulphiodide, $(C^2H^4)^2S^2I^4$, separates on adding iodine to a saturated solution of diethylene bisulphide in ether, alcohol, or carbon bisulphide, in monoclinic needles, iron-black by reflected, red by transmitted light, which are not decomposed by water or by boiling alcohol, but give off iodine at 100° and melt at 132° – 133° .

Diethylene Oxysulphide, $(C^2H^4)^2S^2O^2$, is produced, either by decomposing the sulphochloride or sulphobromide with water, or by oxidising diethylene bisulphide with strong nitric acid. It is slightly soluble in alcohol and ether, easily soluble in water, and crystallises in long white prisms or in rhombohedrons, neutral, inodorous, and infusible. Chlorine passed into its solution forms a crystalline precipitate of dichloroethylene oxysulphide, $(C^2H^4Cl)^2S^2O^2$.

ETHYLIDENE. This diatomic radicle, isomeric with ethylene, has not yet been isolated. Tollens (*Ann. Ch. Pharm.* cxxvii. 311), by heating ethylidene chloride with sodium to 180° – 200° in sealed tubes, obtained a mixture of acetylene, ethylene, chloroethylene, ethane, and probably hydrogen.

The difference of structure between the radicles ethylene and ethylidene is represented by the formulæ:

In the ethylene-compounds the chlorine, oxygen, &c., are placed symmetrically with regard to the two carbon-atoms, whereas in the ethylidene-compounds their position is unsymmetrical; thus:

Ethylidene chloride, produced by the action of phosphorus pentachloride on aldehyde, is identical with monochlorethyl chloride, $C^2H^4Cl.Cl$, and ethylidene bromide with monobromethyl bromide (p. 594). Ethylidene chloride heated with aldehyde in sealed tubes yields crotonic aldehyde, C^4H^6O , together with other products (p. 513).

Ethylene in the free state most probably has its carbon-atoms united by two units of affinity: thus $\begin{array}{c} CH^2 \\ || \\ CH^2 \end{array}$; and under the influence of chlorine, bromine, &c., the bands are loosened as in benzene (p. 196). In ethylidene, on the other hand, this double union of the carbon-atoms is clearly impossible; and consequently ethylidene cannot exist in the free state.

Ethylidene Sulphide. $C^2H^4S = CH^3.CHS$. *Sulphacetyl Hydride* (Weidenbush, *Ann. Ch. Pharm.* lxi. 346. Crafts, *Compt. rend.* liv. 1279).—Produced by the action of hydrogen sulphide upon aldehyde. When a current of the gas is passed into a mixture of aldehyde and water, the liquid ultimately deposits a thick limpid oil,

which is a compound of ethylidene sulphide and hydrogen sulphide. This compound dried in a vacuum has the composition $6C^2H^4S.H^2S$ (i. 107). It has a sp. gr. of 1.134; is slightly soluble in water, very soluble in alcohol and ether; boils at 180° , decomposing at the same time, and leaving an unctuous mass of ethylidene sulphide. At ordinary temperatures it volatilises rapidly, giving off a very strong and persistent allineous odour. Treated with hydrochloric or sulphuric acid, it gives off hydrogen sulphide, and solidifies to a crystalline mass of ethylidene sulphide. The latter is also formed on merely exposing the sulphydric compound to the air.

Ethylidene sulphide is lighter than water, slightly soluble therein, more soluble in alcohol, ether, and carbon bisulphide, and crystallises from the latter in long needle-shaped rhombic prisms of 95° . It distils at 205° , but the boiling point of the fused mass rises with partial decomposition to 260° . As the fused mass cools, the temperature remains stationary for some time at 96° , whilst crystalline laminae form; then the whole mass becomes soft, and solidifies completely at 70° (Crafts, *Jahresb.* 1862, p. 431). With silver nitrate it forms the compound $3C^2H^4S.2AgNO^3$ (Weidenbusch).

ETHYLIDENE-SULPHURIC or SULPHETHYLIDENIC ACIDS (Staedel, *Zeitschr. f. Chem.* [2] iv. 272).—When ethylidene chloride is continuously boiled with solution of neutral potassium sulphite in a flask with upright condenser, two acids are formed which may be separated by the different solubilities of their barium salts. The least soluble of these salts is the *ethylidene-monosulphate* or *monosulphethylidenate*, $C^2H^4SO^4Ba + H^2O$, which forms hard shining transparent crystals, quite different in appearance from the isethionate, with which they are isomeric. The zinc salt of the same acid crystallises in white shining laminae; the silver salt in needles, the copper salt in thin light green laminae. The free acid has not been obtained pure.

The more soluble of the two barium salts above mentioned is the *ethylidene-disulphate* or *disulphethylidenate*, $C^2H^4SO^2Ba$, which crystallises with difficulty. All the salts of these two acids, excepting the copper salts, are insoluble in alcohol.

Monosulphethylidenic and Disulphethylidenic acids are related to isethionic and disulphetholic acids respectively, in the same manner as ordinary lactic to paralactic acid, or as isosuccinic to ordinary succinic acid, as may be seen from the following formulæ:

<i>Ethylidene-compounds.</i>	<i>Ethylene-compounds.</i>
$CH^3.CH \begin{cases} OH \\ COOH \end{cases}$ Lactic.	$\begin{cases} CH^2OH \\ CH^2COOH \end{cases}$ Paralactic.
$CH^3.CH \begin{cases} COOH \\ COOH \end{cases}$ Isosuccinic.	$\begin{cases} CH^2COOH \\ CH^2COOH \end{cases}$ Succinic.
$CH^3.CH \begin{cases} OH \\ SO^3H \end{cases}$ Monosulphethylidenic.	$\begin{matrix} CH^2OH \\ \\ CH^2SO^3H \end{matrix}$ Isethionic.
$CH^3.CH \begin{cases} SO^3H \\ SO^3H \end{cases}$ Disulphethylidenic.	$\begin{matrix} CH^2SO^3H \\ \\ CH^2SO^3H \end{matrix}$ Disulphetholic.

ETTIDINE. $C^8H^{10}N$.—One of the higher bases of the series $C^8H^{2n-11}N$, produced by distilling *cinchonine* with potassium hydrate (C. Gr. Williams, *Laboratory*, p. 109).

EUGENIA. The red juice of the fruit of the Australian myrtle (*Eugenia australis*) is similar in its properties to that of red grapes. It contains free tartaric acid, cream of tartar, sugar, and a red colouring matter very sensitive to the action of acids and alkalis. By fermentation it yields wine possessing a bouquet. The colouring matter, which is soluble in alcohol and in ether-alcohol, but not in pure ether, is precipitated by lead acetate, decolorised by reducing agents, and recovers its red colour on exposure to the air, just like litmus and the red colouring matter of wine (De Luca a. Ubaldini, *J. Pharm.* [4] iii. 44).

EUGENIC ACID or EUGENOL. $C^{10}H^{12}O^2$.—This acid exists in oil of bay (*Laurus nobilis*), together with a hydrocarbon, $C^{10}H^{14}$, boiling at 171° . The eugenic acid from this source boils at 252° , has a sp. gr. of 1.066 at 20° , and a refractive index of 1.5402 for the line D, and 1.5539 for F at 18° (Gladstone, *Chem. Soc. J.* [2] ii. 6). Eugenic acid possessing the same properties (sp. gr. 1.08 at 8° , boiling point 251°) is obtained by the action of potash on oil of pimento (iv. 647).

Eugenic acid distilled with hydriodic acid is resolved into methyl iodide and a residual resinous mass having nearly the composition $C^{10}H^{10}O^2$ (Erlenmeyer, *Zeitschr. f. Chem.* [2] ii. 430). By fusion with *potassium hydrate* it yields protocatechic and acetic acids, the latter being probably due to the decomposition of propionic acid formed in the first instance (Hlasiwetz u. Grubowski, *Ann. Ch. Pharm.* cxxxix. 95):

Phosphoric anhydride converts eugenic acid into a resin intermediate in composition between $C^{10}H^{12}O^2$ and $C^{10}H^{12}(O)^2$, inodorous, having a bitter and aromatic taste, exhibiting violet-blue dichroism in alcoholic solution; by distillation this resin yields a liquid analogous to creosote, which colours ferric salts green (Hlasiwetz u. Barth, *ibid.* 83).

When eugenic acid is gently heated with *phosphorus trichloride*, a large quantity of hydrochloric acid is evolved, together with a small quantity of gas burning with a green-edged flame; and on distilling off the excess of phosphorous chloride, the residual liquid solidifies at 130° to a porous straw-yellow mass, from which ether extracts eugenic anhydride, $(C^{10}H^{10}(O))^2$, in the form of a viscid dark-coloured oil, reconvertible by aqueous potash into eugenic acid. The portion of the product insoluble in ether has the composition of eugenyl-phosphorous acid, $C^{10}H^{11}PO^4 =$

$\left. \begin{array}{c} P'' \\ C^{10}H^{11}O \\ H^2 \end{array} \right\} O^1$. Hence the reaction of phosphorous chloride on eugenic acid may be represented by the equation

Eugenyl-phosphorous acid is an amorphous yellow powder, nearly insoluble in alcohol, and dissolving with difficulty in hot water. The aqueous solution is acid and exhibits the reducing properties of phosphorous acid. Alkalis dissolve it, forming a light brown liquid which quickly becomes darker, and when distilled with sulphuric acid yields eugenic acid. When heated, it swells up, gives off combustible phosphorated gases, and leaves a bulky cinder, from which water extracts phosphoric acid (Oeser, *Ann. Ch. Pharm.* cxxxi. 277).

EUGETIC ACID. $C^{10}H^{12}O^1$.—Formed, as a sodium salt, by passing carbon dioxide into eugenic acid holding sodium in solution. (See Appendix to vol. ii. p. 968.)

EUGLENA SANGUINEA. This plant, which often forms brick-red layers on the surface of ponds, contains a colouring matter insoluble in water, but soluble with garnet-red colour in ether. The solution evaporated on a glass plate leaves an iridescent ring of octohedral crystals, red by transmitted light. The colouring matter is precipitated by alcohol from its ethereal solution, but dissolves in hot alcohol and separates in garnet-red octohedrons, which melt between 70° and 120° ; are decolorised by chlorine-water without change of form, and are turned blue by sulphuric acid, but recover their original colour when washed with water. These crystals dissolve very easily in turpentine-oil, and form with potash-ley a *blood-red* liquid, from which acids separate red drops possessing the properties of the crystals (Wittich, *Chem. Centr.* 1864, p. 576).

EUOSMITE. A fossil resin found in the lignite of Thumsenreuth in the Bavarian Oberpfalz. It occurs sometimes in brownish-yellow pulverulent masses, sometimes in compact lumps having the aspect of pitch. Sp. gr. 1.2-1.5. Has an agreeable odour of rosemary and camphor; melts at 77° ; burns with a bright flame emitting an aromatic odour; dissolves completely in alcohol and ether. According to an analysis by Wittstein, it appears to consist of $C^{10}H^{10}O^2$ (C. W. Gümbel, *Jahresb.* 1864, p. 867).

EUPHORBONE. $C^{12}H^{22}O$.—A substance obtained from euphorbia (ii. 607), by precipitating the aqueous extract with tannin, triturating the washed flocculent precipitate with white lead, then boiling it with alcohol, distilling off the alcohol, and dissolving the brownish-yellow deposit in a small quantity of boiling alcohol of 70-75 p. c. On cooling it crystallises in nodules, which may be obtained colourless by recrystallisation. It dissolves very easily in ether, benzol, amyl alcohol, chloroform, and acetic acid; is nearly insoluble in water; dissolves in 53 pts. of alcohol (of 87 vol. p. c.) at 17.5° , very abundantly in boiling alcohol; melts between 106° and 116° .

Sup.

R R

It is neutral, and is not dissolved by acids or bases more abundantly than by water. Nitric acid oxidises it to oxalic acid and a non-crystallisable acid. Strong sulphuric acid dissolves it somewhat sparingly, forming a yellowish-brown solution which is coloured violet by nitric acid and by chlorate or chromate of potassium. It acts as a drastic purgative (Flückiger, *Zeitschr. f. Chem.* [2] iv. 221).

EUSYNCHITE. See VANADATES.

EUTHIOCHRONIC ACID. See Derivatives of Tetrachloroquinone, under QUINONE.

EUXANTHONE. This substance, produced by the decomposition of euxanthic acid, has hitherto been regarded as $C^{20}H^{12}O^6$ or $C^{18}H^{10}O^4$, its formation being represented by the equation

But according to Baeyer (*Zeitschr. f. Chem.* v. 569), its analysis is more nearly represented by the formula $C^{18}H^{10}O^4$, which, moreover, agrees better than the older formula with the substitution-products obtained by Erdmann (ii. 610). When the vapour of euxanthone is passed over heated zinc-dust, a small quantity of a semi-solid hydrocarbon is formed resembling diphenyl. Euxanthone fused with potassium hydrate is first converted, by assumption of water, into euxanthonic acid, and then at a higher temperature into hydroquinone.

Euxanthonic acid, $C^{18}H^{10}O^5$, possesses but feeble acid properties; forms a reddish-yellow precipitate with basic lead acetate; oxidises quickly when dissolved in potash, and is altogether more easily oxidisable than euxanthone. Ferric chloride colours it red, whereas euxanthone is coloured green by the same reagent. When heated, it is resolved into water and euxanthone, which sublimes. The same decomposition takes place also on boiling an aqueous solution of the acid containing ammonia, the euxanthone separating in bulky yellow needles. Euxanthonic acid is much more soluble in water than euxanthone, and crystallises from a hot solution on cooling, in nodules, by evaporation in long yellow needles (Baeyer).

EUXENITE. A specimen of this mineral from Arendal in Norway (sp. gr. 4.96) was found by Chydenius (*Bull. Soc. Chim.* [2] vi. 433) to contain 54.28 Nb^2O^3 and TiO^2 , 34.58 YO and ElO , 6.28 ThO , and 2.60 volatile matter (= 97.74).

EVANSITE. A hydrated aluminium phosphate, $3Al^2O^3.P^2O^5 + 18aq.$, occurring in Hungary as an incrustation in the cavities of brown hæmatite. It is amorphous, kidney-shaped to botryoidal, colourless or milk-white, sometimes with a tinge of yellow or blue, transparent to translucent. Fracture semi-conchoidal, shining. Hardness, 3.5 to 4. Sp. gr. (mean), 1.939. Perfectly soluble in acids (D. Forbes, *Phil. Mag.* [4] xxviii. 341).

EVERNIIN. $C^6H^{10}O^7$ (Stude, *Ann. Ch. Pharm.* cxxxi. 241).—A substance related to the sugars, extracted from *Evernia prunastri*. The plant is macerated with cold dilute soda-ley till the liquid acquires a dark green colour; the filtrate is mixed with alcohol; and the brown flocks thereby precipitated are redissolved in water and purified by repeated precipitation and boiling with animal charcoal.

Everniin is an amorphous, yellowish, tasteless powder, which swells up in cold water and dissolves easily in hot water. Its aqueous solution gives with lead acetate and ammonia a precipitate soluble in acetic acid. It is precipitated by a large excess of glacial acetic acid. It prevents the precipitation of lead by sulphydric or sulphuric acid, a property likewise possessed by glycogen, inulin, lichenin, and gum. Everniin is not coloured by iodine. Dilute acids easily convert it into glucose.

A substance closely related to, or perhaps identical with everniin, is obtained from *Borreria ciliaris*.

F

FATS. See GLYCERIDES and OILS.

FAUSERITE. A native magnesian-manganous sulphate, $\text{SO}_4\text{Mg} \cdot 2\text{SO}_4\text{Mn} + 16\text{H}_2\text{O}$, occurring in orthorhombic prisms of $88^\circ 42'$, modified by the faces of P, $\infty\text{P}\infty$, $\infty\text{P}2$ ($= 54^\circ 39'$) and $\infty\text{P}\frac{1}{2}$ ($= 107^\circ 50'$). Hardness = 2.5 to 2.75; sp. gr. = 1.88. Reddish and yellowish white, or transparent and colourless (Breithaupt, *Jahresb.* 1865, p. 900).

FERBERITE. A variety of wolfram from the Sierra Almagrera in southern Spain, having, according to Liebe (*Jahresb.* 1863, p. 825) and Rammelsberg (*ibid.* p. 854), the composition $4\text{MO} \cdot 3\text{WO}_3$. The specimen examined by Rammelsberg had n sp. gr. of 7.169 and contained 69.88 p. c. WO_3 , 0.16 SnO_2 , 25.34 FeO , 3.00 MnO , and 1.62 CaO .

FERMENTATION. The main results of Pasteur's researches on alcoholic fermentation are given in vol. ii. pp. 628-630. According to these researches, it appears that the development of the yeast-plant is an essential part of the process; that the yeast-cells grow both in pure sugar-water and in sugar-water containing albuminous substances; but that in the former case, the whole of the nitrogen which, in the original yeast, was partly present in the soluble form, is found, at the end of the fermentation, to have passed into the insoluble form in the newly formed yeast-cells; whereas in the latter case most of the new yeast-cells are found, at the end of the fermentation to be filled with soluble nitrogenous and mineral substances, which, when introduced into a fresh quantity of sugar-water, are capable of giving rise to the formation and development of new yeast-cells. Yeast added to pure sugar-water lives, in fact, at the expense of the sugar and of the nitrogenous and mineral substances contained within itself; and in the process of alcoholic fermentation, part of the sugar is assimilated by the yeast in the form of cellulose and fat.

In a subsequent paper (*Bull. Soc. Chim.* 1861, pp. 61, 79), relating to the influence of oxygen on the development of yeast in alcoholic fermentation, Pasteur observes that ready-formed yeast can germinate and grow in a liquid containing sugar and albuminous matters, even when oxygen is completely excluded. The quantity of yeast formed in this case is, however, but small, and the fermentation goes on slowly; nevertheless, a large quantity of sugar disappears (60-80 pts. to 1 pt. of yeast). If the air has access to a large surface, the fermentation goes on quickly, and a much larger quantity of yeast is formed in proportion to the quantity of sugar which disappears. In this case also oxygen is absorbed by the yeast, which grows quickly, but does not act so decidedly as a ferment, inasmuch as only 4 to 10 pts. of sugar disappear for 1 pt. of yeast produced. When the air is excluded, the same yeast again acts as a powerful ferment. Pasteur therefore infers that yeast which acts as a ferment in the absence of air, abstracts oxygen from the sugar, and that upon this deoxidising power its action as a ferment depends. The violent activity of the yeast at the commencement of the fermentation is due to oxygen dissolved in the liquid. In liquids containing albumin (yeast, water, &c.), yeast likewise grows, though sparingly, even if the solution does not contain a trace of sugar, provided there is sufficient access of air. But if the air is excluded, this does not take place, even though the liquid may contain, besides albumin, a nonfermentable sugar, such as milk-sugar. The yeast formed in a liquid not containing sugar possesses all the properties of a ferment, and excites fermentation in a solution of sugar excluded from the air.

According to Béchamp, the mould developed in sugar-water (both microphytes and microzoa) contains a peculiar soluble ferment, which at low temperatures gives rise to the inversion of cane-sugar, but loses its activity at 60° - 80° . This ferment, called *zymase* by Béchamp, does not act on starch or glucosides. Similar ferments are found in the petals of certain flowers, and in mulberry juice. In the action of beer-yeast on cane-sugar, the latter is first converted by the *zymase* into inverted sugar, which is consumed by the yeast and contributes to its growth, and is afterwards eliminated in the form of the compounds which constitute the products of alcoholic fermentation (*Compt. rend.* lviii. 601, 723; lix. 496; *Jahresb.* 1864, pp. 574-578).

On the nature and development of yeast, see further Joly a. Musset (*Compt. rend.* lii. 368; *Jahresb.* 1861, p. 725), Pasteur (*Bull. Soc. Chim.* 1862, p. 66; *Jahresb.* 1862,

p. 473), Millon (*Compt. rend.* lvii. 235; lix. 144; *Jahresb.* 1863, p. 583; 1864, p. 579), Duclaux (*Compt. rend.* lviii. 1114; *Jahresb.* 1864, p. 578).

Liebig, who has always been opposed to the theory which attributes fermentation to the action of living organisms, has renewed his objections to it in a recently published memoir (*Ann. Ch. Pharm.* cliii. 1). He points out that the amount of growth of the yeast-plant in a solution of pure sugar is utterly inadequate to account for the quantity of sugar transformed at the same time into alcohol and carbon dioxide, if the growth of the yeast be regarded as an essential condition of that transformation. In proof of this he quotes one of Pasteur's experiments, in which 9899 milligrams of sugar were fully decomposed by a very small quantity of yeast, and at the end of the fermentation the quantity of the yeast-plant produced was found to be only 152 milligrams, the cellulose in it amounting to less than 30 milligrams. Liebig asks then: Are we to regard the assimilation of 30 milligrams of cellulose as the cause of the conversion of 9899 milligrams of sugar into carbon dioxide and alcohol? Moreover, yeast is capable of inducing the resolution of calcium malate into carbon dioxide and calcium carbonate, acetate, and succinate, and of bringing about a variety of transformations upon various organic substances. All these phenomena are, in Liebig's opinion, most readily explained by regarding fermentation as a purely chemical or physico-chemical process. The breaking up of sugar into carbon dioxide and alcohol he places side by side with the decomposition of anhydrous acetic acid into acetone and carbon dioxide (a change brought about by heat), and with the change of an aqueous solution of cyanogen gas into oxamide, which is brought about by the action of the merest trace of aldehyde. Just as the vibration produced by the aldehyde determines the rearrangement of the atoms of cyanogen and water so as to constitute oxamide, so Liebig regards the rearrangement of the atoms of sugar as the result of a vibration produced by the chemical changes which take place in some unstable substance produced by the yeast-plant. The growth of the yeast-plant is, according to this idea, only remotely connected with the process of fermentation. 'It is possible,' he says, 'that the physiological process stands in no other relation to the process of fermentation than that, by means of it, a substance is formed in the living cell, which, by an action peculiar to it—resembling that of emulsin on salicin or amygdalin—determines the decomposition of sugar and other organic molecules. In such a case the physiological action would be necessary for the production of this substance, but would be otherwise unconnected with the fermentation properly so called.'

In harmony with this view, Liebig finds that the 'washings' of yeast (which contain no yeast-plant) have the property of instantly converting cane-sugar into grape-sugar; and he anticipates that other very alterable complex substances, besides products of the yeast-plant, will be found to possess the property of setting up that vibration which rearranges grape-sugar into alcohol and carbon dioxide, and is known as the process of alcoholic fermentation.

Pasteur has extended his researches on the action of ferments to the phenomena of putrefaction and decay (*Compt. rend.* lvi. 734, 1189; *Jahresb.* 1863, p. 579). Putrefaction he defines as a kind of fermentation which is induced and maintained by animal ferments of the genus *Vibrio* (the six species of which perhaps also act as peculiar ferments), and in contact with the air is always accompanied by decay or cremacausis. In a putrefying liquid containing air left to itself in closed vessels, infusoria (*Monas crepusculum* and *Bacterium termo*) are first developed, which absorb the oxygen of the air and replace it by carbon dioxide, after which they die, and collect as a precipitate at the bottom of the vessel. After this begins the development of vibrios, if the liquid contains their germs, and at the same time putrefaction is set up. If no such germs are present, or if the oxygen has not been completely absorbed, no putrefaction takes place (in the latter case because the vibrios can live only in an atmosphere free from oxygen). Under all circumstances, however, if the air is excluded, the products of the putrefaction undergo no further alteration. If the putrefiable liquid is freely exposed to the air, the oxygen-consuming infusoria are developed as in the former case, but in a continuous manner; their successive generations cover the surface of the liquid with a film which is continually renewed and completely prevents the access of oxygen to the interior of the liquid. The process then goes on as before, but the products of the putrefaction are completely resolved, under the influence of the superficial layer of infusoria, into water, carbon dioxide, and ammonia. The last phase is therefore a process of decay (in very thin layers of liquid it may take place alone), to which the products of putrefaction, as well as the dead infusoria and vibrios, are subject under the influence of the several species of *Bacteria* and *Mucor*. An example of the different results obtained accordingly as the air is admitted or excluded, is afforded by the putrefaction of calcium lactate, which, when the air is excluded, terminates with the formation of calcium butyrate and other

products, whereas if the air has access to the liquid, the butyrate likewise ultimately disappears. The putrefaction of solid substances (animal carcasses) begins in those parts (such as the surface of the body and the intestinal canal) where vibrios or their germs are present, the activity of the former having hitherto been checked by the normal nutrition of the organs. If no vibrios are present, or if their development is checked (as in a piece of meat wrapped in a cloth soaked in spirit, and placed in a close vessel), true putrefaction or decomposition by vibrios does not take place; but as the solid and liquid constituents of the meat nevertheless react upon each other in a certain way, a change takes place, which with small quantities is indicated by the peculiar odour of game; in larger quantities the phenomena of gangrene are developed. This latter change is regarded by Pasteur as essentially distinct from putrefaction, and as analogous to the ripening of fruits after separation from the plant on which they grow.

With regard to decay or *cremation*, Pasteur adduces a number of experiments which he regards as affording decisive proof that organic substances are not oxidised by perfectly pure air. Aqueous infusion of yeast mixed with sugar and heated to the boiling point was enclosed for three years in a sealed glass flask with twice its volume of previously ignited air, for part of the time at a temperature of 25°-30°. At the end of this time, the liquid was still transparent, and the air in the flask contained 18.1 vol. oxygen, 80.5 vol. nitrogen, and 1.4 carbon dioxide. Urine and milk, whether fresh or previously boiled, exhibited, when similarly treated and kept for the same time, only traces of oxidation; the urine had become somewhat darker and had deposited crystals of uric acid and phosphates; the milk was not curdled and still exhibited alkaline reaction. But when the same liquids were enclosed with air in its ordinary state, the whole of the oxygen of the air was absorbed in a few days, with simultaneous formation of variable quantities of carbon dioxide. Oak sawdust which had been boiled with a small quantity of water absorbed from perfectly pure air only a few cubic centimetres of oxygen in a month; whereas the same quantity moistened but not heated, and left in contact for fourteen days with ordinary air, absorbed nearly 140 c.c. oxygen. The sawdust in this latter case had become coated with a microscopic film of *Mycelia* and spores of *Mucilagineae*. These results are regarded by Pasteur as affording decisive proof that the decay or slow combustion of animal and vegetable substances depends essentially, like fermentation and putrefaction, on the influence of certain lower organisms (*Mucedineae*, *Monads*, *Bacterias*, and *Mucors*), without whose intervention dead organised matter would be almost indestructible.

J. Lemaire (*Compt. rend.* lvii. 958; *Jahresh.* 1863, p. 582) regards Pasteur's views on fermentation and putrefaction as inadmissible. According to his observations, the most various processes of fermentation may be induced by one and the same ferment, and special ferments have no existence, the development of one or another kind of ferment in a liquid depending on the chemical constitution and the neutral or acid reaction of that liquid; atmospheric dust may, however, exert an essential influence, as affording nutriment for infusoria. In a neutral organic liquid, the decomposition is always begun by animal organisms, the vegetable forms (*mycoderms*) not appearing till the liquid becomes acid. In acid solutions (fruit-juices) *mycoderms* are first developed, and subsequently, when the acid reaction has disappeared under their influence, infusoria are produced. Solutions containing only a few thousandths of an organic acid (acetic, tartaric, lactic, malic, &c.) quickly kill infusoria; moreover, carbon dioxide is not essential to the existence of these organisms, and vibrios especially cannot long exist in liquids containing carbonic acid, if excluded from access of oxygen. Infusoria and *mycoderms* are developed in meat according as it is immersed in pure water or in a solution containing organic acids. Lemaire also finds, contrary to Pasteur, that putrefaction does not take place when oxygen is excluded, and that gangrene is essentially the same process. He distinguishes in the process of putrefaction a stage of fetid odour (*période fétide*), in which he has observed 30 different species of infusoria, and a subsequent stage of purification (*période d'épuration*), in which these infusoria disappear, and in the light are replaced by green matter (*Euglene*, *Vorticella*, and species of *Protococcus*); this purification process may also take place in the dark, but in that case the green matter is not produced. From further experiments, Lemaire concludes that the unrestricted access of air is essential to the progress and completion of the process of putrefaction. Organic substances (flour and meat) kept in closed vessels with water and a small quantity of air at varying temperatures, exhibited a commencement of putrefaction, but this soon ceased, so that at the end of a year the substances were not found to be much altered. Similar results were obtained with juicy fruits kept in closed vessels

filled with air or with charcoal powder. The fruits, however, became uneatable (*Compt. rend.* lix. 696).

For an abstract of various researches on the supposed spontaneous generation of minute organisms, and the diffusion of their germs in the air, see *Jahresb.* 1864, p. 580; 1867, p. 743.

Acetous Fermentation.—See ACETIC ACID (p. 6).

Butyrous Fermentation.—The ferment to which this kind of fermentation is due is according to Pasteur (*Compt. rend.* lii. 344) an infusorium. The individuals are small cylindrical stems rounded at the ends, usually straight, and occurring singly or in chains of two, three, or more; their medium thickness is 0.002 mm.; the length of a single stem varies from 0.002 to 0.015 or 0.02 mm. They increase by division, may be sown like beer-yeast, and propagate in any medium adapted to their nutrition, even in a liquid containing only sugar, ammonia, and phosphates, and increase as the butyric fermentation progresses. It is remarkable that these infusoria live and multiply without requiring the smallest quantity of air or oxygen; air indeed kills them. Carbonic acid gas passed into the liquid does not interfere with their life or their reproduction; but on passing air through it for an hour or two, the whole of the animalcules sink to the bottom, and the butyric fermentation ceases altogether. Pasteur has also observed an infusorium which excites the fermentation of calcium tartrate, and, like the true butyric acid ferment, belongs to the vibrios, and is capable of growing without access of oxygen (*Compt. rend.* lvi. 416; *Jahresh.* 1863, p. 382).

In the conversion of calcium lactate into butyrate, carbon dioxide and hydrogen are not evolved in the proportion indicated by the equation $2C^3H^5O^3 = C^4H^7O^2 + 2CO^2 + 2H^2$ (ii. 631). The proportion of hydrogen is always smaller; but the ratio of the two gases varies both in one and the same, and in different fermentations; sometimes even pure carbon dioxide is evolved. Butylic alcohol is probably an ordinary product of the butyrous fermentation. The animalcules which induce this kind of fermentation can develop themselves without any other nutriment than a carbohydrate (such as lactic acid), ammonia, and phosphates (Pasteur, *Bull. Soc. Chim.* 1862, p. 52).

According to Béchamp (*Bull. Soc. Chim.* [2] vi. 484), the function of chalk in lactous and butyrous fermentation is not limited to the neutralisation of the resulting acid, but the chalk is itself capable of acting as a ferment. A mixture of starch-paste and powdered chalk with a few drops of creosote becomes liquid after a few days, soluble starch being formed, with traces of dextrin, and the liquid afterwards passing successively into alcoholic, lactous, and butyrous fermentation. A solution of cane-sugar treated in like manner undergoes the same succession of changes. Now pure precipitated calcium carbonate does not exhibit this reaction in the slightest degree when the air is carefully excluded, and the chalk itself loses the power of exciting fermentation if heated in the moist state to about 300°. Hence Béchamp attributes the action in question to a ferment existing in the chalk, and by microscopic examination he has actually discovered in it extremely small pointed corpuscles having a tremulous motion; these he regards as living organisms, and designates as *Microzyma cretae*. The chalk with which the above-mentioned experiments were made was taken from a block from the cretaceous formation of Sens. Tertiary fresh-water chalk from Pontil (Hérault) exhibited the same fermentative power. Béchamp is of opinion that the *Microzyma* is very widely diffused, especially in cultivated soils.

The vibratory corpuscles (pébrine) generated in the silkworm disease also act as a ferment, a solution of cane-sugar containing creosote being converted by prolonged contact with them, partly into inverted sugar, partly into alcohol, acetic acid, and a non-volatile acid, probably lactic acid. These vibratory corpuscles contain cellulose (Béchamp, *Compt. rend.* lxiv. 231; lxv. 42).

Gallous Fermentation.—According to Ph. van Tieghem (*Compt. rend.* lxx. 1091), tannic acid does not decompose either with or without access of air, unless the mycelium of a mucidinea is developed within it. The formation of gallic acid in a solution of tannic acid is especially promoted by the development of the spores of two fungi, *Penicillium glaucum* and *Aspergillus niger*, with simultaneous access of air. Under these circumstances, and when the fungus is developed in the interior of the solution, gallic acid is produced (together with small quantities of sugar), amounting in a few days to nearly the theoretical quantity. If, on the other hand, the fungus is developed on the surface as a thick fructifying layer, the tannic acid is completely oxidised, with formation of carbon dioxide, so that, after some days, the solution contains only small quantities of gallic acid and sugar. On the other hand, tannic acid remains quite unaltered, when its solution, freed from dissolved oxygen by exhaustion with the

air-pump, is left, either alone or in contact with a large quantity of the mycelium, in bottles filled with carbonic acid.

Influence of Antiseptic Substances on Fermentation and Putrefaction.—According to Béchamp (*Ann. Ch. Phys.* [4] vi. 248), a drop or two of creosote added to 100 c.c. of any liquid is sufficient to arrest the development of the spores of fungi and germs of infusoria, but without interfering with the action of ferments; to kill previously developed organisms, much larger quantities are required. Bucholz found that no fungi or infusoria could be detected in milk mixed with a small quantity of phenol; nevertheless the milk slowly turned sour: hence he infers that the [lactous] fermentation is due, not to the action of living organisms, but to a chemical ferment existing or simultaneously formed in the milk, and acted upon by the phenol less quickly than the organisms (*Jahresb.* 1867, p. 742). According to Nannyn (*ibid.* 1865, p. 606), benzol likewise interferes with the action of yeast on sugar solutions. Pienkowsky (*ibid.* 606) has examined the antiseptic action of a considerable number of salts and of a few acids. Raw meat (50 grms.) impregnated with 10 grms. of either of the following compounds, and left in a cellar for a month, neither underwent putrefaction nor became covered with infusoria or mycoderms: potassium, sodium, ammonium, barium, calcium, or lead acetate; sodium, ammonium, calcium, or stannic chloride; aniline nitrate; phenol; acetic acid; cupric chloride or sulphate; mercuric chloride; potassium dichromate; manganous chloride, zinc chloride, zinc sulphate, ferrous sulphate, potassium sulphite, and lead nitrate. After six months, however, superficial decomposition showed itself, accompanied by development of infusoria and mycoderms, excepting in the samples which were impregnated with the following eleven substances: ammonium acetate, barium acetate, calcium chloride, cupric chloride, mercuric chloride, cupric sulphate, lead acetate, aniline nitrate, phenol, acetic acid, and potassium dichromate. Meat soaked in solution of sodium acetate preserved its agreeable odour, was easily dried, and more easily desalinated than meat preserved with common salt. Sodium and potassium alum, aluminium sulphate, sodium phosphate, strontium and barium nitrates, ammonium and sodium oxalates, barium chloride, sodium sulphite and hyposulphite, ammonium nitrate, potassium chlorate, sodium, potassium, magnesium, and ammonium sulphates, manganous acetate, and arsenious acid, exerted no antiseptic action: meat impregnated with them passed into putrid decomposition, and became covered with fungi or infusoria, even in the course of a week (Pienkowsky). A solution of formic acid or a metallic formate may be kept for six months without exhibiting any development of mycoderms. But if the solution of a metallic formate likewise contains sugar, fungi quickly form in it, part of the formic acid at the same time disappearing. On the other hand, the presence of free formic acid, even to the amount of only 0.1 p. c., is a hindrance to the development of these organisms, whereas in solutions containing from 0.5 to 0.6 p. c. hydrochloric acid, fungi can grow, though not so quickly as in neutral liquids. Formic acid is in this respect a more powerful antiseptic for sugar solutions even than phenol; meat on the other hand keeps longer in water containing phenol than in water containing formic acid, and in the latter longer than in pure water. In water acidulated with formic acid, meat becomes covered with a thick layer of mycoderms (Jodin, *Compt. rend.* lxi. 1179).

According to Severi (*Med.-chem. Unters.* i. 257; *Zeitschr. f. Chem.* [2] iv. 286), alcoholic fermentation is not retarded by pepsin, either alone or in presence of free hydrochloric acid; but natural gastric juice in large quantity arrests the process, and in smaller quantity retards it, this action being exerted on the ferment, not on the fermentable substance. Lactous fermentation is neither arrested nor retarded by pepsin (either alone or with hydrochloric acid) or by natural gastric juice. Putrefactive fermentation, on the contrary, is arrested by natural gastric juice, although the animalcules which Pasteur regards as the exciting cause of this change continue to exist in full health and vigour.

On Fermentation in general, see also Williamson (*Chem. News*, xxii. 234, 247, 258, 268, 292, 304, 316; xxiii. 18, 27, 66, 90, 102, 114); Weinberg (*Bayerisches Industrie- und Gewerbeblatt*, August 1870; *Chem. News*, xxii. 263). On the Development of Fungi in Potable Water: Frankland (*ibid.* ix. 66). On the Carbonic and Alcoholic Fermentation of Sodium Acetate and Ammonium Oxalate: Béchamp (*Compt. rend.* July 4, 1870; *Chem. News*, xxii. 34).

FERREIRA. The resin of *Ferreira spectabilis*, a leguminous plant growing in Brazil, contains an alkalioid which has been examined by Gintl (*Zeitschr. f. Chem.* [2] v. 284), who regards it as a distinct body, and calls it *angeline* (the pharmaceutical name of the resin being *Resina d'angelim pedra*). The base appears however to be identical with ratanhine (v. 77).

FERROTANTALATES. See TANTALATES.

FERULIC ACID. $C^{10}H^{10}O^4$ (Hlasiwetz & Barth, *Ann. Ch. Pharm.* cxxviii, 61; *Jahresb.* 1866, p. 627).—An acid existing in *asafoetida*, and obtained by precipitating the alcoholic tincture of the resin with an alcoholic solution of neutral lead acetate; freeing the light yellow precipitate as completely as possible from adhering resin by repeated washing with alcohol, and pressure; and decomposing it, suspended in water, with dilute sulphuric acid. The filtered liquid duly concentrated, yields crystals of crude ferulic acid, which when purified by recrystallisation from alcohol, and then from boiling water, form long colourless four-sided needles belonging to the rhombic system. Ferulic acid is tasteless; has an acid reaction; dissolves easily in cold alcohol, not very readily in ether; is nearly insoluble in cold, but very soluble in boiling water; dissolves very easily and with yellow colour in alkalis. The aqueous solution is precipitated by lead acetate and ferric chloride; the ammoniacal solution forms with silver nitrate an egg-yellow precipitate, quickly becoming darker when exposed to light. Strong sulphuric acid dissolves the crystals with yellow, or when warm with brownish-red colour, and the solution exhibits a green fluorescence, which disappears on dilution with water. The acid melts at 153° – 154° , and solidifies in the crystalline form.

Ferulic acid is related to eugenic acid, $C^{10}H^{12}O^2$, in the same manner as oxalic acid to acetic acid, and, like eugenic acid, is resolved by fusion with potash into protocatechuic acid, acetic acid, and carbon dioxide, together with a small quantity of oxalic acid:

The acetic acid may be supposed to arise in the first case as a secondary product from malonic acid, and in the second from propionic acid.

Ferulic acid is monobasic. Its *ammonium salt*, $C^{10}H^{10}O^4(NH^4) + H^2O$, is obtained by spontaneous evaporation in laminar crystals, which give off part of their ammonia at 100° . The *potassium salt* $C^{10}H^9O^4K$ is straw-yellow, deliquescent, and sparingly soluble in alcohol. The *silver salt* $C^{10}H^9O^4Ag$ is a lemon-coloured precipitate, sometimes turning grey.

FEUILLEA. The seeds of *Feuillea cordifolia*, a Brazilian climbing plant, contain in 4,000 pts.: 1301.5 pts. of a drying fatty oil, 95.5 feullin, a brownish, uncrystallisable, bitter substance precipitable by basic lead acetate and tannin, 2.1 of a substance crystallising in colourless plates, 57.0 crystallisable fatty acid, 62.0 red resin, 20.4 brown resin, 22.1 gummy substance and iron-greening tannin, and 10.7 glucose (Pekolt, *Arch. Pharm.* [2] cix. 212).

FIBRIN. See PROTEIDS.**FIBROÏN.** See SILK.

FILICIC ACID. This acid, discovered by Luck in the root of *Aspidium Filix mas* (ii. 646), has, according to Grabowski (*Ann. Ch.-Pharm.* cxliiii. 279), the composition $C^{14}H^{18}O^4$. When heated with 4 pts. potassium hydrate and a little water till the mass begins to melt and turn red-brown, it yields as chief products butyric acid and phloroglucin. If, on the other hand, the solution of the acid in strong caustic potash be evaporated only till it becomes pasty, and the mass be then supersaturated with sulphuric acid and treated with ether, the ethereal solution is found to contain, together with phloroglucin, another crystallisable, slightly soluble substance, $C^{10}H^{12}O^4$, which may be regarded as monobutryl-phloroglucin, $C^4H^3(C^6H^7O)O^3$. Filicic acid has therefore the composition of dibutryl-phloroglucin, and its decomposition by potash may be represented by the equation

Phloroglucin treated with butyryl chloride yields, however, not filicic acid, but an oily substance which crystallises only after long standing, is insoluble in water and in alkalis, but soluble in alcohol and ether (Grabowski).

FILITANNIC ACID and **FILIX-RED** (G. Malin, *Ann. Ch. Pharm.* cxliiii. 276).—The aqueous decoction of the root of *Aspidium Filix mas* yields to ether a small quantity of brown greasy resin, and then forms with neutral and basic lead acetate, precipitates containing filitannic acid, which, when separated by decomposing

the washed precipitates with hydrogen sulphide, and evaporating the filtrate, forms a brownish extract, purifiable by partial precipitation with neutral lead acetate and decomposition of the lighter portion of the precipitate. It is very much like cinchonatic acid; hygroscopic; forms a somewhat turbid solution; is sparingly dissolved by strong alcohol, more freely by ordinary spirit; forms with ferric chloride an olive-green solution, turning violet on addition of sodium carbonate; reduces alkaline cupric solutions; and is precipitated by gelatin. On boiling it with dilute sulphuric acid, dark brick-red flocks of filix-red, $C^7H^{10}O^{12}$, are deposited, whilst an uncrystallisable sugar, $C^6H^{12}O^4$, remains in solution. Filix-red, perhaps identical with Luck's tannaspic acid, is resolved by oxidation with potassium hydrate into protocatechuic acid and phloroglucin.

FILTRATION. Bunsen has contrived a method of filtering under pressure, by which the time occupied in washing precipitates, and the quantity of water required for the purpose, are very greatly reduced. The neck of the funnel containing the filter is passed through the caoutchouc stopper of a wide-mouthed flask of thick glass, and through the same stopper there also passes a bent tube connected with a glass water-pump constructed on the principle of Sprengel's mercury-pump; any other exhausting apparatus might, however, be used. By this means a partial vacuum is made within the flask, and the pressure of the external air on the water in the funnel forces it rapidly through the filter. To prevent the paper filter from being broken by the pressure, it is placed within a funnel of thin platinum foil, made to fit exactly the inside of the glass funnel. A filter thus supported will bear the pressure of an atmosphere without tearing. For filtering liquids which contain corroding gases or vapours, a cylindrical tube having a conical lower termination is used instead of the funnel, a disc of artificial pumice (such as is used for polishing), 1 or 2 mm. thick, being placed in the conical neck and fixed water-tight by means of long-fibred flexible asbestos. For details and figures of the apparatus, see the original memoir (*Ann. Ch. Pharm.* cxlviii. 269; also *Zeitschr. f. Chem.* [2] v. 118; *Chemical News*, 1869, xxi. 128).

FLAME. See COMBUSTION.

FLUORHYDRIC ACID, HYDROFLUORIC ACID, or HYDROGEN FLUORIDE. This acid, both in the anhydrous state and in aqueous solution, has recently been submitted to very careful examination by G. Gore (*Phil. Trans.* 1889, p. 173; *Chem. Soc. J.* [2] vii. 368; abstr. *Proc. Roy. Soc.* xvii. 256; *Chem. News*, 1869, p. 74).

The anhydrous acid, HF, was prepared by heating dry hydrogen-potassium fluoride to redness in a suitable platinum apparatus. It is a highly dangerous substance, requiring the most extreme care in its manipulation. At ordinary temperatures it is a perfectly colourless, transparent, mobile liquid, and has a sp. gr. of 0.9879 at 12.8°. It is extremely volatile, boils at 19.4°, fumes densely at ordinary temperatures, and greedily absorbs water from the air. Its vapour-tension at 15° is equal to about 7.58 pounds per square inch. On loosening the lid of a bottle containing it at that temperature, the acid vapour is expelled in a jet like steam from a boiler; it may however be perfectly retained in a platinum bottle having a flanged mouth, with a platinum plate secured by clamp-screws and a washer of paraffin. It does not solidify at 34.5°. The gaseous acid does not attack glass, even when left in contact with it for weeks, provided all moisture be excluded. The acid prepared as above was inferred to be free from oxygen: (1) because the double fluoride from which it was prepared, when fused and electrolysed with platinum poles, evolved abundance of inflammable gas at the negative pole, but no gas at the positive pole, although oxides are decomposed by electrolysis before fluorides; (2) because in the electrolysis of the acid with platinum poles, no odour of ozone was evolved, whereas the aqueous acid of various strengths evolves this odour very strongly where electrolysed; and (3) because the acid obtained by heating pure silver fluoride in dry hydrogen exhibited the same properties as that prepared from the hypopotassic fluoride.

Careful determinations of the molecular volume of the acid prepared by heating silver fluoride in hydrogen showed that it is analogous in constitution to hydrochloric acid, not to water, the results indicating that one volume of hydrogen in uniting with fluorine produces two volumes of gas, just as it does in uniting with chlorine.

Numerous experiments were made to electrolyse the anhydrous acid with positive poles of gas-carbon, charcoal of lignum vitæ, and many other kinds of wood, also of palladium, platinum, and gold. The gas-carbon disintegrated rapidly; all the kinds of charcoal flew to pieces quickly; the palladium, gold, and platinum poles were corroded without evolution of gas. With platinum as the positive pole, the acid

conducted much more readily than pure water; but with gold it conducted scarcely at all.

Anhydrous hydrofluoric acid scarcely exerts any action on the metalloids or the noble metals, and even the other metals in the finely divided state do not eliminate hydrogen from it at temperatures between 0° and 20° . Potassium and sodium react with it as with water. With strong hydrochloric acid it produces an active effervescence. Basic oxides unite readily with it, some of them dissolving; on peroxides it has no effect. Some nitrates are not attacked by it, while others (lead, barium, potassium) are decomposed. Fluorides for the most part remain unaltered, but those of the alkali-metals and thallium produce various degrees of chemical action, those of ammonium, potassium, and rubidium uniting powerfully with the acid. Numerous chlorides were also unaffected, but the pentachlorides of phosphorus and antimony, titanous chloride, and the chlorides of the alkali-metals and alkaline-earth-metals, were decomposed with strong action, and generally with effervescence. The chlorates of potassium and sodium were also decomposed, with evolution of chloric acid. The bromides of the alkaline-earth and alkali metals behaved like the chlorides. Potassium bromate rapidly evolved bromine. Numerous iodides remained unaffected, but those of the alkaline-earth and alkali metals were strongly decomposed, in some cases with liberation of iodine. The anhydrous acid decomposes all carbonates with effervescence, and those of the alkaline-earth and alkali metals with violent action. Alkaline borates also produce very violent action. Silico-fluorides of alkali-metal dissolve with effervescence. Sulphides remain unchanged, except those of the alkaline-earth and alkali metals, which rapidly eliminate hydrogen sulphide. Acid sodium sulphite dissolves with effervescence. Sulphates are variously affected. The acid chromates of the alkali-metals dissolve, with violent action, to blood-red liquids, with evolution of chromium fluoride. Potassium cyanide is violently decomposed, with evolution of hydrogen cyanide. Solid organic bodies immersed in the acid are for the most part quickly disintegrated. Gutta-serena, caoutchouc, and numerous gums and resins dissolve to red liquids. Gun-cotton, silk, paper, cotton-wool, calico, gelatin, and parchment are instantly converted into glutinous substances and generally dissolved. Pine-wood is instantly blackened. Sponge is but little changed. The anhydrous acid mixes with wood-spirit, alcohol, ether, but not with benzol; with oil of turpentine it explodes, forming a blood-red liquid.

Aqueous Hydrofluoric Acid.—The commercial aqueous acid is often very impure; but a pure acid may be prepared from it by passing an excess of hydrogen sulphide through the liquid, neutralising the sulphuric and silico-fluoric acids present with potassium carbonate, decanting from the resulting precipitate, removing the excess of hydrogen sulphide with silver carbonate, filtering, distilling the filtrate from a leaden retort connected with a platinum condenser, and finally rectifying.

A very small quantity of hydrofluoric acid lowers the freezing point of water very considerably. When the aqueous acid was electrolysed with platinum for the positive pole, ozone was evolved, and with acid of 30 p. c. (not with that of 10 p. c.) the platinum was attacked.

The chemico-electric series of metals, &c., in acid of 30 p. c. is as follows: zinc, magnesium, aluminium, thallium, indium, cadmium, tin, lead, silicon, iron, nickel, cobalt, antimony, bismuth, mercury, silver, copper; arsenic, osmium, ruthenium, gas-carbon, platinum, rhodium, palladium, tellurium, osmiridium, gold, iridium.

FLUORINE. According to Prat (*Compt. rend.* Lxiv. 345, 511; *Jahresb.* 1867, p. 175), the ordinary metallic fluorides are oxyfluorides, fluor-spar, for example, having the composition CaFIO (the atomic weight of fluorine being 29.6); and by heating an ordinary fluoride (oxyfluoride) with potassium chlorate or perchlorate, a mixture of oxygen and fluorine is evolved, from which the fluorine may be removed by metallic silver. By passing the same gaseous mixture over heated baryta, the oxygen is said to be absorbed and pure fluorine left. Fluorine thus obtained is described by Prat as a gas heavier than air, nearly colourless, fuming in the air, and smelling like chlorine; combining in diffused daylight with hydrogen, decomposing water, hydrochloric acid, bromides, and iodides at ordinary temperatures, bleaching indigo and litmus, uniting with bromine, silicon, and most metals. By mixing dilute aqueous hydrofluoric acid with aqueous hypochlorous acid, Prat obtained a gas which he regarded as a compound of chlorine and fluorine; it was darker than chlorine, and formed with silver a mixture of silver chloride and fluoride.

P. Cillis, however, in repeating Prat's experiments, finds that a mixture of calcium fluoride and potassium chlorate yields by ignition nothing but pure oxygen, which exerts no action on metallic silver, and that this oxygen is derived solely from the chlorate, the fluor-spar remaining unaltered, and the residue after washing with

water exhibiting exactly the weight of the original fluoride. Hence he concludes that Prat's statements are erroneous, and that his supposed fluorine has no existence (*Zeitschr. f. Chem.* [2] iv. 660).

Estimation of Fluorine.—Fresenius has described a modification of Wohler's method of estimating fluorine, by the quantity of silicon fluoride evolved on heating a fluoride with sulphuric acid and silica, which consists in determining the quantity of silicon thus evolved by the increase in weight of an absorption apparatus containing, in different parts, pumice moistened with water, soda-lime, and fused calcium chloride (*Zeitschr. anal. Chem.* v. 190; *Jahresb.* 1866, p. 1791).

For Kobell and Zalesky's methods of estimating fluorine in phosphates by the quantity of silica which it can remove from glass when evolved in contact therewith, see *Bull. Soc. Chim.* [2] iii. 70; *Zeitschr. anal. Chem.* v. 205; *Jahresb.* 1864, p. 696; 1866, p. 792).

FORMAMIDE, $\text{CH}_3\text{NO} = \begin{matrix} \text{CHO} \\ | \\ \text{H}^2 \end{matrix} \text{N}$, first obtained by Hofmann (ii. 681) by

heating ethyl formate with dry ammonia, is likewise produced: α . By heating a dry mixture of 2 pts. dry ammonium formate and 1 pt. urea to 140° , as long as ammonium carbonate is given off (Berend, *Ann. Ch. Pharm.* cxxviii. 355).— β . By heating ammonium formate by itself to between 160° and 200° , and leaving the distillate over sulphuric acid, till its weight becomes nearly permanent; formamide then remains as a colourless liquid. A solution of ammonium formate in 4 or 5 pts. water also yields a small quantity of formamide when distilled (Lorin, *Compt. rend.* lix. 51).— γ . By heating a mixture of 1 mol. sodium formate and 1 mol. sal-ammoniac, carbon monoxide being then also evolved. If calcium formate be substituted for the sodium salt, a higher temperature is required, less formamide is produced, and the gas evolved contains 2 vol. carbon monoxide to 3 vol. hydrogen, with small quantities of hydrocarbons, hydrocyanic acid, and ammonium carbonate (Lorin, *ibid.* 788).

Formamide mixes with ether containing alcohol, but not with pure ether. With sodium it decomposes, producing explosion and ignition. Heated with zinc-sodium or sodium-amalgam, it emits the odour of methylamine, and yields a residue containing cyanides; with zinc-sodium in the cold, only ammonia is given off, and the residue does not contain cyanides. Strong potash solution eliminates ammonia from it at ordinary temperatures. With alcohol and hydrochloric acid, it yields sal-ammoniac and ethyl-formate.

Methyl-formamide. $\text{C}^2\text{H}^5\text{NO} = (\text{CHO}.\text{CH}^3.\text{H})\text{N}$ (Linnemann, *Wien. Akad. Ber.* lx. 44; *Chem. Centr.* 1870, 138).—This compound, isomeric with acetamide, is produced by evaporating the aqueous solution of methylamine formate to a syrup, distilling, evaporating the aqueous distillate on the water-bath, and redistilling with potassium carbonate, which does not decompose this amide or its homologues. It is a thickish, scentless liquid, of sp. gr. 1.011 at 190° , boiling at 190° (under a pressure of 0.14 met.), burning with a faintly violet-edged flame, soluble in all proportions of water and alcohol, insoluble in ether; resolved by boiling with strong aqueous potash into methylamine and formic acid, and by boiling with dilute sulphuric acid into carbon monoxide and methylamine: $(\text{CHO}.\text{CH}^3.\text{H})\text{N} = \text{CO} + \text{CH}^3.\text{H}^2.\text{N}$. This last decomposition is also produced by phosphoric anhydride at ordinary temperatures, hydrocyanic acid being also found amongst the volatile products.

Ethyl-formamide. $(\text{CHO}.\text{C}^2\text{H}^5.\text{H})\text{N}$.—Prepared like the preceding. Colourless, thickish, nearly scentless liquid, burning with a bright flame. Sp. gr. 0.952 at 21° . Boils at 196° – 197° . Soluble in all proportions of water, alcohol, and ether; easily separated from aqueous solution by potassium carbonate. At -30° it becomes thicker, but does not solidify. By prolonged boiling it is for the most part resolved into carbon monoxide and ethylamine. By strong potash-solution it is resolved slowly in the cold, quickly at the boiling heat, into ethylamine and formic acid; similarly by sodium-amalgam. Phosphoric anhydride acts upon it in the same way as on methyl-formamide. Fused and pulverised zinc chloride decomposes it at incipient boiling heat into carbon monoxide, ethylene, and ammonia (Linnemann, *loc. cit.*).

Diethyl-formamide, $\text{CHO}.\text{(C}^2\text{H}^5)^2.\text{N}$, is prepared by heating a mixture of diethylamine and formic acid. Colourless, scentless, thickish liquid, of sp. gr. 0.908 at 19° , not solidifying at -20° , boiling at 175° – 178° , easily soluble in alcohol, ether, and water; separated from aqueous solution by potassium carbonate, as a light layer of liquid (Linnemann, *loc. cit.*).

FORMENE. Syn. with METHANE.

FORMIC ACID. $\text{CH}^2\text{O}^2 = \text{H}—\text{COOH}$.—Produced, according to Maly (*Jahresb.* 1865, p. 297), by the action of sodium-amalgam on aqueous ammonium carbonate;

also, though in smaller quantity, by boiling finely granulated zinc and zinc carbonate with potash-ley. It is likewise formed by exposing carbon bisulphide to sunshine in sealed tubes containing a little water (Loew, *Zeitschr. f. Chem.* [2] iv. 622):

Thirdly, it is formed, together with aldehyde, by boiling ordinary lactic acid for several hours with dilute sulphuric acid, the reaction appearing to take place by two stages, and ethylidene dihydrate, $\text{CH}^3 \cdot \text{CH}(\text{OH})^2$, isomeric with glycol, being formed as an intermediate product; thus:

(Erlonmeyer, *Zeitschr. f. Chem.* [2] iv. 343).

Preparation.—Lorin (*Bull. Soc. Chim.* [2] v. 7, 12) obtains aqueous formic acid of 75 p. c. by distilling dehydrated oxalic acid with glycerin; the decomposition begins below 50° , and the temperature must be carefully regulated, on account of the frothing which takes place.

Crystallisable formic acid is more easily obtained from the copper salt than from the lead salt by decomposition with hydrogen sulphide. A better method of preparing it is however to dissolve dehydrated oxalic acid at a gentle heat in aqueous formic acid of 70 p. c., decant the liquid when cold from the crystallised oxalic acid, and distil the portion which remains liquid. The nearly anhydrous distillate when well cooled deposits crystallisable formic acid. Cupric formate heated by itself yields formic acid of 87 p. c. When formic acid of about 57 p. c. is left over concentrated sulphuric acid, there ultimately remains an acid of 63 p. c., corresponding in composition with the hydrate $2\text{CH}_2\text{O}^2 \cdot 3\text{H}_2\text{O}$ (Lorin).

Decompositions.—A mixture of formic acid, CH_2O^2 , with an equal volume of water, electrolysed with a battery of moderate power (4 Bunsen's elements), gives off at the positive pole a mixture of carbon dioxide and oxygen; so likewise does a solution of 37 pts. sodium formate in 63 pts. water; potassium formate mixed with potash gives off only carbon dioxide (Burgoin, *Ann. Ch. Phys.* [4] xiv. 157). By chromic acid, formic acid is completely oxidised to water and carbon dioxide (Chapman, *Chem. Soc. J.* [2] v. 289); also by potassium permanganate, either in alkaline or in acid solution (Berthelot, *Jahresh.* 1867, p. 335). With strong aqueous hydriodic acid, it yields water and carbon monoxide. Methyl-formate similarly treated is converted into carbon monoxide, water, and methane (Berthelot, *ibid.* p. 345).

On the antiseptic properties of formic acid, see p. 615.

Metallic Formates. *Iron Formates.*—*Ferrous formate*, $(\text{CHO}^2)^2\text{Fe} + 4\text{H}_2\text{O}$, forms green crystals only slightly soluble in cold water, more easily in formic acid, insoluble in alcohol. *Ferric formate*, $(\text{CHO}^2)^3\text{Fe}^2 + \text{H}_2\text{O}$, is deposited from a solution of recently precipitated ferric hydrate in formic acid, in yellow shining crystals, easily soluble in hot water; when ignited it leaves ferric oxide still in the form of the crystals. The neutral ferrous salt, when exposed to the air, deposits ferric hydrate, while a more or less basic ferric formate remains dissolved. On boiling the solution of the ferrous salt in an open vessel, a basic ferric salt is deposited, containing $(\text{Fe}^3)^n \left\{ \begin{smallmatrix} \text{CHO}^2 \\ (\text{OH})^n \end{smallmatrix} \right\}$

Ferric triformonitrate, $\text{Fe}^3 \left\{ \begin{smallmatrix} (\text{CHO}^2)^3 \\ \text{NO}^3 \\ (\text{HO})^3 \end{smallmatrix} \right\} + 3\text{H}_2\text{O}$, is deposited, on evaporating in a

vacuum a solution of ferrous formate oxidised by nitric acid, in red, iridescent, very easily decomposable crystals, while the mother-liquor retains neutral ferric formate *Ferric dichlorotetraformate*, $\text{Fe}^3(\text{CHO}^2)^4\text{Cl}^2 + 3\text{H}_2\text{O}$, separates gradually from a solution of ferrous chloride in formic acid oxidised by nitric acid in reddish-yellow nodules

slightly soluble in alcohol. *Ferric diformodiacetonitrile*, $\text{Fe} \left\{ \begin{array}{c} (\text{CHO})^2 \\ (\text{C}^2\text{H}^2\text{O})^2 \\ \text{NO}^2 \\ \text{HO} \end{array} \right\} + 5\text{H}^2\text{O}$, is

formed by oxidising a mixture of equivalent quantities of ferrous formate and acetate with nitric acid, and separates from the solution, by evaporation over sulphuric acid, as a red, crystalline, very deliquescent mass which gradually loses 3 mol. water (Scheurer-Kästner, *Ann. Ch. Phys.* [3] lxxviii. 472).

Lead Formates (Barfoed, *J. pr. Chem.* cviii. 1; *Chem. Centr.* 1870, 171).—Normal lead formate, $(\text{CHO})^2\text{Pb}$, is usually said to dissolve in 36 pts. of cold and 5.5 pts. of boiling water.

Basic salts.—The *biplumbic* salt $(\text{CHO})^2\text{Pb} \cdot \text{PbO}$ or $2\text{PbO} \cdot \text{C}^2\text{H}^2\text{O}^2$ is produced by briskly agitating a solution of the normal salt saturated at ordinary temperatures with an equivalent quantity of finely pulverised lead oxide, or by treating a boiling solution of the normal salt, three or four times as strong, with lead oxide, heating the liquid to 100° in a closed flask till it becomes quite clear, and leaving it to cool slowly. It then separates in colourless, transparent, shining, heavy, needle-shaped crystals, somewhat more soluble in cold water, and somewhat less soluble in hot water than the normal salt; distinguished, moreover, from the latter by the property that its solution is strongly alkaline and gives a copious precipitate with carbonic acid. Soluble in 58.7 pts. of cold and 10 pts. of boiling water; insoluble in alcohol; the aqueous solution is completely precipitated in 12 to 24 hours, when mixed with about six times its volume of alcohol. Biplumbic formate is likewise precipitated on mixing a solution of 2 eq. of the normal salt with 1 eq. of alkali. Its aqueous solution added to a warm solution of sodium sulphate in excess forms a crystalline precipitate of biplumbic sulphate, $\text{SO} \cdot \text{Pb} \cdot \text{PbO}$.

Triplumbic Formate, $(\text{CHO})^2\text{Pb} \cdot 2\text{PbO}$ or $3\text{PbO} \cdot \text{C}^2\text{H}^2\text{O}^2$, produced by boiling a solution of the normal salt with 2 mol. lead oxide, or by mixing the solution of the normal salt with $\frac{2}{3}$ mol. soda, or with rather more than $\frac{2}{3}$ mol. ammonia, forms colourless, silky, slender, needle-shaped crystals, having a silky lustre, and a beautiful zeolitic aspect while immersed in the liquid, but falling to pieces when it is poured off. Soluble in 25.5 pts. cold and 7.5 pts. boiling water, forming a strongly alkaline solution which gives a copious precipitate with carbonic acid. By prolonged boiling it loses formic acid, as do likewise the solutions of the preceding salts.

Quadriplumbic Formate, $(\text{CHO})^2\text{Pb} \cdot 3\text{PbO}$ or $4\text{PbO} \cdot \text{C}^2\text{H}^2\text{O}^2$, is produced by boiling a strong solution of the tribasic salt with a large quantity of lead oxide, or by digesting a solution of the same salt saturated at ordinary temperatures with lead oxide at 100° for a week. It is thus obtained as a bulky, dirty yellow precipitate, appearing under the microscope as a mixture of slender needles and unaltered lead oxide. Soluble in about 90 pts. of cold water; insoluble in alcohol (Barfoed).

Alcoholic Formates. Formic Ethers.—These ethers are easily prepared in considerable quantity by distilling equivalent quantities of oxalic acid and the corresponding alcohols with dehydrated glycerin. The vapours are allowed for some time to fall back into the retort, the ether not being distilled off till the oxalic acid is completely decomposed: 500 grms. amyl alcohol thus treated yield an equal weight of amyl formate (Lorin, *Bull. Soc. Chim.* [2] v. 7, 12).

Allyl Formate, $\text{C}^3\text{H}^5\text{O}^2 = \text{CHO}^2 \cdot \text{C}^2\text{H}^3$, is obtained as a secondary product, in the preparation of formic acid by distilling oxalic acid with glycerin. On rectifying the crude product, this ether passes over first, and floats as an oil on the first portions of the distillate. When purified by washing with water and sodium carbonate, and dried with calcium chloride, it forms a light yellow ethereal liquid having an extremely irritating odour, like allyl compounds in general, boiling at 82° – 83° , and having a sp. gr. of 0.9322 at 17.5° . Caustic potash resolves it into allyl alcohol and formic acid. The mode of its formation in the process just mentioned is not yet understood: perhaps a glyceryl formate is produced in the first instance, and afterwards decomposed as the temperature rises (Tollens, *Zeitschr. f. Chem.* [2] ii. 518; Tollens & Weber, *ibid.* iv. 441).

Ethyl Formate, $\text{C}^2\text{H}^5\text{O}^2 = \text{CHO}^2 \cdot \text{C}^2\text{H}^5$.—Löwig & Weidmann observed that this ether when treated with sodium gives off pure carbon monoxide, without admixture of hydrogen, and likewise yields sodium ethylate, alcohol, and sodium formate. According to Wanklyn (*Zeitschr. f. Chem.* [2] iv. 674), the reaction is in the first instance analogous to that which takes place with ethyl acetate, yielding sodium-triformyl and sodium ethylate:

the sodium triformyl being then resolved into sodium methylate and carbon monoxide:
 $(\text{CHO})^3\text{Na} = 3\text{CO} + \text{CH}^3\text{NaO}.$

The greater part of the carbon monoxide however is due to the decomposition of the excess of ethyl-formate under the influence of the sodium ethylate, the products being carbon monoxide and alcohol: $\text{C}^2\text{H}^4\text{O}^2 = \text{CO} + \text{C}^2\text{H}^4\text{O}.$ Direct experiments by Geuther (*Zeitschr. f. Chem.* [2] iv. 655) have indeed shown that ethyl formate is decomposed in this manner when heated in sealed tubes with sodium ethylate, the latter remaining unchanged.

Ethyl Orthoformate. $\text{C}^2\text{H}^4\text{O}^3 = (\text{CH})^3(\text{OC}^2\text{H}^3)^3.$ —This ether, discovered by Williamson a. Kay (*Proc. Roy. Soc.* vii. 135), is produced by the action of chloroform on sodium ethylate, or by heating chloroform with a solution of potash in absolute alcohol:

Ladenburg a. Wichelhaus (*Bull. Soc. Chim.* [2] ix. 356) prepare it by dropping a mixture of absolute alcohol and chloroform on sodium (1 mol. chloroform to 3 at. sodium), under a layer of ether. A brisk reaction takes place at first, after which the mixture is distilled, first over a water-bath, then over an oil-bath, and the portion which distills above 110° is washed, dried, and rectified: 170 grms. sodium treated in this manner with about 300 grms. chloroform and 350 grms. absolute alcohol yielded 50 grms. ethyl orthoformate.

Ethyl orthoformate is a colourless, aromatic, easily inflammable liquid having a sp. gr. of 0.8694, remaining liquid at -18° , and boiling at 145° – 146° (Kay), at 146° – 148° (Ladenburg a. Wichelhaus). Bromine decomposes it at ordinary temperatures, yielding ethyl bromide, ethyl carbonate, ordinary ethyl formate, and alcohol (L. a. W.):

Heated in sealed tubes with aqueous ammonia or ethylamine, it yields crystals of ammonium or ethylammonium formate. With perfectly anhydrous alcoholic ammonia a base is obtained which yields a well-crystallised platinum salt. With aniline it yields methenyl-diphenyl-diamine, $(\text{CH})^3(\text{C}^6\text{H}^5)^2\text{HN}^2$ (Wichelhaus, *Zeitschr. f. Chem.* [2] v. 284).

The relation between orthoformic ether and ordinary formic ether may be represented by the following formulæ:

FORMIC ALDEHYDE. $\text{CH}^2\text{O} = \text{H}.\text{COH}.$ *Methylic Aldehyde* (Hofmann, *Proc. Roy. Soc.* xvi. 156).—This compound, which may also be regarded as the ketone of formic acid, is produced when a current of air charged with vapour of methyl alcohol is passed over a glowing spiral of platinum wire. A three-necked bottle having a capacity of 2 litres is filled to about 2 centim. with gently warmed methyl alcohol. Through one of the necks passes a tube reaching to the surface of the liquid; the second is fitted with a cork carrying a spiral of platinum wire, also reaching to the surface of the liquid; and the third is connected with a Liebig's condenser, the lower extremity of which is fitted into a two-necked receiver. The second tubulus of this receiver is connected with a series of wash-bottles, the last of which is connected with an aspirator. The apparatus being thus prepared, the platinum spiral is heated to whiteness and introduced into the three-necked bottle. In a few seconds the slow combustion of the methyl alcohol is made evident by the irritating odour emitted, the whole apparatus at the same time becoming heated, and drops of liquid collecting in the receiver. The apparatus is now in good working order, and if the stream of air be properly regulated, the platinum wire may be kept glowing uninterruptedly for hours, or even days.

The liquid which collects in the receiver is a solution of formic aldehyde in methyl alcohol. When rendered slightly alkaline by ammonia and gently warmed with silver nitrate, it yields a beautiful specular deposit of silver, with greater ease even than common acetic aldehyde. The same solution heated with a few drops of caustic potash, deposits drops of a brownish oil having the odour of the resin of acetic aldehyde.

Formic aldehyde has not yet been obtained in the pure state; but on treating its solution with hydrogen sulphide, and heating the resulting liquid with strong hydrochloric acid, it solidifies on cooling to a dazzling white mass of felted needles, consisting of the corresponding sulphur-compound $\text{CH}^2\text{S}.$

According to E. Mulder (*Zeitschr. f. Chem.* [2] iv. 265), formic aldehyde is also produced by the dry distillation of calcium formate. Formic sulphaldehyde is one of

the products of the action of nascent hydrogen on sulphocyanic acid: $\text{SCNH} + 2\text{H}^+ = \text{NH}^+ + \text{CH}_3\text{S}$ (Hofmann, *Zeitschr. f. Chem.* [2] iv. 689).

FORMOBENZOIC ACID. Syn. with MANDELIC ACID (iii. 799).

FRANGULIC ACID and **FRANGULIN.** Frangulin, the yellow colouring matter of the bark of the berry-bearing alder (*Rhamnus Frangula*), has lately been examined by A. Faust (*Zeitschr. f. Chem.* [2] v. 17), who finds that in the pure state, as prepared by Casselmann's process (ii. 706), it has the composition $\text{C}^{20}\text{H}^{20}\text{O}^{10}$, and that it is a glucoside, being resolved by acids into sugar and frangulic acid:

Frangulic acid, $\text{C}^6\text{H}^{10}\text{O}^5 + \text{H}^2\text{O}$, may also be prepared directly from the bark by boiling it with water containing soda instead of ammonia, as in the preparation of frangulin. It is an orange-yellow, loosely coherent, crystalline mass, appearing under the microscope to be composed of long prisms. It melts between 246° and 248° , and gives off its water of crystallisation at 120° ; dissolves slightly in water, chloroform, and benzol, easily in alcohol and ethers. Alkalis dissolve it, forming solutions of a fine red colour, from which acids precipitate it unaltered. From its slightly ammoniacal solution, it is precipitated by alkaline earths and by many metallic salts. It dissolves in fuming nitric acid, and the solution when diluted and evaporated, leaves a red mass, probably identical with the nitrofrangulic acid which Casselmann obtained, together with oxalic acid, by the action of fuming nitric acid upon frangulin. *Dibromo-frangulic acid*, $\text{C}^6\text{H}^8\text{Br}^2\text{O}^5$, is precipitated on mixing an alcoholic solution of frangulic acid with excess of bromine. It is a light-red crystalline mass composed of short slender microscopic needles, sparingly soluble in cold alcohol.

Difrangulic acid, $\text{C}^{12}\text{H}^{16}\text{O}^9 = 2(\text{C}^6\text{H}^{10}\text{O}^5) - \text{H}^2\text{O}$, is formed in small quantity in the preparation of frangulic acid from the bark of *Rhamnus Frangula* by boiling with water containing soda, and may be separated from the lead precipitates obtained in the course of the preparation. It is very much like frangulic acid, but has a darker colour; crystallises with 2 mol. water, which are given off at 120° ; melts at 248° – 250° , that is to say nearly at the same temperature as frangulic acid. This coincidence of melting point appears to be due to the circumstance that frangulic acid, at or a little below its melting point, gives off water and is converted into difrangulic acid.

FRANKLINITE. From an analysis by v. Kobell (*Jahresb.* 1866, p. 922), and a new analysis by Rammelsberg (*ibid.* 1867, p. 979), this mineral appears to have the general formula of the spinels, $\text{MO} \cdot \text{M}^2\text{O}^3$. The mean of Rammelsberg's analyses gave 66.05 p. c. Fe^2O^3 , 12.23 Mn^2O^3 , and 21.88 ZnO , agreeing with the formula $(\frac{2}{3}\text{MnO} \cdot \frac{1}{3}\text{ZnO}) \cdot \text{Fe}^2\text{O}^3$.

FRAXIN or **PAVIN.** From a renewed examination of this substance, obtained from horse-chestnut bark, Rochleder (*J. pr. Chem.* xc. 433; *Jahresb.* 1863, p. 688) concludes that it has the composition $2(\text{C}^{12}\text{H}^{18}\text{O}^{10}) \cdot \text{H}^2\text{O}$, and that when heated in a stream of carbon dioxide to 150° (more quickly at 200°) it gives off its water, and then contains $\text{C}^{12}\text{H}^{18}\text{O}^{10}$. After crystallisation from hot alcohol, it is pure white, and gives off its water at 110° – 113° . Its decomposition into fraxetin and glucose is represented by the equation:

FRAXINUS. The leaves of the ash-tree (*Fraxinus excelsior*) contain, according to W. Gintl (*Zeitschr. f. Chem.* [2] iv. 731; v. 377), fat, pectin, a resinous body, mostly inactive malic acid (partly free, partly as calcium salt), inosite, mannite, dextroglucose, and a gummy substance not yet examined.

FRUIT. A. Dupré (*Chem. Soc. J.* [2] v. 378) has examined the variations in the proportions of acid and sugar which take place in the ripening of grapes. He finds that a considerable increase in the quantity of sugar is not attended with any essential alteration in the amount of acid: whence it seems to follow that the sugar is not formed from the acid, but that the acid determines the formation of sugar from some other constituents of the fruit.

Sestini (*Bull. Soc. Chim.* [2] vii. 236) has determined the quantities of water, sugar (glucose), and acid in various dried fruits. The numbers in the column headed 'Acid' indicate the volume in cub. cent. of a normal alkaline solution (containing 20 grams soda in a litre) which is neutralised by 100 grams of the fruits.

	Water p. c.	Glucose p. c.	Acid c.c.
Ordinary dry figs	34.38	42.00	10.5
Figs à pièces	43.36	45.50	5.2
Marseilles figs	32.67	48.35	5.3
Dates (stoned)	39.18	43.40	2.8
Dried currants (Corinth grapes)	34.64	53.97	36.3
Dry grapes (Zibibbo)	37.83	54.08	17.3
Dry pears* (from Farli)	32.86	23.93	15.4
Black Marseilles plums	31.95	23.28	35.9
White Italian plums	33.09	31.95	56.2

Boussingault (*Ann. Ch. Phys.* [4] viii. 210) has examined the products of fermentation of saccharine fruits. Having observed that the quantity of alcohol obtained by distilling fermented cherry or plum juice, is only a fraction of that which corresponds to the sugar contained in the substances subjected to fermentation, he endeavoured to ascertain the cause of this loss by a comparative estimation of the amount of sugar in the fruit, and of the quantities of sugar and alcohol in the products of the fermentation. In the following table (p. 625) the numbers marked *a* in the column headed 'Glucose' denote the sugar which directly reduces cupric oxide; *b* that which is formed by heating with acids. The 'calculated' numbers denote the quantity of alcohol corresponding to the glucose which disappears in fermentation. The quantity of acid is expressed by its equivalent in hydrogen sulphate, SO_4H^2 . All weights are given in grams.

Out of 100 pts. glucose and other kinds of sugar contained in the fresh juice there remained undecomposed by the fermentation :

Of Grapes	Apples	Damsons	Mirabelles	Cherries
1.9 to 3.4	2.8 to 16.7	7.7 to 8	5.9 to 18	35.2 to 38.4 pts.

The fermented juico (1 litre) still contained the following quantities of sugar or saccharine substances :

In Wine	Cider	Damson wine	Mirabelle wine	Cherry wine
4 to 8	4 to 8	6 to 7	12 to 19	40 to 46 grams.

Boussingault surmises that the sugar in wine and cider may gradually disappear in consequence of a slow fermentation, although it had not sensibly diminished after the samples had been kept for a year or two.

Grapes contain only glucose; apples only glucose, with sometimes an invertible sugar (cane-sugar?); but the pulp of stone-fruits contains also non-fermentable substances. Cherries contain, besides glucose, a considerable quantity of a crystallisable substance, which reduces potassio-cupric tartrate, and after treatment with acids is not fermented by yeast: hence it is found in the fermented juice. Damsons and mirabelles contain a substance (gum?) which is converted by acids into fermentable glucose (galactose?), and appears also to undergo this change during the fermentation of the juice, as it disappears, partly at least, during that process. Hence it follows that the estimation of glucose by means of potassio-cupric tartrate before fermentation may lead to totally erroneous results regarding the quantity of alcohol that may be expected, unless it has been previously ascertained that the directly reducing substance is really fermentable sugar, and that the substance which reduces after treatment with acids is cane-sugar or an analogous body.

The amount of acid in wine from the grape is greater than that in must, whether the fermentation takes place with or without access of air; in other fruits, the quantity of acid diminishes in fermentation without access of air. The quantity of alcohol of the fermented product is in all cases less—probably in consequence of evaporation—than that which is calculated from the glucose which disappears; a further loss (about 10 p. c. of the alcohol formed) takes place in the distillation of cherry- and damson-brandy. Black cherries and the variety known as *mérises* contain in their sarcocarp the substances required for the formation of prussic acid, and therefore yield must and fermented products containing that acid, even if the kernels have been previously removed. Damsons and mirabelles, on the other hand (unless mixed with bruised kernels), always yield a distillate free from prussic acid. In a litre of cherry-brandy Boussingault found from 0.120 to 0.183 grm. prussic acid.

* The pears, for better preservation, had been dipped in boiling water before drying: hence the small amount of sugar.

Fermentation-products of Saccharine Fruits.

* The number for glucose includes the non-fermentable sweet substance (s/r/s). V. Small black sweet cherries (*maries*); VI. Ordinary black cherries.
† In the fermentation of mirabelles and damsons, a white pulverulent substance like inulin settled to the bottom; the yeast formed remained enclosed in the fruit-pulp.

FUCHSINE. See ANILINE-DYES.

FUCUS. The ash of various species of fucus has been analysed by E. Marchand (*J. Pharm.* [4] ii. 276; *Ann. Ch. Phys.* [4] viii. 320; *Jahresb.* 1865, p. 640; 1866, p. 703).

FULMINOSE. A modification of cellulose supposed by Blondeau to exist in gun-cotton, and produced by the action of acids or of heat on ordinary cellulose (p. 419).

FUMARIC ACID. $C^4H^4O^4$.—This is an unsaturated acid containing 2 at. hydrogen less than succinic acid. Respecting its constitution, and that of the isomeric compound, maleic acid, see ACIDS, ORGANIC (p. 47).

Fumaric acid treated with water and sodium-amalgam, or with hydriodic acid, takes up 2 atoms of hydrogen and is converted into succinic acid (ii. 743). According to Kekulé, however (*Ann. Ch. Pharm. Suppl.* ii. 108), zinc dissolves in aqueous fumaric acid, with evolution of hydrogen, forming zinc fumarate; but when fumaric acid is gently heated with zinc and excess of potash-solution, the hydrogen, instead of escaping, attaches itself to the fumaric acid, and converts it into succinic acid. According to v. Victor (*Zeitschr. f. Chem.* [2] iv. 454), when zinc and fumaric acid are placed together in cold water, the zinc is rapidly attacked, without evolution of hydrogen, the fumaric acid gradually dissolves, and the liquid deposits four-sided prisms of zinc fumarate, while succinic acid remains in solution:

FUMARINE. This base, obtained by Peschier and afterwards by Hennon from *Fumaria officinalis*, has been further examined by Preuss (*Zeitschr. f. Chem.* [2] ii. 414; *Bull. Soc. Chim.* [2] vii. 453), who, however, has not determined its composition. It is described as crystallising in irregular, six-sided, monoclinic prisms, soluble in alcohol, chloroform, benzol, carbon bisulphide, and amyl alcohol, sparingly soluble in water, insoluble in ether. The solution has a bitter taste and alkaline reaction. It is not coloured by strong nitric acid. With strong sulphuric acid it forms a dark violet liquid, which turns brown on addition of non-oxidising agents. The easily soluble acetate crystallises in silky tufts of needles; the sparingly soluble hydrochloride and sulphate in prisms; the platinum and gold salts in octohedrons.

FURFUROL, $C^4H^4O^2$, is evolved in considerable quantity in the preparation of munjistin by boiling munjeet with aluminium sulphate (iii. 1061); also in the preparation of garancin by boiling ordinary madder with sulphuric acid (Stenhouse, ii. 751).

Furfurol is the aldehyde of pyromucic acid, $C^4H^4O^3$, and is converted into that acid by oxidation with silver-oxide (ii. 752), or better by boiling with concentrated alcoholic potash (Ulrich, *Jahresb.* 1860, p. 269). According to Limpricht (*Zeitschr. f. Chem.* [2] v. 599), furfural alcohol is produced at the same time:

The furfural alcohol may be extracted from the product by agitation with ether; and the residue decomposed by sulphuric acid yields pyromucic acid, which may then also be extracted by agitation with ether.

According to Stalman (*Jahresb.* 1867, p. 586), furfural alcohol may be obtained by the action of sodium-amalgam on furfural (? pyromucic) acid, in the form of a light brown viscid liquid, insoluble in water and decomposed by distillation.

G

GADOLINITE. This mineral has been regarded by some crystallographers as orthorhombic (Nordenskjöld, *Jahresb.* 1859, p. 779; Scheerer, *ibid.* 1861, p. 988; V. v. Lang, *Phil. Mag.* [4] xxviii. 145), by others as monoclinic. Waage (*Jahresb.* 1867, p. 986) found large well-defined crystals from Hitteröe to be combinations of the monoclinic prism ∞P with the pyramidal face P and several secondary faces, and having the clinodiagonal, orthodiagonal, and principal axis in the ratio 0.6249:1:1.31713. Descloizeaux and Damour showed in 1860 (*Ann. Ch. Phys.* [3] lix. 357) that some varieties of gadolinite are monorefractive, some birefractive, and others mixtures of the two kinds. In a recent paper (*Ann. Ch. Phys.* [4] xviii. 305) Descloizeaux reports: (1) That the crystals of gadolinite from Hitteröe, measured by himself and Waage, and analysed by Scheerer, have an energetic bi-axial refraction on two optic axes; the orientation of these axes, that of their bisectrix, and their *inclined* dispersion, prove that the primitive form is an oblique rhomboïdal prism (? triclinic) whose plane of symmetry is the same as that of the axis: this variety contains from 10 to 12 p. c. of glucina. (2) The most homogeneous of the Ytterby crystals measured by von Lang, and analysed by Berlin, are monorefractive; they exhibit a certain number of peculiar modifications, in addition to those shown in the Hitteröe crystals, of which they are the pseudomorphs, and they do not contain glucina. (3) The heterogeneous specimens are forms in transition from the first to the second variety; they contain from 2 to 6 p. c. of glucina. These three kinds of gadolinite differ entirely in their symbolic chemical relations. The birefractive kind has the formula $3M^{\circ}O \cdot SiO_2$; the mono-

refractive is a sort of peridote $2M^{\circ}O \cdot SiO_2$ or M^2SiO_4 ; and the transition-forms give an undecided result, the ratio between the oxygen of the silica and that of the bases varying between 3:4 and 4:5. These differences of constitution probably originate in local circumstances. The Hitteröe mineral appears to be associated with malacene and polycrase in a granitic vein composed of quartz, orthoclase, and oligoclase (with a little mica), and crossing the gabbro of which the greater part of the island of Hitteröe is formed; but that of Ytterby is chiefly accompanied by yttroutantalite and fergusonite, and is imbedded over a red lamellar orthoclase, divided by large plates of black mica.

On the behaviour of gadolinite when heated, see Church (*Chem. Soc. J.* [2] ii. 416).

GALLIC ACID. See HYPOGALLIC ACID.

GALBANUM. This resin fused with potash yields resorcin, $C^6H^2O^3$ (iv. 216).

GALLIC ACID, $C^6H^3O^5$, occurs, according to Phipson (*Chem. News*, xx. 116), together with ellagic and nucitannic acids, in the epispem of walnuts. According to von Tieghem (*Compt. rend.* lxx. 1091), the formation of gallic acid in a solution of tannic acid is especially promoted by the development of the spores of *Penicillium glaucum* and *Aspergillus niger*, the solution being exposed to the air (p. 614). According to Bolley and Bähr (*Zeitschr. f. Chem.* [2] iv. 501), gallic acid is produced from the tannin of the sumach by warming it with sulphuric acid.

A solution of barium gallate treated with excess of silver nitrate yields a black precipitate containing metallic silver, and the filtrate contains an acid which when separated by hydrogen sulphide from its lead salt, exhibits all the properties of quercitannic acid (J. Löwe, *J. pr. Chem.* cii. 111; *Jahresb.* 1867, p. 446; see also Barfoed, *ibid.* p. 447). A certain portion of the gallic acid is at the same time converted into ellagic acid, the greater part of which however undergoes further oxidation; but by using arsenic acid as the oxidising agent, ellagic acid may be obtained in considerable quantity. Its formation from gallic acid is represented by the equation:

(Löwe, *Zeitschr. f. Chem.* [2] iv. 608).

When the solution of acid barium gallate, $(O^6H^3O^5)_2Ba$ (ii. 761), is saturated with baryta-water, a white precipitate is formed which quickly turns blue in contact with the air; but if the precipitation and washing with de-aerated water be performed in an atmosphere of hydrogen, and the precipitate quickly dried in a vacuum over

sulphuric acid, it exhibits (at 150°) the composition $C^4H^4Ba^2O^3$; hence gallic acid appears to be quadribasic. In the air-dried state this barium salt contains 5 mol. or 17 p. c. water (Hlasiwetz, *J. pr. Chem.* ci. 113).

Bromogallic Acid. When gallic acid is triturated with bromine, a brisk action takes place, hydrobromic acid is evolved, and mono- or di-bromogallic acid is formed, according to the proportion of bromine used (Grimaux, *Bull. Soc. Chim.* [2] vii. 479).

Monobromogallic acid, $C^4H^3BrO^3$, crystallises by spontaneous evaporation of the aqueous solution, in small, transparent, yellow, hexagonal plates, becoming white and opaque at 100° ; from a hot-saturated solution it crystallises in needles. It is easily soluble in boiling, sparingly in cold water, soluble also in alcohol and in ether; melts above 200° without decomposition; oxidises easily in the air, and is coloured successively rose-red, greenish, and orange-yellow by lime- or baryta-water, orange-yellow by ammonia or potash, black by ferric chloride.

Dibromogallic acid, $C^4H^2Br^2O^3$ (at 135°), is obtained by triturating gallic acid with excess of bromine (2 or 3 pts.) and dissolving the product in three times its weight of boiling water; it is formed also in the preparation of the monobrominated acid and crystallises out after the latter. It forms long, brittle needles or prismatic laminae, which retain 1 mol. water at 100° . Dissolves slightly in cold, more easily in boiling water, in ether and in alcohol, is coloured rose-red, light green, and dark red by lime- or baryta-water, indigo-blue in ethereal solution by baryta-water, and then red by water. Ammonia and potash form with the acid an orange-yellow solution becoming rose-red on dilution; with ferric chloride it forms a black-blue liquid (Grimaux). According to Hlasiwetz (*Bull. Soc. Chim.* ix. 501), dibromogallic acid forms with ferric chloride a splendid violet-blue solution, with ammonia a fiery-red solution afterwards turning brown, and with baryta-water a precipitate which turns blue on agitation.

GAMBOGE (Hlasiwetz a. Barth, *Ann. Ch. Pharm.* cxxxviii. 61; *Jahresb.* 1866, p. 628).—This gum-resin, purified by solution in alcohol, filtration, distillation, and precipitation of the residual liquid with water, froths strongly when fused with potash, giving off vapours smelling like lemon and balm. The fused mass, almost wholly soluble in dilute sulphuric acid, contains (besides much acetic and apparently also butyric acid) four products soluble in ether—viz. phloroglucin; a crystallised acid not precipitated by neutral lead acetate; a crystallisable and an uncrystallisable acid, both of which are precipitated by lead acetate. To separate these products: a. The aqueous solution of the residue from the ether-distillation is neutralised with sodium carbonate and then agitated with ether, which dissolves the phloroglucin (6 to 8 grm. from a pound of gamboge).—b. The liquid filtered therefrom is warmed, acidulated with sulphuric acid, and then exhausted five or six times with ether. The residue of this ethereal extract is dissolved in water and precipitated by neutral lead acetate. The white bulky precipitate A contains the two precipitable acids; the liquid B filtered therefrom contains the third non-precipitable acid. The lead precipitate A and the liquid B are decomposed with hydrogen sulphide, the lead sulphide is washed with boiling water, and the filtered liquids are evaporated. The filtrate thus obtained from the liquid B still contains, however, a small quantity of the acids precipitable by lead acetate, inasmuch as part of the precipitated lead salt is redissolved by the liberated acetic acid.

The liquid from the lead salt A, evaporated to a syrup and left to itself for several days, yields granular crystals, whilst the other amorphous syrupy acid (not obtained pure) remains in the mother-liquid. The crystallised acid is isomeric with uvitic acid, $C^4H^4O^4$ (v. 971), and is therefore called iso-uvitic acid. After recrystallisation from boiling water with aid of animal charcoal, it forms rather thick, short, prismatic crystals belonging to the rhombic system, often with saddle-shaped faces. It has a strong acid taste and reaction, melts without loss of water at 180° , and solidifies again in the crystalline form. Its ammonium salt forms very deliquescent laminae; the calcium salt crystallises from a solution of the ammonium salt mixed with calcium chloride in spherical aggregates; another (probably acid) calcium salt is formed by saturating the acid with calcium carbonate. The barium salt $C^4H^4BaO^4$ crystallises in shining scales; the cadmium salt $(C^4H^4O^4)_2Cd + 5H^2O$ in warty groups of short prisms; the silver salt $C^4H^4AgO^4$ is a bulky precipitate sparingly soluble in cold water, not altered by light.

The acid not precipitable by lead acetate obtained from the liquid B, is pyrotartaric acid, $C^4H^4O^4$.

GASES, ABSORPTION OF. 1. *By Liquids.*—Khanikoff a. Louguine (*Ann. Ch. Phys.* [4] xi. 412) have shown that the absorption of carbon dioxide

by water at a constant temperature is not exactly proportional to the pressure (see p. 404). On the absorption of carbon dioxide by solution of sodium phosphate, see Heidenhain & Meyer (*Ann. Ch. Pharm. Suppl.* ii. 157; *Jahresb.* 1863, p. 92).

H. Doicke (*Pogg. Ann.* cxix. 156) has determined the absorption-coefficient of hydrogen chloride for water at different temperatures. The results, calculated for a barometric pressure of 760 mm., are given in the following table:

Temperature	Absorption-coefficient	Percentage of HCl in solution	Specific gravity of solution
0°	525.702	45.148	1.2257
4	494.722	44.361	1.2265
8	480.288	43.828	1.2185
12	471.336	43.277	1.2147
14	462.375	42.829	1.2074
18	451.222	42.344	1.2064
18.25	450.660	42.283	1.2055
23	435.034	41.536	1.2013

The experiments of Roscoe (*Chem. Soc. Qu. J.* viii. 14) have shown that the constituents of a gaseous mixture are not always absorbed by water in the proportions required by Dalton's law of partial pressures (ii. 800). This subject has been further examined by W. M. Watts (*Chem. Soc. J.* [2] ii. 88), who finds that the quantity of ammonia absorbed by water from a mixture of ammonia and air, and that of sulphurous oxide absorbed from a mixture of that gas with carbon dioxide, agree with the law of partial pressures. The same chemist has confirmed the fact, previously observed by Roscoe and others, that the quantities of ammonia and sulphurous oxide absorbed by water under different pressures do not vary directly as the pressure.

Borthelot has made the following observations on the absorption of gases by solutions of metallic salts: 1. Ammoniacal cuprous chloride directly absorbs oxygen, carbon monoxide, acetylene, ethylene, allylene, propylene (slightly); it does not act immediately on nitrogen dioxide.—2. A solution of ferrous sulphate in sal-ammoniac and ammonia rapidly absorbs, as is well known, oxygen and nitrogen dioxide, but does not act upon acetylene, allylene, ethylene, propylene, or carbon monoxide.—3. A solution of chromous sulphate in sal-ammoniac and ammonia absorbs oxygen, nitrogen dioxide, acetylene, and allylene, but does not act upon carbon monoxide, ethylene, or propylene.

2. **Absorption of Gases and Vapours by Charcoal.** J. Hunter (*Phil. Mag.* [4] xxv. 364; xxix. 166) finds that different kinds of charcoal absorb gases in different proportions, cocoa-nut charcoal being the most absorbent of all. In the following table the numbers placed opposite the names of the several gases indicate the volumes of gas (reduced to 0° and 760 mm.) absorbed at ordinary temperatures by 1 volume of charcoal ignited and quenched under mercury, the numbers in the first column relating to cocoa-nut charcoal, those in the second to Campeachy-wood charcoal, those in the third to charcoal from vegetable ivory:

Ammonia . . .	171.7	—	130.1	Nitrogen monoxide . .	70.5	—	—
Cyanogen . . .	107.5	—	—	Hydrogen phosphide . .	69.1	27.5	—
Nitrogen dioxide .	86.3	—	—	Carbon dioxide . . .	67.7	—	—
Methyl chloride .	76.4	—	—	Carbon monoxide . . .	21.2	—	—
Methyl oxide . . .	76.2	39.8	64.7	Oxygen	17.9	10.07	—
Ethylene . . .	74.7	—	—				

The experiments with hydrogen phosphide and with oxygen did not give very accordant results; in the case of oxygen the discordance probably arose from formation of carbon dioxide.

Hunter has also determined the absorptive power of cocoa-nut charcoal for a considerable number of vapours (*Chem. Soc. J.* [2] iii. 285; v. 160; vi. 186). The substance to be converted into vapour was enclosed in glass bulbs, which were introduced into a graduated tube filled with warm mercury. This tube stood in a mercury trough, and its upper part was surrounded by a glass vessel, into which the vapour of amyl alcohol (boiling at 127°–131°), or of turpentine oil (at 158°–161°), was introduced for the purpose of heating the vapours. For higher temperatures, the

glass vessel was replaced by a copper bath containing paraffin, the upper part of the absorption-tube passing through an aperture in its base. When the liquid in the bulb was completely converted into vapour, the pressure and volume of the vapour were read off; and the charcoal heated to redness out of contact with the air was plunged into the mercury and then introduced into the absorption-tube. At the end of the absorption, which takes place much more quickly than with permanent gases, the temperature and pressure were again determined.

In Table I., V denotes the number of volumes of vapour absorbed by 1 vol. of cocoa-nut charcoal; T the mean of the temperatures at the beginning and end of the experiment; P the pressure at the beginning; and P' that at the end of the absorption. In Tables II. and III., T denotes the mean of the temperatures at the beginning of the several experiments; T' that of the temperatures at the end of the absorption; V, P, and P' have the same significations as before.

A comparison of the numbers found in the case of mixed alcohol and water vapours at different temperatures (Table III.) shows that the absorption is greatly increased when one of the vapours is at a temperature near to its point of condensation. Thus at 100° one volume of cocoa-nut charcoal absorbs 187.2 vol. of a mixture of alcohol and water vapour in equal volumes, and 255.4 vol. of a mixture of 1 vol. alcohol-vapour and 3 vol. water-vapour; at 160°, on the other hand, the absorption diminishes with the increased proportion of water, from 58.1 to 37.6. At the higher temperature, in fact, both the alcohol and the water are absorbed as vapours, and the alcohol is absorbed in larger proportion than the water: hence the diminished absorption of the mixed vapour with the increase in the proportion of water; but at 100° a portion of the water-vapour absorbed by the charcoal becomes liquefied, and the water thus formed within the pores of the charcoal absorbs a considerable quantity of the alcohol-vapour, this effect of course increasing with the proportion of water-vapour in the mixture. The alcohol-vapour in this case is absorbed partly by the charcoal, partly by the water condensed within its pores. In accordance with this view, it is found that vapour of water mixed with gaseous ammonia (as obtained by heating aqueous ammonia) is much more largely absorbed than either ammonia gas or water-vapour separately (*Chem. Soc. J.* [2] viii. 73).

In a recent paper (*ibid.* ix. 76) Hunter has further examined the effects of pressure on the absorption of gases by charcoal.

Reichardt a. Blumtritt (*J. pr. Chem.* xlviii. 418; *Jahresb.* 1866, p. 53) have determined the quantity and composition of the gas absorbed by various dry substances on exposure to the air, and expelled from them by heating. The results show that the quantity of the absorbed gases which can be expelled by heat is very different for different substances, and varies in the same substance according to the degree of moisture. The expelled gases rarely exhibit the proportions existing in atmospheric air (as in the case of gypsum), the nitrogen being in almost all cases greatly in excess, whereas oxygen appears to be but sparingly absorbed by the greater number of bodies. [It is probably in many cases absorbed by the solid body, and enters into combination with some of its constituents: charcoal and vegetable mould, for example, may absorb oxygen from the air and afterwards give it out in the form of carbon dioxide.] Carbon dioxide, on the other hand, appears to be an almost invariable constituent of the absorbed gases, and is taken up in especial abundance by ferric oxide, alumina, and clay. Ammonia was found only in very small quantities; carbon monoxide only in organic detritus and in charcoal. Nitric acid also was but rarely found, and when present appeared to be in the form of salts. The following table exhibits the mean results of numerous experiments:

	Gases		100 vol. of the Gases contained

3. Absorption and Dialectic Separation of Gases by Colloidal Septa and by Metals.

1. By Caoutchouc: The experiments of Mitchell in 1831 showed that different gases are absorbed by caoutchouc, and capable of passing through it with different degrees of facility (ii. 818). These phenomena have recently been investigated with great care by Graham (*Phil. Trans.* 1866, p. 399; *Chem. Soc. J.* [2] v. 235). The permeability of thin membranes of caoutchouc by different gases, passing through it either into a vacuum or into other gases, was measured by means of a diffusimeter consisting of a glass tube 1 metre long and 22 mm. in diameter, open at the lower end and closed at top by a thin plate of gypsum, over which the caoutchouc membrane was fastened with copper wire and cemented to the glass with fused gutta-percha. If such a tube be filled with mercury and inverted, a Torricellian vacuum is formed in the upper part, into which the atmospheric air gradually penetrates, passing through the

* The mark — signifies undetermined.

caoutchouc film, and depressing the mercurial column. To compare the penetrating power of different gases, a hood of thick vulcanised caoutchouc, provided with a small entrance- and exit-tube for gas, is placed over the upper end of the diffusiometer, and cemented to it with fused gutta-percha. The gas to be operated on can thus be conveyed from the generating apparatus or from the gas-holder into the hood or upper chamber of the diffusiometer, and the excess of gas may be allowed to escape by the exit-tube. The stucco-plate used as a support to the film of caoutchouc, being very porous, and having no absorbing power for gases, does not add sensibly to the resistance experienced by the gases in passing through the caoutchouc. By means of this apparatus equal volumes of different gases were found to pass through the caoutchouc membrane in the times indicated in the following table :

	CO ²	H	O	CH ⁴	Air	CO	N
Times . . .	1	2.470	5.316	6.326	11.850	12.203	13.685

The volumes which pass through in equal times—that is to say, the velocities—are therefore as follows:

	CO ²	H	O	CH ⁴	Air	CO	N
Velocities . .	13.685	5.500	2.556	2.148	1.149	1.113	1

These numbers do not exhibit the relation of the coefficients of gas-diffusion, and therefore show that dialytic penetration is a process essentially different from diffusion, in which nitrogen, for example, penetrates a septum less quickly than the heavier oxygen. They therefore show also that thin membranes of caoutchouc do not possess the porosity of paper, plates of gypsum, or artificial graphite (ii. 813), earthenware tubes, or even gutta-percha, and that they consequently completely arrest the molecular diffusion of gases. The permeation of caoutchouc and other colloidal membranes by gases appears to takes place in this way: the gas is first absorbed by the colloidal substance, passes into the liquid state, as when it is absorbed by water, and in that state penetrates the membrane, and volatilises into the vacuum or the gaseous atmosphere on the other side. A lump of caoutchouc immersed for several days in pure oxygen was actually found to absorb 6.82 p. c. of its volume of that gas. The permeability of caoutchouc by gases increases with rise of temperature. Thus the quantity of atmospheric air which passed in a minute through a square metre of silk cloth coated on one side with caoutchouc, into a vacuum, was 0.66 c.c. at 4°, 2.26 c.c. at 14°, and 6.63 c.c. at 60° (all the volumes being reduced to 20° and 760 mm.). These values appear however to vary to some extent with the time during which the particular temperature is kept up, the change in degree of softness of the caoutchouc with change of temperature requiring hours or even days to complete it. The retentive power of caoutchouc for gases appears also to be modified by its softening by heat. Caoutchouc saturated with a gas, and then made rigid by cold, gives up the gas, but very slowly, when subsequently warmed in contact with the air.

When a very thin caoutchouc balloon filled with hydrogen or carbon dioxide is exposed to the air, it contracts, because the gas which escapes outwards is replaced by a smaller volume of air; and as oxygen passes through the caoutchouc more quickly than nitrogen, the air which has entered the balloon is found after a certain time to be richer in oxygen than atmospheric air. Thus when a balloon filled with hydrogen was exposed to the air for three hours, the gas within it was found to consist of 8.98 oxygen, 12.60 nitrogen, and 78.42 hydrogen, giving a proportion of 41.6 vol. oxygen to 68.4 vol. nitrogen; a balloon filled with carbon dioxide and exposed to the air for four hours was found to contain (after absorption of the residual carbon dioxide) 37.1 vol. O to 62.9 vol. N. Similar results were obtained by dialysis into the vacuum of the diffusiometer. When the balloon is left exposed to the air for a considerable time, the proportion of the oxygen to the nitrogen within it diminishes and ultimately sinks to the normal value.

The process of dialytic separation by caoutchouc may be varied in three points: (1) in the condition of the septum, which may consist of a film of caoutchouc formed from caoutchouc varnish, or of distended sheet caoutchouc; (2) in the nature of the support given to the septum, which may be a backing of cotton cloth or of silk, as well as a plate of stucco, earthenware, or wood; and (3) in the means employed for sustaining a vacuum, or at least a considerable degree of exhaustion, on one side of the dialytic septum, while atmospheric air or any other gaseous mixture to be dialysed has access to the other side. A very convenient exhaustor for the purpose is Sprengel's mercury-pump, having its vertical tube turned up at the end for the purpose of transferring the gases from one vessel to another, as in the apparatus for water-analysis

figured in vol. v. p. 1030. The air to be dialysed may also be compressed on one side of the septum, and left of the usual tension on the other side.

A large number of experiments made under these several conditions showed that, under given circumstances, the dialytic transfer is accelerated by rise of temperature, and retarded by increased thickness of the membrane.

The quantity of air which passed through a square metre of surface of a caoutchouc balloon 0.114 mm. thick was 16.9 c.c. in a minute; through an equal surface 1 mm. thick, 19.2 c.c. in an hour, or 0.32 mm. per minute; and through an elastic air-cushion (vulcanised caoutchouc between two sheets of cotton), 44.95 c.c. in an hour, or 0.749 c.c. per minute.

The usual proportion of oxygen in air once dialysed by caoutchouc is about 41.6 p. c.: it may be described as air deprived of one-half its usual proportion of nitrogen; but a second and a third dialysis would not increase the amount of oxygen in the same proportion, inasmuch as only half the residual nitrogen would be removed at each operation. The practical problem suggested by the air-dialyser is to attain the means, on a large scale, of reducing to one-half or so the proportion of nitrogen in atmospheric acid. Such air will rekindle a glowing slip of wood, and might be applied to many useful purposes.

On the permeability of caoutchouc for gases, see also Aronstein & Sirks (*Zeitschr. f. Chem.* [2] ii. 260; *Jahresb.* 1866, p. 52).

2. *Action of Metallic Septa at a Red Heat.*—Deville and Troost in 1863 (*Compt. rend.* lvi. 977; lvii. 894, 965; *Jahresb.* 1863, pp. 23, 26) showed that platinum and iron at a red heat are permeable to hydrogen gas. Graham has confirmed this result and finds that red-hot platinum is very much more permeable to hydrogen than caoutchouc at ordinary temperatures. A square metre of sheet caoutchouc 0.014 mm. thick allowed 127.2 c.c. hydrogen gas to pass through it at 20° in a minute, whereas through an equal surface of platinum tube 1.1 mm. thick at a bright red heat, 489.2 c.c. hydrogen passed in the same time. Oxygen, nitrogen, chlorine, hydrochloric acid, carbon dioxide, carbon monoxide, marsh gas, and ethylene, as well as aqueous vapour, hydrogen sulphide, and ammonia, are not capable of passing through red-hot platinum, the last two perhaps because they are decomposed at that temperature, and only hydrogen passes through the metal. For nitrogen, in presence of hydrogen, platinum appears to be permeable to a slight extent.

This peculiar action of platinum may be explained to a certain extent by its property of absorbing hydrogen at a red heat and retaining it for an indefinite length of time at lower temperatures. To demonstrate this property, designated by Graham as 'occlusion,' the metal to be examined, in the form of wire or fragments, is placed within a porcelain tube glazed inside and out, connected at one end with a Sprengel's vacuum apparatus (as in fig. 823, vol. v. p. 1030), and at the other with a gas-generator or gas-holder. The tube, having been exhausted, is gradually heated to redness, while a copious stream of hydrogen (or other gas) is passed through it, and after prolonged ignition, is left to cool slowly. Finally the unabsorbed gas is expelled by a stream of air; the tube is again exhausted and heated to redness; and the gas thereby expelled from the metal is collected and measured.

Platinum wire (drawn from fused platinum and cleansed by washing with caustic alkali and water) gave off, after an hour's agitation in a vacuum, 0.17 vol. hydrogen to 1 vol. platinum (mean of 4 experiments); platinum-sponge similarly treated yielded 1.48 vol.; old wrought platinum (not originally fused), 3.83 to 5.53 vol. hydrogen; platinum foil at 230° took up 1.45 vol., and between 97° and 100°, in three hours, 0.76 vol. hydrogen. The appearance and lustre of the platinum are not altered by this absorption of hydrogen, but after its expulsion the metal appears white and blistered.

Palladium exhibits a much higher absorbing power for hydrogen. In the form of foil, after recent ignition in a vacuum, it takes up, even at ordinary temperatures, 376 times its volume of hydrogen; at 90° to 97°, 645 vol.; at 245°, 526 vol. The spongy metal obtained by igniting palladious cyanide absorbs 686 times its volume at 200°; foil beaten from the fused metal, only 68 vol.; and an alloy of 5 pts. palladium and 4 pts. silver absorbs 20.5 vol. at a dull red heat. The absorbed hydrogen is given off, partly at ordinary temperatures, quickly at a red heat. In this absorbed and condensed state the hydrogen appears to possess intensified affinities, inasmuch as the palladium which has absorbed it reduces ferric to ferrous salts, ferriocyanides to ferrocyanides, and in contact with aqueous chlorine or iodine, forms hydrochloric or hydriodic acid. These properties, viewed in connection with the power which palladium possesses of absorbing perceptible quantities of different liquids, were regarded by Graham as tending to support the assumption that the hydrogen thus absorbed passes into the liquid state. The absorptive power of palladium for hydrogen is related to its permeability by that gas, though the two properties are not exactly proportional.

one to the other. Palladium foil is not permeable at ordinary temperatures to hydrogen, though it is so to ether-vapour. A wrought palladium tube having its sides 1 mm. thick began to give passage to hydrogen through its substance at 240° ; at 265° the quantity of hydrogen which passed in a minute through a square metre of its surface amounted to 327 c.c., and at a heat near redness 423 c.c. When the tube was surrounded with an atmosphere of coal-gas, nothing but pure hydrogen penetrated the palladium, the other constituents of the gaseous mixture remaining without.

Granules of osmiridium do not absorb hydrogen. Copper at a red heat, in the form of sponge absorbs 0.6 vol., in the form of wire 0.306 vol. (wrought copper ignited in a vacuum gives off, together with the hydrogen, small quantities of carbon monoxide). Gold in the form of assay-cornets, which had been recently ignited, took up 0.48 vol. hydrogen, 0.29 vol. carbon monoxide, 0.16 vol. carbon dioxide, when heated in these gases; heated in atmospheric air, it took up from 0.19 to 0.24 vol. of a gaseous mixture in which nitrogen was the prevailing constituent. Pure silver in the form of wire (which when heated alone gave off 0.29 vol. of nearly pure carbon dioxide) absorbed at a red heat 0.211 vol. hydrogen, 0.745 oxygen, and in atmospheric air 0.545 vol. oxygen. Fritted silver obtained by reduction of the oxide exhibited a greater absorbing power, taking up from 6.15 to 7.47 vol. oxygen, 0.907 to 0.938 vol. hydrogen, 0.486 to 0.545 vol. carbon dioxide, and 0.15 vol. carbon monoxide, when heated to redness in these gases. Pure thin silver-leaf ignited in air absorbed 1.37 vol. oxygen, 0.20 vol. nitrogen, and 0.04 vol. carbon dioxide. This oxygenated silver still exhibits the colour and lustre of the pure metal, and retains the oxygen firmly at all temperatures below redness. Thin iron wire, carefully purified with potash-ley and water, yielded, when heated in a vacuum for two hours, 7.94 times its volume, and after seven hours, 12.5 times its volume of a gaseous mixture chiefly consisting of carbon monoxide. Such iron previously heated to redness in a vacuum absorbed at a dull red heat 0.46 vol. hydrogen and 4.15 vol. carbon monoxide. Iron saturated with carbon monoxide remains soft and appears to be incapable of hardening by sudden cooling from red heat; in other respects it does not differ from ordinary iron. The meteoric iron of Lenarto, containing 90.88 p. c. iron, 8.45 nickel, and 0.66 cobalt, yields, when heated in the vacuum apparatus, 2.85 times its volume of a gas consisting almost wholly of hydrogen, with small quantities of carbon monoxide and nitrogen. This fact, viewed in connection with the result established by direct experiment, that wrought iron under the ordinary atmospheric pressure does not absorb more than its own volume of hydrogen, seems to show that the hydrogen contained in the Lenarto iron has been absorbed from a stellar atmosphere denser than that of the earth (*Proc. Roy. Soc.* xv. 502).

3. *Action of Metals at Ordinary Temperatures.*—Palladium, platinum, and iron are also capable of absorbing and retaining at ordinary temperatures considerable quantities of hydrogen, when that element is presented to them in the nascent state. Zinc immersed in dilute sulphuric acid does not take up hydrogen; but thin palladium plate placed in the acid liquid in metallic contact with the zinc becomes charged with hydrogen, which afterwards shows itself on the surface. At the temperature of 12° a palladium plate thus treated took up in an hour 173 times its volume of hydrogen. When employed as the negative electrode of a battery of six Bunsen's elements, it exhibited a still stronger absorption, the evolution of hydrogen being completely suppressed for the first twenty seconds, and the gas absorbed ultimately amounting to 200.4 times the volume of the metal, whereas the same plate on cooling in an atmosphere of hydrogen took up only 90 times its volume. Hydrogen thus absorbed by palladium exhibits no perceptible tension at comparatively low temperatures, and is given off only in traces at ordinary temperatures even in a vacuum, but easily and completely at 100° or when the metal is made to serve as the positive electrode of a decomposing cell; in this case the palladium does not take up any oxygen. Palladium thus charged with hydrogen sometimes becomes suddenly heated on exposure to the air, and then loses its hydrogen by oxidation. Platinum under similar circumstances (as negative electrode) likewise takes up hydrogen (2.19 times its volume in one experiment), and is thereby brought into the well-known polarised state; it gives up the combined hydrogen when heated nearly to redness in a vacuum, or when used as positive electrode in a decomposing cell; in this latter case, like palladium, it does not absorb oxygen. Soft iron immersed in dilute acid takes up a small quantity of hydrogen (0.57 vol. in one experiment), and gives it up in a vacuum at a red heat.

From these results it appears that at comparatively low temperatures, platinum, palladium, and iron are not permeated by hydrogen, though at higher temperatures hydrogen passes through them with facility. Graham supposed, however, that even in this latter case, a condensation or occlusion of the hydrogen by the metal takes

place in the first instance, and that even at very high temperatures a small quantity of hydrogen may be retained by the metal; direct proof of this retention was indeed obtained in one instance by heating a piece of palladium foil in a hydrogen flame and rapidly plunging it into cold water; the hydrogen thus occluded (measured in the cold) amounted to 1.3 times the volume of the metal. Platinum similarly treated took up only 0.06 vol. The velocity of transmission of the gases, which increases rapidly with rise of temperature, is not proportional to the volume taken up by the same metal at lower temperatures. Bar iron takes up a larger quantity of carbon monoxide (4 vol.) than of hydrogen; nevertheless a wrought-iron tube 1.7 mm. thick, after being freed from gases, transmitted through a square metre of surface only 0.284 c.c. carbon monoxide, whereas the hydrogen which passed through the same surface in the same time amounted to 76.5 c.c.* A palladium tube transmitted at 165°, through a square metre of surface, 327 c.c. hydrogen in a minute, at a red heat (melting point of gold) 3992.2 c.c., and of carbon dioxide at the same high temperature only 1.86 c.c. On passing a mixture of equal volumes of hydrogen and carbon dioxide through a small palladium tube, 3 mm. in internal diameter, and 0.3 mm. thick, heated to redness while a vacuum was made around it, 1017.5 c.c. of perfectly pure hydrogen passed through a square metre of its surface in a minute. The rapid diffusion of hydrogen (and partially of carbon monoxide) in palladium, platinum, and iron, at very high temperatures, and their passage through these metals, are regarded by Graham as depending upon a solution of the liquefied gas in the colloid-metal; in fact, as similar to the passage of gases through a thin membrane of caoutchouc. The solution-affinity of these metals appears, however, to be limited to the two gases just mentioned.

In palladium more or less saturated with hydrogen, Graham assumes the existence of a palladium hydride, the hydrogen alloying itself with the palladium like a metal (see HYDROGEN). The quantity of hydrogen taken up by the palladium, when made to form the negative pole of an electrolytic cell, approximates to the formula PdH^2 (no such hydride can however be formed by the action of sodium hypophosphite on palladium sulphate). The palladium hydride formed by occlusion of hydrogen in palladium wire exhibits the colour and lustre of palladium; its tenacity is but slightly less than that of pure palladium; its electric conductivity is 5.99, that of pure palladium being 8.10 (copper = 100). It is distinctly magnetic, more so than palladium itself. Its density is less than that of pure palladium (*Proc. Roy. Soc.* xvi. 422; xvii. 212, 500; *Chem. Soc. J.* [2] vii. 419).

GLAUCODOTE. A specimen of this mineral from Hakansbö in Sweden, analysed by E. Ludwig (*Jahresb.* 1867, p. 974), gave 19.80 p. c. sulphur, 44.03 arsenic, 19.34 iron, 16.06 cobalt (= 99.23). It has the form of arsenical pyrites, and in respect to its amount of cobalt, is intermediate between the glaucodote of Huasco in Chile (ii. 848), and the less cobaltiferous arsenical pyrites distinguished by Tchernak as danaita.

GLAUCONITE. Analyses of this mineral from various localities by Haushofer gave, on the average, 49.6 p. c. silica, agreeing approximately with the formula $RO \cdot R^2O^2 \cdot 3SiO^2 + 3aq.$ (*Jahresb.* 1866, p. 938; 1867, p. 995).

GLUCOSE. See SUGAR.

GLUCOSIDES. Hlasiwetz (*Ann. Ch. Pharm.* cxliii. 290) divides compounds which yield sugar or saccharine substances when treated with acids or alkalis, into the following groups: 1. *Glucosides* yielding by decomposition with dilute mineral acids (or with ferments), glucose and another substance. (a) 1 mol. glucose and 1 mol. of the other product; e.g. arbutin, helicin, ruberythrin, salicin. (β) More than 1. mol. glucose: daphnin, aesculin, jalappin, scammonin, helleborin, turpethin. (γ) 1 mol. glucose to 2 mol. of another body: populin, benzohelicin, gratiolin (?), bryonin (?), ononin (?).—2. *Phloroglucides*, which when decomposed by alkalis or strong mineral acids yield phloroglucin: phloretin, quercitrin, maelurin, luteolin, catechin, fillic acid.—3. *Phloroglucosides*; these yield glucose and phloroglucin, the first of which may be separated by dilute acids, the second from the resulting phloroglucide by alkalis: phlorizin, quercitrin, robinin, rutin.—4. *Gummides* yielding glucose as product of transformation: to this division belong perhaps tannic acid and caffeic acid.—5. *Mannides*, yielding a derivative of mannite as a product of decomposition: quinovin, caffetannic acid (?).—6. *Nitrogenous glucosides*: amygdalin, solanin, indicin, chitin.

GLUTAMIC ACID. $C^2H^4NO^2$ (Ritthausen, *J. pr. Chem.* xcix. 454; cvii. 218).—An acid obtained by decomposition of gluten. It may be prepared by boiling the portion of wheat-gluten which is insoluble in alcohol (vegetable fibrin), or better,

* According to Callotet (*Compt. rend.* lvi. 847; *Jahresb.* 1868, p. 187), iron is under certain circumstances permeable to hydrogen at ordinary temperatures.

the portion soluble in alcohol (mucin or mucedin, ii. 873), for 20 to 24 hours with $2\frac{1}{2}$ pts. sulphuric acid and 6 to 7 pts. water, supersaturating with milk of lime, removing the lime with oxalic acid, the excess of the latter by boiling with lead carbonate, and lastly the dissolved lead with hydrogen sulphide. The strongly acid liquid yields by evaporation a crystalline mixture of tyrosine, leucine, and glutamic acid, from which, by treatment with hot water (which leaves the tyrosine undissolved), and then with alcohol of 30 p. c. (which chiefly dissolves the leucine), and recrystallisation from water (with addition of animal charcoal), and from alcohol of 30 p. c., the glutamic acid is obtained pure. The portion of gluten insoluble in alcohol yields only about $1\frac{1}{2}$ p. c. glutamic acid, but mucedin yields more than 30 p. c., with no tyrosine, and only a small quantity of leucine.

Glutamic acid is likewise obtained, together with aspartic acid and a non-crystallisable body, by treating conglutin with sulphuric acid. On repeatedly boiling the resulting knobby crystalline masses with alcohol of 50–60 p. c., the greater part of the aspartic acid remains undissolved, and an additional quantity of that acid separates from the hot alcoholic solution, while the glutamic acid remains in the mother-liquors, and may be obtained by distillation and concentration over sulphuric acid, in shining tetrahedral crystals.

Glutamic acid dissolves at 15° in 100 pts. water, 302 pts. alcohol of 30 p. c., and 1,500 pts. alcohol of 80 p. c.; at higher temperatures its solubility in water and in dilute alcohol is much greater. The solutions have a strong acid reaction, an astringent taste, and decompose carbonates, forming soluble salts. From hot-saturated solutions the acid separates in white crystalline crusts composed of shining laminae, by slow evaporation in crystals having a bright adamantine lustre and the form of distorted rhombic octohedrons with basal end-face. Axes $a:b:c = 0.8059:1:0.8521$. They are anhydrous, melt with partial decomposition at 135° – 140° , then solidify very slowly to a crystalline mass, which decomposes at a higher temperature, emitting an odour like that of burnt horn. It is dextrograde; but when heated with nitrous acid it yields an optically inactive acid homologous with malic acid. The glutamates of the alkali-metals are very soluble, and crystallise with difficulty; those of the alkaline-earth-metals are also very soluble in water and alcohol, and dry up to gummy masses. The copper salt separates from aqueous solution in well-defined deep blue crystals, consisting—according to Ritthausen's latest observations—of $C^3H^4NO^2Cu + 2\frac{1}{2}H^2O$; from a very strong solution slightly acidulated with nitric acid, it crystallises in small prisms containing only $2H^2O$, and when precipitated by alcohol, it has the composition $C^3H^4NO^2Cu + 3H^2O$. Lead salts do not precipitate glutamic acid even on addition of ammonia.

GLUTARIC ACID. $C^5H^8O^4$.—An acid homologous with malic acid, produced by the action of nitrous acid on glutamic acid, dissolved in dilute nitric acid. It is bibasic. The calcium salt $C^5H^6CaO^4 + \frac{1}{2}H^2O$, obtained by neutralisation and precipitation with alcohol, is white, non-crystalline, and flocculent. Decomposed with lead acetate it yields the lead salt in form of a white precipitate, which crystallises from solution in hot water in nodular crystals containing $C^5H^4PbO^4 + \frac{1}{2}H^2O$. In presence of ammonia a basic salt is precipitated. The silver salt is a curdy precipitate, having when dried the composition $C^5H^4Ag^2O^4 + \frac{1}{2}H^2O$. The acid itself crystallises with difficulty from its solution evaporated to a syrup (Ritthausen, *J. pr. Chem.* ciii. 239; *Zeitschr. f. Chem.* [2] iv. 529).

GLUTEN. For a continuation of Ritthausen's investigation of the constituents of gluten (ii. 873), see *J. pr. Chem.* xcix. 462; *Jahresb.* 1864, p. 719.

GLYCERALS. Compounds analogous to the acetals produced by heating glycerin with aldehydes to 170° – 200° for 24 to 30 hours:

The following have been obtained:

	B.P.	Sp. gr. at 0°	Vap. density obs.
Acetoglyceral, $\left. \begin{array}{l} C^5H^8 \\ H \\ C^3H^5 \end{array} \right\} O^4$	184° – 188°	1.081	4.162
Valeroglyceral, $\left. \begin{array}{l} C^5H^8 \\ H \\ C^3H^5 \end{array} \right\} O^4$	224° – 228°	1.027	5.526
Benzoglyceral, $\left. \begin{array}{l} C^5H^8 \\ H \\ C^3H^5 \end{array} \right\} O^4$			

Benzoglycerol can only be partially distilled under ordinary pressure; at 20 mm. pressure it boils between 190° and 200° . It is heavier than water. All the glycerols are insoluble or very slightly soluble in water, inodorous when recently prepared, but are gradually decomposed by moist air, with separation of the corresponding aldehydes (Harnitzky a. Menshutkin, *Bull. Soc. Chim.* [2] iii. 253).

GLYCERIC ACID, $C^3H^3O^4$, is converted by dry distillation, first into pyro-racemic acid: $C^3H^3O^4 - H^2O = C^3H^3O^3$; then, with evolution of carbon dioxide, into pyrotartaric acid: $2C^3H^3O^3 - CO^2 = C^6H^6O^4$ (Moldenhauer, *Ann. Ch. Pharm.* cxxxi. 223).

Concentrated glyceric acid heated for several hours to 100° with saturated hydriodic acid is converted into iodopropionic acid (Moldenhauer):

Treated with 3 mol. phosphorus pentachloride, it yields chloropropionic acid (Wichelhaus, *Ann. Ch. Pharm.* cxxv. v. 248).

p. 501) has determined the melting points of frozen aqueous solutions of glycerin of various degrees of concentration:

Glycerin solution .	$10^{\circ}B.$	$12^{\circ}B.$	$14^{\circ}B.$	$15^{\circ}B.$
Melting point . .	-9°	-13°	-18°	-21°

The freezing point is very close to the melting point, perhaps a little lower. On mixing snow or finely pounded ice with glycerin, a reduction of temperature equal to 10° or more is produced.

A considerable quantity of glycerin having been sent from Germany to England during a very cold winter (January 1867), was found to be solidified to a crystalline mass resembling sugar-candy, and composed of shining, apparently octohedral crystals of about the size of peas, having a strong refracting power, grating between the teeth, and exhibiting the reactions of chemically pure glycerin. In small quantities they melted quickly, the mass during fusion exhibiting a constant temperature of $7^{\circ}2$. After complete fusion, the glycerin did not resolidify even when cooled to -18° and agitated (Gladstone, *Chem. Soc. J.* [2] v. 384; Crookes, *Chem. News*, xv. 26). According to Werner (*Zeitschr. f. Chem.* [2] iv. 413), commercial glycerin may be made to crystallise by passing a few bubbles of chlorine into it.

Berthelot found that glycerin fermented in contact with chalk and animal substances yields alcohol (ii. 888). According to Béchamp, the process is more complex, yielding ethyl alcohol and some of its higher homologues, together with acetic, propionic, butyric, and valeric acids; the evolved gases consisted of carbon dioxide, water, and nitrogen (*Zeitschr. f. Chem.* [2] v. 663).

Glycerin oxidised by nitric acid of sp. gr. 1.5 yields—in addition to glyceric acid (ii. 875)—racemic, formic, glycollic, and glyoxylic acids (Heintz, *Ann. Ch. Pharm.* clii. 325).

Glycerin treated with sulphur chloride, as for the preparation of dichlorhydrin (ii. 890), yields also a viscid liquid, which contains chlorine and sulphur, is insoluble in water, sparingly soluble in alcohol, easily in ether, and decomposes, especially in contact with water or moist air, with continued evolution of sulphurous acid and separation of sulphur. It is decomposed by sodium ethylate, yielding ethyl chloride, ethyl oxide, glycerin-mercaptan, and sodium sulphite. It appears to be a mixture or compound of equal molecules of the bodies $O^2Cl.SO.C^3H^3$ and $OSCl.(C^3H^3)H^3$, or it perhaps has the constitution of a chlorinated hyposulphurous ether, $O^2Cl^2.(S^2O)(C^3H^3)^2$ (Wolff, *Ann. Ch. Pharm.* cli. 59).

Glycerides containing Monatomic Alcohol-radicles.—The ethers of this class containing 3 at. ethyl, &c., are formed, similarly to the acetals, by heating acrolein with the corresponding alcohol and a little acetic acid (Alsberg, *Ann. Ch. Pharm.* cxxxi. 123). **Trimethylin**, $C^3H^3O^3 = C^3H^3(CH^3)^3O^3$, obtained by heating 1 vol. acrolein, 3 vol. methyl alcohol, and 0.5 vol. acetic acid to 100° for several hours, is a fragrant ethereal liquid, moderately soluble in water, boiling at 148° , and having a sp. gr. of 0.9483 at 0° . **Triethylin**, $C^3H^3O^3 = C^3H^3(C^2H^5)^3O^3$, which Reboul a. Lourenço obtained by treating diethyl-chlorhydrin with sodium-ethylate (i. 884), is also produced by heating 1 vol. acrolein, 1 vol. alcohol, and 0.5 vol. acetic acid. It is a fragrant ethereal liquid, moderately soluble in water, boiling at 186° , and having a

sp. gr. of 0.8955 at 15°. *Triamylin*, $C^3H^9O^2 = C^3H^4(C^3H^{11})^3O^2$, appears to be formed by heating 1 vol. acrolein, 3 vol. amyl alcohol, and 0.5 vol. acetic acid to 110°, but is decomposed by distillation.

Diethyl chlorhydrin, $C^2H^5(OC^2H^5)(OH)Cl$, is formed by passing hydrochloric acid gas into a mixture of acrolein with 2 vol. absolute alcohol:

It is a heavy oily liquid, having a sweetish ethereal odour, and sp. gr. 1.03 at 10.5°. By sodium ethylate in alcoholic solution it is converted into triethylin (Alsberg, *Jenaische Zeitschr.* i. 407).

Nitroglycerin. $C^3H^5(NO^2)_3O^2$.—This compound, related to glycerin in the same manner as gun-cotton to cellulose, is violently explosive, but nevertheless requires the fulfilment of special conditions for the development of its explosive force. Its explosion by the simple application of heat can only be accomplished if the source of heat be applied for a long time in such a manner that chemical decomposition is established in some part of the mass, and is favoured by the continued application of heat to that part. Under these circumstances, the chemical change proceeds with rapidly accelerating violence, and eventually the heated portion is suddenly transformed into gaseous products, which transformation is instantly communicated throughout the whole mass. This result can be obtained more expeditiously and with greater certainty by exposing the substance to the convulsive action of a detonation produced by the ignition of a small quantity of fulminating powder, closely confined and placed in contact with or in proximity to the nitroglycerin (Abel, *Chem. Soc. J.* [2] viii. 46). See COMBUSTION, p. 487.

Nitroglycerin is well adapted for blasting, its destructive action being estimated at about ten times that of an equal weight of gunpowder. The first attempts to apply it as a mining agent were made by A. Nobel, a Swedish engineer, in 1864. Some experiments were first made with gunpowder saturated with nitroglycerin. This powder burnt much as usual in the open air, but when confined in shells or blast-holes, it produced greater destructive effects than ordinary powder. Nitroglycerin cannot be employed as a blasting agent in the ordinary way, as the application of flame from a common fuze would not cause it to explode; but when it is introduced in a suitable case into a blast-hole, and a fuze having a small charge of gunpowder attached to its extremity is fixed immediately above it, the concussion produced by the exploding gunpowder effects the explosion of the nitroglycerin. The use of nitroglycerin is, however, attended with very great danger, on account of its great liability to explode by concussion or by friction during transport. Moreover, it solidifies at a temperature probably as high as 8° C. (56° F.), and the friction of the frozen particles is very apt to give rise to explosion. Nobel has, however, found that the danger of accidental explosion of nitroglycerin may be obviated by mixing it with wood-spirit, which renders it non-explosive by percussion or by heat. When required for use, it may be recovered by adding water to the mixture, which precipitates the nitroglycerin. (See Richardson and Watts's *Chemical Technology*, pt. v. p. 395.)

GLYCEROGEL and **GLYCEROSOL**. Graham's names for the gelatinous and soluble compounds of glycerin and silicic acid (v. 1089).

GLYCOCINE. See GLYCOLLAMIC ACIDS.

GLYCODRUPOSE. See DRUPOSE (p. 547).

GLYCOGEN. This substance exists in mollusca, especially in oysters, which yield 9.5 p. c. of it (reckoned on the dry weight). *Cardium edule* contains 14 p. c. The glycogen of mollusks is very quickly converted into lactic acid (which, when formed in considerable quantity, protects the animal from putrefaction (G. Bisio, *Compt. rend.* lxii. 675; lxx. 175; *Jahresb.* 1866, p. 752; 1867, p. 741).

From the observations of Tichanowitch (*On the Origin of Carbohydrates within and without the Organism*, Cracow, 1866, Russian), it appears that glycogen may be produced in four modifications, according to the diet of the animal which yields it—viz. A, produced by exclusively amylaceous diet; B, by feeding with purified white of egg; C, with purified cheese and a little hogs' lard; D, with purified cheese alone. These four modifications differ in solubility and in their action on polarized light:

	[α] _D	100 c.c. water dissolves at 100° :
A	+ 199.3	2.5 grams.
B	+ 140	203.9 "
C	+ 170.7	0.228 "
D	+ 211	27 "

Stacherbakoff (*Zeitschr. f. Chem.* [2] vi. 240) has shown that glycogen (prepared from the livers of dogs fed for several days on brown bread after three days fasting) is resolved by boiling with dilute sulphuric acid into glucose and a body, α (together with smaller quantities of other bodies, β , γ , and δ , to be presently noticed), which is precipitated by alcohol as a white amorphous viscid mass, drying up in thin layers to a membrane resembling collodion: it dissolves completely in water to a tasteless liquid; dissolves cupric oxide in presence of alkalis, without reducing it; and is coloured red by iodine. This body α is resolved by boiling with sulphuric acid for six hours into glucose and another body, β , which resembles α in appearance and solubility, is coloured dark red by iodine, and reduces cupric oxide in alkaline solution. β is resolved by boiling with sulphuric acid for three hours into glucose and a third body, γ , which also resembles α in appearance, but is not reddened by iodine, and dissolves cupric oxide in presence of potash without reducing it. This body γ is resolved by boiling with sulphuric acid for two hours into glucose, and a fourth body, δ , similar in external character to α , β , and γ , not coloured by iodine, but capable of reducing cupric oxide in alkaline solution. α , β , and γ are insoluble in strong alcohol; δ dissolves easily in water, sparingly in alcohol. The four bodies α , β , γ , δ are all dextrogyrate, but differ in the amount of their specific rotatory power. Lastly, δ boiled with dilute sulphuric acid is completely converted into glucose without the formation of any other body. From these results, Stacherbakoff infers that δ contains at least 6 atoms of carbon, γ at least 12, β at least 18, α at least 24, and glycogen itself at least 30 carbon-atoms, its formula being $C^{30}H^{40}O^{23}$.

GLYCOLIGNOSE. $C^{30}H^{40}O^{21}$ (J. Erdmann, *Ann. Ch. Pharm. Suppl.* v. 223; *Jahresb.* 1867, p. 738).—A substance remaining after exhausting the wood of the spruce fir (*Abies excelsa*, De C.; *Pinus Abies*, L.) with dilute acetic acid, alcohol, and ether. It is yellowish-white and insoluble in all liquids, yielding only traces of cellulose to ammoniacal copper solution; this behaviour is regarded by Erdmann as showing that in fir-wood, as in the stony concretions of pears (p. 547), the primitive cellulose is associated with another substance. Fir-wood is decomposed by boiling with hydrochloric acid, yielding, together with glucose, from 60 to 65 p. c. of an insoluble body, designated by Erdmann as *lignose*:

Lignose is reddish-yellow, insoluble in ordinary solvents, and likewise yields to ammoniacal copper solution only small quantities of cellulose. Boiled with dilute nitric acid it leaves a residue of cellulose. Glycolignose fused with potash yields, together with acetic and succinic acids, a substance which appears to be nearly related to pyrocatechin and protocatechuic acid. The same products are obtained with lignose or with glycodrupose, but not with pure cellulose prepared as above. Cellulose may be regarded as pure when the residue left after repeated treatment with nitric acid, dilute ammonia, and water, is no longer coloured by further boiling with nitric acid.

GLYCOLINIC ACID. $C^8H^8O^4$.—A monobasic acid, isomeric with glyoxylic acid, formed, according to Friedländer (*J. pr. Chem.* xciii. 65; *Jahresb.* 1864, p. 366), by the action of sodium-amalgam on ethyl oxalate mixed with 3 pts. of absolute alcohol [pure ethyl oxalate treated with sodium-amalgam yields desoxalic or racemo-carbonic acid, v. 40]. Sodium-glycolinate, the immediate product of the reaction, crystallises in stellate groups of needles or prisms containing $C^8H^8O^4Na + H^2O$, which are easily soluble in water, nearly insoluble in absolute alcohol, and give off their water at 100° . The acid may be separated from a solution of the sodium salt in weak spirit by an alcoholic solution of oxalic acid, and purified by recrystallisation from alcohol. By evaporation over sulphuric acid, it is obtained as a deliquescent radio-crystalline mass, containing $2C^8H^8O^4 + 9H^2O$, and giving off its water of crystallisation at 100° . It is non-volatile, easily soluble in water and in alcohol, has a strongly acid taste, and is decomposed by heating with strong sulphuric acid.

GLYCOLLIC ACID. $C^3H^3O^3 = \left. \begin{array}{l} \text{CH}^1\text{OH} \\ \text{COOH} \end{array} \right\} \text{or } \left(\begin{array}{c} \text{H} \\ \text{C}^3\text{H}^3\text{O}^3 \\ \text{H} \end{array} \right)^{\text{O}^2}$.—This acid exists in

the juice of unripe grapes, but disappears as the fruit ripens (Erlenmeyer, *Jahresb.* 1864, p. 359; 1866, p. 372). It is formed by the action of hydriodic acid, not in excess, upon diglycollic acid (p. 641), and is found among the products of the action of nitric acid upon glycerin (p. 637). Heated with saturated hydrobromic acid to 100° for two days, it is converted into bromacetic acid: $C^3H^3O^3 + HBr = H^2O + C^2H^2BrO^2$ (Kekulé, *Ann. Ch. Pharm.* cxxx. 360). According to Krupsky

(*Zeitschr. Ch. Pharm.* [2] v. 177), glycollic acid yields by dry distillation chiefly dioxymethylene, $C^2H^4O^2$. The formation of this body in small quantity, together with glycollic acid, in the distillation of glycollic acid, had previously been observed by Heintz (ii. 919), who has since also obtained it, together with glycollic acid, by heating the glycolates of copper and aluminium (*Ann. Ch. Pharm.* cxl. 257):

Calcium glycolate and diglycolate heated with strong sulphuric acid also yield dioxymethylene, together with other products (Heintz):

and

A double salt of glycolate and chloride of calcium, $(C^2H^3O^2)^2Ca.CaCl^2 + 6H^2O$, is formed on leaving a highly concentrated mixed solution of the two salts to itself, or by boiling benzoglycollic acid with hydrochloric acid, neutralising the liquid filtered from benzoic acid with lime, and evaporating to a syrup. It forms large, transparent octohedral crystals, which do not alter in the air or over sulphuric acid, but give off 5 mol. water at 70° , the greater part of the remainder at 180° , and decompose at 200° (Jazukowitsch, *Zeitschr. Ch. Pharm.* 1864, p. 62).

Butyroglycollic Acid. $C^4H^6O^4 = C^2H^3(C^2H^3O^2)O^2$.—The ethylic ether of this acid, $C^6H^{10}O^5.C^2H^5$, is produced by heating ethyl monobromacetate with potassium butyrate. It is a liquid insoluble in water, boiling at 295° – 297° , and resolved by distillation with potassium hydrate into ethyl butyrate and potassium glycolate (Gal, *Bull. Soc. Chim.* [2] vii. 329).

The constitutional formula of this acid is deduced from its mode of formation, viz. by abstraction of H^2O from two molecules of glycollic acid:

also by oxidation of diethylenic alcohol, $(C^2H^3)^2 \left. \begin{array}{l} H^2 \\ \end{array} \right\} O^2$.

Malic acid, with which it is isomeric, is formed by the action of alkalis on

Diglycollic acid crystallises in imperfectly developed orthorhombic prisms of $107^\circ 30'$, having their acute angles truncated by two faces, one of which makes an angle of $69^\circ 58'$ with the faces of the prism. The plane of the optic axes is parallel to the smaller diagonal of the base of the prism (Friedel, *Jahresb.* 1863, p. 362). It melts at 148° and distils at 250° , for the most part undecomposed, a small portion being however resolved into glycollic acid, dioxymethylene, carbon dioxide, carbon monoxide, hydrogen, and carbon (Heintz, *Ann. Ch. Pharm.* cxxviii. 129).

Diglycollic acid heated with *hydriodic acid* is converted into glycollic and acetic acids, or into acetic acid alone, according to the proportion of hydriodic acid used:

and

Sup.

T T

With fuming hydrochloric acid at 130°–140° it yields glycollic acid as chief product, with traces of acetic acid (Heintz, *Ann. Ch. Pharm.* cxxx. 257).

Neutral ammonium diglycollate, obtained by boiling the calcium salt with excess of ammonium carbonate, and evaporating the filtrate, is converted, by heating to 120°, into the acid salt $C^H^2O^2(NH^4)$; and this latter heated to 250°, gives off 2 mol. water, and is converted into diglycollimide, $C^H^2NO^2$, which melts at 142°, dissolves in about 57 pts. water at 14°, more easily in hot water, and crystallises from alcohol in splendid colourless needles (Wurtz, *Ann. Ch. Phys.* [3] lxi. 342).

For the preparation of *calcium diglycollate*, Heintz (*ibid.* cxlv. 91) recommends the following process: 1 pt. of monochloroacetic acid is boiled with excess of quicklime, 3 pts. calcium chloride, and 10 pts. water, for ten hours in a flask provided with an upright condenser; and the liquid, diluted with boiling water, is quickly filtered, freed from excess of lime by carbon dioxide, evaporated to a thin syrup, and then mixed with 3 vol. alcohol. The liquid filtered from the calcium salt thus separated is again evaporated to dryness; the residue boiled with alcohol; and the solution mixed with absolute alcohol as long as a turbidity is thereby produced. The calcium salts precipitated by alcohol and washed therewith are then dissolved in boiling water, and the calcium diglycollate which first crystallises out is separated from the mother-liquor, and purified by washing with cold water. If the mother-liquors on further evaporation yield slender microscopic needles of the glycollate, together with transparent prisms of the diglycollate, the two salts may be separated by washing or levigation with a small quantity of hot water, which dissolves the glycollate and leaves the diglycollate: 10.5 grms. of chloroacetic acid thus treated yield more than 8 grms. of calcium diglycollate and nearly 5 grms. of glycollate.

Ethyl diglycollate, $C^H^2O^2$, C^2H^2 , is prepared by heating the silver salt (obtained by precipitating the hot concentrated solution of the calcium salt with silver nitrate) with excess of ethyl iodide and anhydrous ether in a sealed tube in the water-bath; washing the silver iodide with ether; distilling off the ether and excess of ethyl iodide; volatilising the last portions of these ethers by heating to 100° in a stream of dry air; and finally distilling. It is a colourless liquid, boiling at 240°, heavier than water, having a faint odour, and slightly sweetish, somewhat burning taste. Boiling water dissolves and slowly decomposes it into diglycollic acid and alcohol. The same decomposition is instantly produced by boiling with alkalis and alkaline earths. By alcoholic ammonia it is converted into diglycollodiamide, $N^2(C^H^2O^2)^2H^4$ (Heintz, *Ann. Ch. Pharm.* cxliv. 95).

Amidoglycollic or Glycollamic Acids.

By the action of ammonia on monochloroacetic acid, three amidated acids are produced, viz.,

The ethylic ethers of the same acids are produced by heating ethyl chloracetate with ammonia or ammonium carbonate (Heintz. ii. 905; *Ann. Ch. Pharm.* cxli. 355).

According to Ziegler (*Zeitschr. f. Chem.* [2] v. 659), a concentrated solution of amidoglycollic acid boiled with chloroacetic acid yields the hydrochloride of amidodiglycollic acid; and in like manner, amidodiglycollic acid boiled with chloroacetic acid yields the hydrochloride of amidotriglycollic acid; whereas by boiling glycollic acid with ammonia, neither amidoglycollic, amidodiglycollic, nor amidotriglycollic acid is obtained. Hence it may be inferred that in the preparation of these acids from chloroacetic acid and ammonia, they are formed successively one from the other, an atom of hydrogen directly connected with nitrogen uniting at each step with the chlorine of the chloroacetic acid, while the residue takes the place of the chlorine; thus,

Amidoglycollic acid, Glycollamic acid, Glycolamine, or Glycecoll, $C^2H^2NO^2 = NH^2(CH^2COOH)$, is also formed by heating uric acid with saturated hydriodic acid to 160°–170° in sealed tubes:

On opening the tubes, carbon dioxide escapes, and the solution, treated with lead

hydrate and freed from dissolved lead by sulphydric acid, yields on evaporation colourless crystals of glycocine (Strecker, *Zeitschr. f. Chem.* [2] iv. 215).

On the preparation of glycocine from hippuric acid, see Kraut a. Hartmann (*Ann. Ch. Pharm.* cxxiii. 99). According to the same chemists, glycocine decomposed by baryta-water at 250° gives off ammonia, but no methylamine (compare ii. 903). Ammonia is also formed on heating it with hydriodic acid. When glycocine is heated with lead dioxide and sulphuric acid, the hydrocyanic acid produced, together with carbon dioxide and water, is in great part decomposed, so that the reaction may be represented by the equation, $C^2H^3NO^2 + O^4 = 2CO^2 + NH^3 + H^2O$.

Diglycocine hydrochloride, $2C^2H^3NO \cdot HCl$, is deposited in needles on passing ammonia gas into the alcoholic solution of the neutral salt $C^2H^3NO \cdot HCl$.

Silver-glycocine, $C^2H^3AgNO^2$, is obtained by evaporating a solution of glycocine saturated while hot with silver oxide, over sulphuric acid: if the solution be evaporated by heat, silver is reduced; alcohol throws down from the solution a compound containing 3 at. silver to 4 mol. glycocine. When silver-glycocine is heated with ethyl iodide, 1 at. hydrogen is replaced by ethyl; but the product is decomposed by silver oxide, with reproduction of glycocine. Silver-glycocine distilled with barium hydrate gives off ethyl-methylamine, together with other bases. Boiled in excess with acetyl chloride and anhydrous ether, it yields silver chloride and aceturic acid, $C^4H^5NO^2$ (p. 30) (Kraut a. Hartmann, *loc. cit.*).

Glycocine nitrate, $C^2H^3NO^2 \cdot NO^3H$, forms vitreous crystals belonging to the rhombic system, and having the axes $a : b : c$ (principal axis) in the ratio of 0.74972 : 1 : 0.68865 (Loschmidt, *Jahresb.* 1865, p. 319).

Produced by prolonged boiling of chloracetic acid with ethylamine:

The product evaporated to dryness with excess of barium hydrate, and treated with boiling water, yields a solution containing ethylglycocine, together with a small quantity of the lead salt of ethylamidodiglycollic acid, and an insoluble residue B, consisting chiefly of the latter. On evaporating the solution A, and treating the residue with absolute alcohol, a small quantity of the lead salt B still remains undissolved, whilst the ethylglycocine passes into solution, together with other substances which interfere with the crystallisation. This solution is warmed with baryta-water (after the lead has been removed by hydrogen sulphide); the baryta is precipitated by cupric sulphate; and the filtrate is boiled with cupric hydrate, and mixed after evaporation with alcohol and ether. The cupric salt of ethylglycocine is thereby precipitated, and this when recrystallised from water and mixed in boiling solution with hydrogen sulphide, yields pure ethylglycocine.

Ethylglycocine crystallises from alcohol in indistinct laminae; from the syrupy solution by evaporation over sulphuric acid, in small rectangular tables with truncated edges and summits. It has a sweetish, somewhat sharp, almost metallic taste, melts with decomposition above 160° , and deliquesces on exposure to the air. Its solution in hydrochloric acid evaporated at 100° leaves the hydrochloride $C^2H^3NO^2 \cdot HCl$, which dissolves easily in water and in hot absolute alcohol, and crystallises from the aqueous solution by spontaneous evaporation in right rhombic prisms. The platinumchloride $2(C^2H^3NO^2 \cdot HCl) \cdot PtCl^4 + 6H^2O$ crystallises from water in large orange-red monoclinic prisms. On mixing the solution of ethylglycocine with mercuric chloride, the compound $C^2H^3NO^2 \cdot 2HgCl^2$ is formed as a crystalline precipitate, which crystallises from water in small rhombic prisms; and on dissolving these in hydrochloric acid, the syrupy compound $2(C^2H^3NO^2 \cdot HCl) \cdot HgCl^2$ is produced. Cupric ethylglycocine or cupric ethylamidoglycolate, $(C^2H^3NO^2)^2Cu + 4H^2O$, crystallises in oblique, apparently triclinic prisms, very soluble in water and alcohol, insoluble in ether. Ethylglycocine hydriodide is anhydrous, deliquescent, insoluble in ether, and crystallises like the hydrochloride.

A compound isomeric with this hydriodide is obtained by heating glycocine with

1 mol. ethyl iodide is a sealed tube to 115°–120° (in a paraffin-bath). On evaporating the solution over sulphuric acid, rhombic crystals are obtained consisting of the compound $C^2H^4(C^2H^3)NO^2.HI$, which has an acid reaction, dissolves easily in water, alcohol, and ether, and when treated with silver oxide, is resolved, like a compound ether, into alcohol and glycocine (Schilling, *Ann. Ch. Pharm.* cxxvii. 97); hence, as pointed out by Kraut and Hartmann, the base $C^2H^4(C^2H^3)NO^2$ contained in it is not the ethylglycocine, or ethylamidoglycollic acid, obtained by Heintz, but the ethylic ether of amidoglycollic acid:

Diethylglycocine, $C^4H^{10}NO^2 = \begin{array}{c} CH^2N(C^2H^3)^2 \\ | \\ COOH \end{array}$, is produced by boiling chlor-

acetic acid with diethylamine. The product treated with hydrated lead oxide, freed from lead by hydrogen sulphide, and evaporated, yields diethylglycocine in deliquescent, rhombohedral crystals, very soluble in alcohol, subliming below 100°. Boiled with cupric hydrate, it yields the copper-compound $(C^4H^{12}NO^2)_2Cu + 4H^2O$, in small blue prismatic crystals. The *platinum-compound* $2C^4H^{10}NO^2.PtCl^4 + H^2O$ forms orange-red crystals (Heintz, *Ann. Ch. Pharm.* cxli. 217; *Jahresb.* 1866, p. 378; further, *Zeitschr. f. Chem.* [2] v. 152).

Methylglycocine, $C^2H^4(CH^3)NO^2$.—When glycocine is heated with methyl iodide to 100° for seven hours, sparingly soluble crystals separate, belonging to the rhombic system: they contain iodine, but their composition has not been ascertained. The mother-liquor yields transparent rhombic crystals easily soluble in water and alcohol, and consisting of the compound $C^4H^{10}NO^2I$, regarded by Schilling as the hydriodide of dimethylglycocine, $C^2H^4(CH^3)^2NO^2.HI$. Kraut and Hartmann, on the other hand, regard it as the methyl-iodide of monomethylglycocine. Its formation may be represented by the equation,

inasmuch as only one-third of the glycocine is converted into the methyl-compound, the rest being separated as diglycocine hydriodide, insoluble in absolute alcohol. The iodine-compound, when freed from alcohol and shaken up with silver chloride, is converted into the more stable chlorine-compound $C^4H^{10}(ClI^3)NO^2.CH^3Cl$, which crystallises in white needles, and is not decomposed by water, but is resolved by silver oxide into glycocine and methyl alcohol, like the ethylic ether of glycollamic acid (Kraut a. Hartmann).

Phenylglycocine, $C^2H^4(C^6H^5)NO^2$, is produced, together with aniline hydrobromide, by the action of aniline on bromoacetic acid. On dissolving the product in water, and evaporating, the phenylglycocine crystallises out first, and may be purified by pressure between paper and repeated crystallisation. It forms small indistinct crystals, melting at 110°, moderately soluble in water, sparingly in ether. The aqueous solution has an acid reaction, and dissolves the oxides of silver, lead, and zinc. The silver-compound decomposes partially in the cold, completely at the boiling heat, with formation of a silver speculum (Michaelson a. Lippmann, *Zeitschr. f. Chem.* 1866, p. 15).

Amidodiglycollic Acid. $C^4H^7NO^4 = NH \begin{Bmatrix} CH^2COOH \\ CH^2COOH \end{Bmatrix}$ *Diglycollamidsäure*.—

This acid is formed, together with glycocine and amidotriglycollic acid, by the action of ammonia on monochloroacetic acid (ii. 905). It forms large, anhydrous, strongly acid crystals, having the form of rhombic prisms of about 129°, decomposes above 210°, dissolves in 41 pts. water at 5°, very easily in boiling water, is insoluble in alcohol and ether. It is bibasic. The *acid ammonium salt* $C^4H^7NO^4(NH^4)$, polymeric with glycocine, crystallises in large rhombic prisms of 95° 42'. The *silver salt* $C^4H^7NO^4Ag^2$ is thrown down from the ammonium salt by ammoniacal silver nitrate as a sandy white precipitate. The *monobasic salt* $C^4H^7NO^4Ba$ and the *bibasic salt* are gummy and uncrystallisable. The *cupric salt* $C^4H^7NO^4Cu + 2H^2O$, formed by decomposing the barium salt with cupric sulphate, is a blue crystalline powder, very slightly soluble in water. The *zinc salt* $C^4H^7NO^4Zn$, which is also very slightly soluble, is formed on boiling the acid with recently precipitated zinc carbonate (Heintz, *Ann. Ch. Pharm.* cxxii. 276; cxxiv. 297).

Amidodiglycollic acid also forms salts with the stronger acids. The *hydrochloride* $C^4H^2NO^4 \cdot HCl$ forms large, laminar, right rhombic prisms easily soluble in water, sparingly in alcohol. The *nitrate* $C^4H^2NO^4 \cdot NO^3H$ is a crystalline deliquescent mass. A solution of amidodiglycollic acid in 2 mol. sulphuric gradually deposits the neutral sulphate of amidodiglycollic acid, as a crystalline mass which is resolved by water or alcohol into the acid salt and free amidodiglycollic acid (Heintz, *Ann. Ch. Pharm.* cxxxvi. 213).

An acid isomeric with the preceding, which for distinction may be called diglycollamic (*Diglycollaminsäure*), is produced by treating diglycollimide (p. 649), with excess of warm baryta-water. The solution treated with carbonic acid, filtered, and evaporated, leaves an amorphous residue, from which hot alcohol extracts diglycollamic acid. The portion insoluble in alcohol is barium diglycollamate, $(C^4H^2NO^4)^2Ba + H^2O$, which, by covering the evaporated solution with a layer of alcohol, may be crystallised in small apparently oblique rhombic prisms. This salt is neutral, moderately soluble in water, insoluble in alcohol and ether, decomposes above 145° , and is decomposed by prolonged boiling of its aqueous solution (more easily in presence of excess of baryta), giving off ammonia, and forming diglycollic acid, which is partly precipitated as barium salt. Diglycollamic acid separated from the barium salt by sulphuric acid forms unsymmetrical rhombic prisms of $84^\circ 15'$. It is permanent in the air, moderately soluble in hot water, less in cold water and in alcohol, nearly insoluble in ether; melts above 125° to a mass which slowly solidifies and becomes opaque on cooling (Heintz, *Ann. Ch. Pharm.* cxxviii. 129; *Jahresb.* 1863, p. 364).

Amidodiglycollic and Diglycollamic acids are respectively isomeric with aspartic and malamic acids, which are amidated acids derived from malic acid. Aspartic and amidodiglycollic acids are bibasic; malamic and diglycollamic acids are monobasic. The constitutional formulæ of these acids, and their mode of derivation from malic and diglycollic acids, are indicated by the following formulæ:

The formation of amidodiglycollic acid by the action of ammonia (3 mol.) on chloracetic acid (2 mol.) is represented by the equation:

Diglycollamic acid, being formed by addition of 1 mol. H^2O to diglycollimide, $C^4H^2NO^2$ —which is itself produced from acid ammonium diglycollate by abstraction of $2H^2O$ —may evidently be regarded as formed from the same acid ammonium salt by abstraction of 1 mol. H^2O ; thus:

Ethyl-amidodiglycollic Acid. $C^2H^3NO^4 = NH \left\{ \begin{array}{l} CH(C^2H^3)COOH \\ CH^2COOH \end{array} \right.$ —The neutral ethylic ether of this bibasic acid,

is obtained by heating silver amidodiglycollate with ethyl iodide to 100° . It is a liquid soluble in ether, more soluble in alcohol than amidodiglycollic acid, distilling slowly in a stream of air at 200° – 220° . By boiling with barium hydrate it yields a very sparingly soluble barium salt, from which, after separation of the barium by sulphuric acid, cupric ethyl-amidodiglycollate, $C^2H^3NO^4Cu$, may be prepared. It forms very soluble, blue, microscopic tables, which do not lose weight at 100° (Heintz, *Ann. Ch. Pharm.* cxlv. 214; *Zeitschr. f. Chem.* [2] v. 153).

Nitrosamidodiglycollic Acid. $C^2H^3N^2O^5 = C^2H^3(NO)NO^4$.—Formed, together with oxalic acid, by passing nitrous acid vapour into a solution of amidodiglycollic acid in nitric acid of sp. gr. 1.32. Separated from its barium salt by sulphuric acid, it crystallises from the syrupy solution in small pale yellow rectangular or six-sided tables, very much like the crystals of amidodiglycollic acid, but more soluble in water; it dissolves also in alcohol and ether, and melts without decomposition above 100° . Its calcium salt may be prepared by mixing a cold solution of amidodiglycollic acid in strong nitric acid with calcium nitrite till the liquid turns green, saturating the warm diluted solution with lime, evaporating to dryness, and treating the residue with alcohol. Calcium nitrosodiglycollamate then remains undissolved, which after recrystallisation from water has the composition $C^2H^3N^2O^5Ca + H^2O$; it is more soluble in cold than in hot water, nearly insoluble in alcohol, and crystallises from the syrupy aqueous solution in crusts which do not give off any water at 180° ; the salt crystallised in a vacuum gives off 4 p. c. ($\frac{1}{4}$ mol.) water at 100° , and has then the composition of the salt dried at 160° . By treatment with ammonia and ammonium carbonate it is converted into ammonium nitrosamidodiglycollate; and this, by boiling with baryta-water, is converted into the barium salt, which by evaporation at the boiling heat is deposited in crystalline crusts containing $2C^2H^3N^2O^5Ba + H^2O$, and giving off their water (2.9 p. c.) at 180° – 190° . The salt crystallised at lower temperatures has the composition $C^2H^3N^2O^5Ba + 2H^2O$, and becomes anhydrous at 126° . The silver salt $C^2H^3N^2O^5Ag^2$ crystallises from the warm dilute solution of the calcium salt, mixed with silver nitrate not in excess, in colourless sparingly soluble prisms, which detonate slightly when heated (Heintz, *Ann. Ch. Pharm.* cxxviii. 300).

Amidotriglycollic Acid. $C^2H^3NO^6 = N \left\{ \begin{array}{l} CH^2COOH \\ CH^2COOH \\ CH^2COOH \end{array} \right.$ *Triglycollamidsäure*

(Heintz, *Ann. Ch. Pharm.* cxvii. 269).—Formed, together with amidoglycollic and amidodiglycollic acids, by the action of ammonia on chloracetic acid:

For the mode of separating it from the other two acids, see ii. 904. It forms small anhydrous crystals, of prismatic character, colourless, inodorous, and having only a faint acid reaction; they become white and opaque at 190° ; fuse and decompose at a higher temperature. The acid dissolves in 747 pts. of water at 5° , somewhat more freely in boiling water, is insoluble in alcohol and ether. Hydrochloric acid precipitates it from the concentrated solution of its salts. The slightly ammoniacal solution of the acid gives with silver nitrate a white crystalline precipitate; with mercuric nitrate a precipitate which turns grey; cupric sulphate forms in the slightly acid solution of the ammonium salt an amorphous blue precipitate; lead acetate a white crystalline precipitate. The precipitate formed by barium chloride consists of regular six-sided microscopic tables, very soluble in hot water. Calcium chloride forms a precipitate only at the boiling heat (Heintz).

Amidotriglycollic acid is tribasic, but its monometallic salts have not been obtained. The diammoniac salt $C^2H^3NO^6(NH^4)^3 + H^2O$ crystallises from an aqueous solution covered with a layer of alcohol, in needles very soluble in water; the triargentic salt $C^2H^3NO^6Ag^3$ is a white crystalline powder which detonates when heated (Heintz). The dipotassic salt $C^2H^3NO^6K^2 + H^2O$ crystallises slowly from a solution of 1 mol. amidotriglycollic acid and 1 mol. potassium carbonate mixed with alcohol, in long

needles which give off their water at 110° . The *barium salt* $C^*H^*NO^*Ba + H^*O$, obtained by boiling 1 mol. of the acid with the corresponding quantity of barium hydrate or carbonate, forms sparingly soluble needles which give off their water at 120° , and decompose between 200° and 210° . The corresponding *lead salt* $C^*H^*NO^*Pb + 2H^*O$ crystallises in monoclinic prisms of $37^{\circ} 30'$ and $142^{\circ} 30'$, much truncated in the lateral direction, and with several hemidomes; soluble in about 80 pts. water; becomes anhydrous at 110° – 120° , and decomposes at 210° . The *tribaric salt* $(C^*H^*NO^*)^3Ba^2 + 4H^*O$, produced by boiling the acid or its ammonium salt with excess of barium hydrate, forms thin nacreous quadrate plates, which give off their water at 180° . The *tripbumbic salt* $(C^*H^*NO^*)^3Pb^2$, obtained by adding ammonium amidotriglycollate to an excess of basic lead acetate at the boiling heat, separates in opaque laminae, which do not lose weight at 180° (W. Lüddecke, *Ann. Ch. Pharm.* cxlvii. 272; *Zeitschr. f. Chem.* [2] v. 153).

Triethylic amidotriglycollate, $C^*H^*NO^*. (C^*H^*)^3$, is obtained by heating the triargentic salt with ethyl iodide to 100° for six or eight hours; at higher temperatures it explodes. The ether obtained by distilling the filtered and dehydrated contents of the tube is a yellowish oily liquid having a fruity odour, distilling, with partial decomposition, between 280° and 290° , somewhat more soluble in cold than in hot water. It is decomposed by hydrochloric acid and by alkalis, with formation of amidotriglycollic acid. Its alcoholic solution, saturated with ammonia gas, gradually deposits crystals of amidotriglycollotriamide, $N(CH^*CONH^*)^3$ (Heintz, *Jahresb.* 1866, p. 397).

Amidotriglycollic acid subjected to dry distillation gives off water, ammonia, dimethylamine, carbon dioxide, probably mixed with carbon monoxide and a hydrocarbon, and leaves a carbonaceous residue. Nearly the same products are obtained by distilling the acid barium salt. Amidotriglycollic acid treated with *zinc* and *dilute sulphuric acid* is reduced to ethyl-amidodiglycollic acid: $C^*H^*NO^* + 3H^2 = 2H^*O + C^*H^*NO^*$ (Lüddecke).

On the constitution of diglycollic, diglycollamic, and triglycollamic acids, see also Heintz (*J. pr. Chem.* [2] iii. 69, 120; *Chem. Soc. J.* [2] ix. 236; Kolbe, *J. pr. Chem.* [2] iii. 73; A. Claus, *ibid.* 123).

Glycollamides.

Glycollamide, isomeric with glycocino, is represented by the formula $\begin{array}{c} CH^*OH \\ | \\ (C^*H^*O^*)^n \\ | \\ H^2 \end{array} \Bigg\} O$ or $CONH^2$.

Ethyl-glycollamide, $C^*H^*NO^2 = \begin{array}{c} CH^*OC^*H^2 \\ | \\ CONH^2 \end{array}$, is produced by leaving an alcoholic solution of ethylamine and ethyl glycollate to evaporate over sulphuric acid, and heating the syrupy residue to 120° in a current of air. It is syrupy, boils at 250° , becoming red at the same time, and is decomposed by alkalis, even in the cold, into ethylamine and glycollic acid. It is not altered by boiling with water. When evaporated with hydrochloric acid, it leaves a syrupy residue not containing glycollic acid (Heintz, *Ann. Ch. Pharm.* cxxix. 27).

Amidodiglycollamide, **Glycocinamide**, or **Glycocollamide**. $C^*H^*N^*O$
 $\begin{array}{c} CH^*NH^2 \\ | \\ CONH^2 \end{array} = N \left\{ \begin{array}{c} CH^2(CONH^2) \\ H^2 \end{array} \right\}$ (Heintz, *Ann. Ch. Pharm.* cxlviii. 177; *el.* 67; *Zeitschr. f. Chem.* [2] v. 161).—This compound is formed, together with amidodiglycollodiamide and amidotriglycollotriamide, by the action of alcoholic ammonia in large excess on ethylic monochloracetate, this ether being first converted into chloracetamide:

and the latter, by prolonged action of the ammonia, into the three amides mentioned; thus:

GLYCOLLIC ACID.

To prepare amidoglycollamide, the ethylic chloracetate is left in contact for some days with eight times its volume of saturated alcoholic ammonia; the mixture is then heated to 60° or 70° for 24 hours; the sal-ammoniac which crystallises out on cooling is separated by filtration; the free ammonia is left to evaporate over sulphuric acid; the solution obtained with the smallest possible quantity of water is mixed with alcoholic platonic chloride containing free hydrochloric acid, then with a quantity of ether equal to twice the volume of the liquid; and the precipitate which forms after standing for some time is washed on a filter with ether-alcohol. A small quantity of lukewarm water extracts from this precipitate the platinochloride of amidoglycollamide, whilst ammonium platinochloride and the platinochlorides of amidodiglycollodiamide and amidotriglycollotriamide remain undissolved. The solution yields by spontaneous evaporation large crystals of the platinochloride of amidoglycollamide, which may be freed from an adhering syrupy mass by treatment with dilute alcohol, and from any remaining portions of the three other platinum salts by picking out the crystals and recrystallising them from water.

Amidoglycollamide is also formed by heating glycocine with a large excess of alcoholic ammonia in a sealed tube to 155°–165°.

The *platinochloride of amidoglycollamide*, $2(\text{C}^2\text{H}^3\text{N}^2\text{O}\cdot\text{HCl})\cdot\text{PtCl}_4 + 2\text{H}^2\text{O}$, crystallises in monoclinic prisms with strongly developed oblique end-faces and predominant truncation of the acute prismatic edge; it is easily soluble in water, sparingly soluble in weak spirit, insoluble in strong alcohol and in ether; gives off its water of crystallisation at 105°, intumesces when heated, and yields a sublimate consisting chiefly of sal-ammoniac. Heated with a little hydrochloric acid and platonic chloride dissolved in dilute alcohol, it is converted into another platinum-compound, yellowish-red by transmitted, black-green by reflected light, easily soluble in water, insoluble in water mixed with an equal volume of alcohol. The same compound is formed as a secondary product in the preparation of the platinochloride of amidoglycollamide.

Hydrochloride of Amidoglycollamide, $\text{C}^2\text{H}^3\text{N}^2\text{O}\cdot\text{HCl}$, is obtained by mixing the solution of the platinochloride in a small quantity of water with the quantity of sal-ammoniac required to convert the platinum into ammonium platinochloride; evaporating the filtrate in a vacuum; precipitating the filtered aqueous solution of the residue with alcohol and ether; washing the long thin needles thereby obtained with ether-alcohol; redissolving them in water; and leaving the solution to evaporate. The hydrochloride then separates partly in needles, partly in monoclinic prisms having their acute prismatic edges very much truncated. It is easily soluble in water, sparingly in alcohol, insoluble in ether; does not lose weight at 105°; melts when cautiously heated to a colourless liquid, which solidifies in the crystalline form on cooling; blackens at a higher temperature, boiling and giving off white vapours, and leaves a difficultly combustible, tumefied cinder. By boiling with barium hydrate, half the nitrogen is given off as ammonia, glycocine being at the same time produced. Its concentrated aqueous solution yields with platonic chloride the platinum salt above described; and with *auric chloride*, yellow microscopic right rhombic prisms with angles of about 114°, and sparingly soluble in alcohol.

Amidoglycollamide itself has not been obtained quite pure, because its aqueous solution is easily decomposed by evaporation, or by boiling with aqueous alcohol, into glycocine and ammonia. It is separated from the hydrochloride by silver oxide, and the solution, freed from silver by hydrogen sulphide, leaves, when evaporated in a vacuum, a strongly alkaline syrup, which ultimately solidifies; the solid residue dissolves in the smallest quantity of cold water, but gives off ammonia even in

GLYCOLLIC ACID.

the act of dissolution. If the residue be exhausted with absolute alcohol, in which glycocine is insoluble, the amidoglycollamide dissolves, forming an alkaline solution, which deposits nothing on cooling, but when evaporated leaves amidoglycollamide, partly in microscopic rhombic tables, partly in slender needles, which deliquesce quickly on exposure to the air, impart a strong alkaline reaction to water, and alcohol, and taste like a very weak alkaline-ley. With platinic chloride containing hydrochloric acid the solution yields the platinochloride above described. Amidoglycollamide absorbs carbon dioxide from the air, and its solution, saturated therewith, leaves on evaporation in a vacuum, a strongly alkaline syrup which solidifies in the crystalline form, effervesces with acids, and yields a solution which renders baryta water turbid.

the action of ammonia on ethyl diglycollate, crystallises from warm water in rhombic prisms of about 81° , combined with the end-face and two brachydomes (inclined to the principal axis at 64° and 80°); the prismatic faces are striated, and sometimes replaced by curved octohedral faces. Dissolves easily in boiling water (not quite without decomposition), less easily in cold water and in boiling alcohol, and is nearly insoluble in cold alcohol. It begins to give off ammonia at 115° , and melts at a stronger heat to a transparent colourless liquid, which solidifies in the crystalline form on cooling, but is resolved at a higher temperature into ammonia and diglycollimide: $\text{C}_4\text{H}_8\text{N}_2\text{O}_2 = \text{NH}_3 + \text{C}_2\text{H}_3\text{NO}$. By prolonged boiling of its aqueous solution, diglycollodiamide is converted into ammonium diglycollamate. It dissolves in dilute hydrochloric acid, but concentrated hydrochloric acid added to the solution throws down a crystalline precipitate of hydrochloride of diglycollodiamide, which gradually decomposes even during drying in a vacuum, leaving the pure diamide. The hydrochloric acid solution of diglycollodiamide leaves on evaporation a residue of sal-ammoniac and diglycollic acid (Heintz, *Ann. Ch. Pharm.* cxliv. 95).

Diglycollimide, $\text{C}_2\text{H}_3\text{NO}$ $= \text{N} \left\{ \begin{array}{c} (\text{C}_2\text{H}_3\text{O})'' \\ \text{H} \end{array} \right\}$, is obtained by heating acid ammonium diglycollate, and passes over as a crystalline distillate, which, when purified by recrystallisation from hot alcohol, forms long silky prismatic crystals sparingly soluble in ether, easily soluble in hot water or alcohol, melting at a gentle heat, and subliming slowly at 100° . It crystallises without alteration from hot hydrochloric acid, is not precipitated by platinic chloride, but immediately gives off ammonia when treated with strong solution of potash. A crystalline silver-compound, $\text{C}_2\text{H}_3\text{AgNO}_2$, is obtained by precipitating a hot concentrated solution of diglycollimide with silver nitrate mixed with a little ammonia. When diglycollimide is supersaturated with warm baryta-water, and the liquid is treated with carbonic acid, then filtered and evaporated, an amorphous residue is left, from which hot alcohol extracts amidodiglycollic acid (p. 644) (Heintz, *Ann. Ch. Pharm.* cxxviii. 129; *Jahresb.* 1863, p. 364).

(Heintz, *Zeitschr. f. Chem.* [2] v. 161).—Prepared, together with amidotriglycollotriamide, by heating ethyl chloracetate to 60° – 70° with ammonia not in excess, or only in slight excess, expelling the excess of ammonia in the latter case by evaporation over sulphuric acid, and digesting the residue with absolute ether. The aqueous solution of the portion insoluble in ether generally deposits a certain portion of sal-ammoniac when evaporated in a vacuum, and the mother-liquor mixed with absolute alcohol yields a crystalline precipitate of the hydrochlorides of amidodiglycollodiamide and amidotriglycollotriamide, which must be washed with alcohol, redissolved in water, again precipitated with alcohol, and washed. The solution of these two hydrochlorides in cold water is mixed with silver oxide; the liquid filtered from the silver chloride is freed from silver by hydrogen sulphide; and the liquid filtered from the silver sulphide is evaporated in a vacuum over sulphuric acid. From the residue absolute alcohol extracts the amidodiglycollodiamide, while amidotriglycollotriamide remains dissolved. The two compounds may be purified by crystallisation from cold aqueous solution by spontaneous evaporation, the diamide also by recrystallisation from boiling alcohol.

Amidodiglycolodiamide is moderately soluble in water, and crystallises therefrom in rhombic tables. In hot alcohol it is more soluble than triglycolotriamide, nearly insoluble in cold alcohol. It has a cooling, somewhat nauseating taste; the concentrated aqueous solution is strongly alkaline. When cautiously heated, it melts to a liquid which crystallises on cooling; at a stronger heat it decomposes, giving off chiefly water and ammonium carbonate, and leaving difficultly combustible charcoal. The *hydrochloride* $C^4H^{12}N^4O^2 \cdot HCl$ dissolves easily in water, and crystallises therefrom in rhombic prisms; sparingly in alcohol; it has an acid reaction; melts and decomposes when heated; does not unite with mercuric chloride. The *platinochloride* $2(C^4H^{12}N^4O^2 \cdot HCl) \cdot PtCl^4$ is insoluble in alcohol, sparingly soluble in cold, more easily in hot water, from which it crystallises in small, yellow, shining, elongated, six-sided tables apparently belonging to the rhombic system. The *aurchloride* $C^4H^{12}N^4O^2 \cdot HCl \cdot AuCl^3$ crystallises from hot water in very thin six-sided tables; from boiling alcohol in long needles.

Amidotriglycolotriamide. $C^6H^{12}N^4O^3 = N(CH^2CONH^2)^3$.—Prepared as above described, together with amidodiglycolodiamide, by heating ethyl chloracetate with an equivalent quantity or a slight excess of ammonia (p. 649); also by saturating an alcoholic solution of ethyl amidotriglycolate with ammonia gas. It is easily soluble in hot water, sparingly in alcohol, and crystallises from the latter in rectangular tables, often with truncated summits. It is neutral to vegetable colours, but immediately gives off ammonia when treated with dilute soda-ley, or when its aqueous solution is boiled. On mixing the solution of the amide in cold hydrochloric acid with alcohol, the *hydrochloride* $C^6H^{12}N^4O^3 \cdot HCl$ is formed, which crystallises from its aqueous solution by evaporation over sulphuric acid in rhombic prisms with angles of nearly 55° and 124° . The *platinochloride* $2(C^6H^{12}N^4O^3 \cdot HCl) \cdot PtCl^4$ is insoluble in alcohol and ether, and crystallises from water in deep golden-yellow tables or thin laminae, which when heated with excess of hydrochloric acid, are resolved into ammonium platinochloride and another sparingly soluble platinum salt. The *aurchloride* $C^6H^{12}N^4O^3 \cdot HCl \cdot AuCl^3$ forms golden-yellow needles or elongated laminar crystals. The sulphate, nitrate, and oxalate are also crystallisable; the solution in acetic acid leaves on evaporation the pure triamide (Heintz, *Ann. Ch. Pharm.* cxl. 264).

GLYCOLURIC ACID and **GLYCOLURIL.** See DERIVATIVES OF URIC ACID, v. 960.

GLUCOSE. Syn. with GLUCOSE.

GLYCOTARTARIC ACID. $C^4H^4O^4$.—An acid isomeric with tartaric acid, produced by heating with alkalis a compound formed by the combination of glyoxal with hydrogen cyanide:

and

It is deliquescent, permanent at 100° , but decomposes at higher temperatures, giving off the same odour as tartaric acid. Its alkali-metal salts, even the acid potassium salt, are easily soluble, and their solutions are precipitated by calcium chloride, barium chloride, lead acetate, and silver nitrate. The barium salt consists of $C^4H^4O^4 \cdot Ba + H^2O$; the lead salt of $C^4H^4O^4 \cdot Pb + H^2O$ (Schöyen, *Ann. Ch. Pharm.* cxxxii. 168).

GLYOXYLIC ACID. This acid is found amongst the products of nitric acid on glycerin (p. 638). Debus assigned to it the formula $C^2H^2O^3$, based chiefly on the constitution of the ammonium salt, which consists of $C^2H(NH^2)O^3$. Most of the glyoxylates, however, contain the elements of at least one molecule of water, and may be represented either as $C^2HMO^3 + H^2O$, or as $C^2H^2MO^4$, the acid being regarded as $C^2H^2O^4$. The latter formula is most in accordance with the composition of the silver salt $C^2H^2AgO^4$, for silver salts are almost always anhydrous. The formula $C^2H^2O^4$ is further corroborated by the formation of the acid by heating the silver salt of bromoglycollic acid with water (Perkin a. Duppa, ii. 912):

Further experiments by Perkin a. Duppa (*Chem. Soc. J.* [2] vi. 197) point to the conclusion that the compound $C^2H^2O^3$ is the anhydride of glyoxylic acid, and analogous in composition to glycolide:

Glycolide.

Glyoxylic acid.

Silver dibromacetate, heated with anhydrous ether, is converted into a yellow powder.

GOLD. For analyses of native gold from Siam, see Terreil (*Jahresb.* 1864, p. 825); from Bolivia: D. Forbes (*Phil. Mag.* [4] xxix. 122; *Jahresb.* 1865, p. 865); from Wales: D. Forbes (*Phil. Mag.* [4] xxxiv. 338; *Jahresb.* 1867, p. 972).

For the refining of gold—which is usually effected by fusing it with silver and treating the alloy with nitric or sulphuric acid (ii. 926)—F. B. Miller (*Chem. Soc. J.* [2] vi. 506) recommends the use of chlorine gas, which does not attack the gold even at high temperatures, but converts the silver and the other metals into chlorides. The gold is fused with borax in an earthenware crucible, previously dipped in borax solution to prevent it from being penetrated by the silver chloride. The crucible is closed by a well-fitting, but not luted cover, through which a small hole is bored. As soon as the gold is melted, a tobacco-pipe stem is inserted through this aperture to the bottom of the crucible, and chlorine gas, which need not be dried, is passed into the fused metal. By this simple method, as much as 100 ounces of gold may be refined at once. By means of a heated pipe-stem used as a pipette, a sample of the gold is taken out from time to time and its fineness tested in the usual way. When the operation is completed, the crucible is removed from the fire, left to cool till the gold solidifies, and the chlorides of the other metals, which still remain liquid, are poured into a mould so as to form them into a plate. The gold remaining in the crucible is remelted, and cast into ingots. To reduce the silver chloride, the plate is laid between two flat pieces of iron and immersed for 24 hours in water acidulated with sulphuric acid. The metal thus reduced still contains a little gold, which may be extracted from it by treatment with nitric acid, the gold being thereby separated however, not in globules, but in the flocculent state. It may also be separated by fusing the silver chloride with a small quantity of alkaline carbonate, whereby a certain quantity of metallic silver is separated, which reduces the gold completely. In this manner a regulus of argentiferous gold is obtained, together with silver chloride quite free from gold. By experiments carried out in the Royal Mint at Sidney, it has been found that the method above described is well adapted for practical use, and is not attended with greater loss than the methods generally practised.

Metallic gold dissolves when heated with strong sulphuric and a little nitric acid (the finely divided precipitated metal dissolving most readily), forming a yellow liquid, which when diluted with water, deposits the metal as a violet or brown powder. The solution also becomes covered with a shining film of reduced metal on exposure to moist air. On addition of hydrochloric acid or a metallic chloride, auric chloride is formed, no longer precipitable by water. A gold-solution exhibiting the same properties is formed by electrolysis of a mixture of 9 pts. sulphuric and 1 pt. strong nitric acid by means of a Grove's battery having a gold plate for the positive, and platinum for the negative pole. Gold is likewise attacked in the electrolysis of strong sulphuric acid alone, but immediately reduced again by the evolved hydrogen (Spiller, *Chem. News*, x. 178).

According to Nicklès (*Ann. Ch. Phys.* [4] x. 318), the easily decomposable higher metallic chlorides, bromides, and iodides are capable of dissolving gold. The ether-compounds of the perbromides and perchlorides (p. 596) are easily reduced by gold-leaf, with separation of chlorides and bromides insoluble in ether, and formation of a yellow ethereal solution which exhibits the characteristic reactions of auric chloride. The bromides and chlorides corresponding to the sesquioxides of manganese, cobalt, and nickel (?) dissolve gold even without the aid of ether; so likewise does a solution of ferric bromide at 50° or in sunshine, and the solution of plumbic tetrachloride, whereas a solution of ferric chloride remains unaltered in contact with gold. Free iodine in water does not act upon gold under ordinary pressure; but gold-leaf heated to 50° in a sealed tube with iodine and water is gradually dissolved; also, though more slowly, when the water is replaced by ether. An ethereal solution of iodine dissolves gold-leaf under ordinary pressure in very bright sunshine. Iodine in the nascent state also unites with gold. Ferric iodide, and the iodides corresponding to the higher oxides of manganese, bismuth, and other metals, are decomposed by gold, the formation of aurous iodide (it is sufficient to pour hydriodic acid upon the oxides and add gold-leaf). In presence of ether, hydriodic acid itself is decomposed, with formation of aurous iodide; gold-leaf immersed in ether is quickly dissolved on passing hydriodic acid into the liquid. Hydrobromic acid does not exhibit this reaction (Nicklès)*.

A strip of metallic zinc introduced into a solution of gold in ammonium sulphide becomes coated with metallic gold (C. D. Braun, *Zeitschr. f. Chem.* [2] v. 308).

Auric Hydrate.—The light chestnut-brown compound obtained by precipitating dilute auric chloride with ammonia, and treating the precipitate with nitric acid, forms

* Ferric oxide forms with ether and hydriodic acid a red solution which does not precipitate with potassium ferrocyanide till after standing for some time (Nicklès, x. 479).

off at 100° a quantity of water corresponding to the formula $\text{Au}^{\text{O}}\text{O}^{\text{O}}\text{H}^{\text{O}}$ or $\text{Au}^{\text{O}}\text{H}^{\text{O}}$ (Wittstein, *Zeitschr. f. Chem.* [2] ii. 59).

Gold-purple.—According to J. C. Fischer (*Dingl. pol. J. chem.* 31, 129; *Jahresh.* 1866, p. 265), gold-purple in the air-dried state contains, as essential constituents, only metallic gold, stannic oxide, and water. Its formation takes place in two stages, as shown by the equations:

and

If the solutions are mixed in the requisite proportions (100 pts. gold to 90 pts. tin), the precipitate contains 1 mol. gold to 3 mols. stannic oxide. Any excess of gold remains in solution; but if the solutions are sufficiently dilute, an excess of stannous chloride renders the precipitate richer in stannic oxide: the proportion of the latter is likewise increased by addition of stannic chloride, although this compound has no influence on the formation of the true gold-purple.

Gold Chlorides.—Auric chloride, AuCl^3 , is resolved at about 200° into metallic gold and aurous chloride, AuCl , and at higher temperatures into gold and chlorine. Nevertheless, auric chloride may be sublimed and obtained thereby in rather large crystals, even at a temperature higher than that at which it ordinarily decomposes—namely, by passing chlorine over gold-leaf heated to 300° in a tube; auric chloride is then formed, and condenses on the cooler parts of the tube in long needles. In this case the resolution (dissociation) of the trichloride into gold and chlorine is prevented by the tension of the atmosphere of chlorine by which it is surrounded (see CHEMICAL AFFINITY, p. 425) (Debray, *Compt. rend.* lxi. 984; *Zeitschr. f. Chem.* [2] vi. 87).

According to Prat (*Compt. rend.* lxx. 840; *Zeitschr.* [2] vi. 275), an intermediate chloride is formed by dissolving gold-sponge in a solution of the trichloride, or by heating the monochloride with the trichloride. By passing chlorine over any chloride of gold at a suitable temperature a volatile chloride may be obtained containing more chlorine than the trichloride (?).

GRAHAMITE. A pitch-black mineral resembling albertite, occurring in Ritchie County, Virginia. It is insoluble in alkalis and in alcohol, partially soluble in benzol and in ether, almost wholly in chloroform and carbon bisulphide; softens at about 200°, and contains 76.45 p. c. carbon, 7.82 hydrogen, 13.46 oxygen, and 13.46 ash (H. Wurtz, *Sill. Am. J.* [2] xlii. 420).

GRANATIN. This name is applied by R. Hermann (*Jahresh.* 1867, p. 996) to a mineral, hitherto regarded as serpentine, found near the mouth of the river Achtaargda in Eastern Siberia. It is massive, opaque, ash-grey with a tuffaceous aspect, and uneven dull fracture; hardness = 8; sp. gr. = 2.66. According to Hermann's analysis, it is a mixture of 57.43 p. c. garnet and 42.57 serpentine.

GROFFITE. This mineral has been found by Descloizeaux in the form of greenish granules in the anhydrite of Modane in Savoy (*Bull. Soc. Géol. de France*, xxii. 25; *Jahresh.* 1865, p. 893).

GUAIACOL, $\text{C}^{\text{H}}\text{H}^{\text{O}}\text{O}^2$, has the composition of methyl-pyrocatechin, $\text{C}^{\text{H}}\text{H}^{\text{O}}(\text{CH}^{\text{O}}\text{O}^2)$, and is resolved by distillation with iodine, phosphorus, and water, into methyl iodide and pyrocatechin:

Conversely it is formed by heating pyrocatechin in a sealed tube to 160°–170° with equivalent quantities of hydrate and methyl-sulphate of potassium:

(Gorap-Besanez, *Jahresh.* 1867, p. 668; *Zeitschr. f. Chem.* [2] iv. 392).

Guaiacol occurs, together with creosol, $\text{C}^{\text{H}}\text{H}^{\text{O}}\text{O}^2$, in certain kinds of wood-tar creosote (p. 606). Rhenish beach-tar creosote treated with hydrochloric acid and potassium chlorate yields two compounds, tetrachloroguaiacone and tetrachlorocreosone, whose formation is represented by the equations:

They are separated by cold chloroform, in which tetrachloroguaiacone is insoluble. This compound forms lemon-yellow inodorous scales having a golden lustre, or a laminar crystalline mass. It is idioelectric, sublimes at about 120°, but is decomposed by rapid heating, with formation of copper-red needles and laminae. It is nearly insoluble in cold water and alcohol, dissolves slowly in cold ether, easily in boiling alcohol or chloroform (Gorup-Besanez).

According to Marasse (*Ann. Ch. Pharm.* clii. 80), these compounds are formed, not from guaiacol and creosol, but from cresyl alcohol and phloryl alcohol existing in the creosote (p. 504).

GUANIDINE, $\text{CH}^{\text{N}}\text{N}^{\text{N}}$, or *Carbotriamine*, $\text{C}^{\text{N}}\text{H}_3\text{N}^{\text{N}}$ (Hofmann, *Zeitschr. f. Chem.*,

[2] ii. 1073; iv. 721).—This base is formed: α . By the action of ammonia on chloropierin:

It is easily prepared in large quantity by heating chloropierin to 100° for several hours with a strong alcoholic solution of ammonia, exhausting the resulting saline mixture with anhydrous alcohol, which leaves the sal-ammoniac completely undissolved, and repeating this process once more with the guanidine hydrochloride dissolved in alcohol.

Guanidine is also produced: β . In small quantity by the action of ammonia at 150° on ethyl orthocarbonate:

γ . Together with urea and other products, by the action of ammonia on carbonyl chloride (Bouchardat, *Compt. rend.* lxix. 961).— δ . By heating cyanamide in alcoholic solution with ammonium chloride:

(Erlenmeyer, *Zeitschr. f. Chem.* [2] vii. 28).

Guanidine Nitrate, $\text{CH}^{\text{N}}\text{N}^{\text{N}}.\text{HNO}^{\text{N}}$, is precipitated from a solution of the hydrochloride mixed with potassium nitrate, as a crystalline powder, and may be obtained by recrystallisation from boiling water, in sparingly soluble laminar crystals. Mixed with *silver nitrate*, it forms the crystalline compound $\text{CH}^{\text{N}}\text{N}^{\text{N}}.\text{AgNO}^{\text{N}}$. Moderately concentrated solutions of guanidine hydrochloride and *auric chloride* yield long needles of the gold salt, $\text{CH}^{\text{N}}\text{N}^{\text{N}}.\text{HCl}.\text{AuCl}^{\text{N}}$.

Dry guanidine hydrochloride dissolves easily in heated *aniline*, the solution giving off ammonia when boiled and solidifying on cooling. Water extracts from this product aniline hydrochloride, and leaves a compound which crystallises from alcohol in needles, does not dissolve in acids or in alkalis, and has the composition of *mel-aniline*, $\text{CH}^{\text{N}}(\text{C}^{\text{H}}\text{H}^{\text{N}})^{\text{N}}\text{N}^{\text{N}}$, but differs altogether from it in properties. *Toluidine* acts upon guanidine hydrochloride in a similar manner.

Substituted Guanidines.

Erlenmeyer has obtained methyl-, phenyl-, and tolyl-guanidine by a process similar to that above mentioned for the production of guanidine itself, viz. by the action of cyanamide on the hydrochlorides of methylamine, phenylamine, and toluidine. The *methyl-guanidine* thus obtained does not differ perceptibly in its own properties from those of its salts from methyluramine obtained by oxidising creatine or creatinine (iii. 1009), excepting in the platinochloride, which appears to differ somewhat in crystalline form from that of methyluramine.

Triphenyl-guanidine or **Carbo-triphenyl-triamine**. $\text{C}^{\text{H}}\text{H}^{\text{N}}\text{N}^{\text{N}} = \text{N}^{\text{N}} \left\{ \begin{array}{l} \text{C}^{\text{H}} \\ (\text{C}^{\text{H}}\text{H}^{\text{N}})^{\text{N}} \\ \text{H}^{\text{N}} \end{array} \right.$

—A base having this composition was first obtained by Hofmann (iv. 464) by the action of aniline on carbon tetrachloride:

Bassett (*Chem. Soc. J.* [2] iii. 31) obtained the same compound by the action of aniline on chloropierin; and a base isomeric with this (at first however regarded as *trichloro-hexanilide*, $\text{C}^{\text{H}}\text{H}^{\text{N}}\text{N}^{\text{N}}$) has been obtained by Merz a. Weith (*Zeitschr. f. Chem.* [2] iv. 518, 609; v. 583, 659) by the action of heat and of various desulphurating agents on *asphocarbonilide*.

1. When sulphocarbaniide is distilled, carbon bisulphide and hydrogen sulphide are given off, while an amorphous vitreous mass remains, consisting of triphenyl-guanidine mixed with aniline. The decomposition is represented by the following equations:

The decomposition begins below the boiling point of aniline, and after heating for several hours to 160°, considerable quantities of triphenyl-guanidine are obtained. Carbanilide, $\text{N}^2(\text{CO})^2(\text{C}^6\text{H}^5)^2\text{H}^2$, when thoroughly dry, splits up in the same manner, yielding triphenyl-guanidine, together with aniline, carbon dioxide, and water. The decomposition is represented by equations precisely similar to the above, the sulphur in each being replaced by oxygen.

2. Triphenyl-guanidine is also produced, as a hydrochloride, when sulphocarbaniide is fused with lead chloride:

On exhausting the product with a little alcohol, adding a large quantity of water, and evaporating the filtrate, the pure hydrochloride crystallises out.

3. Ammonium sulphocyanate heated with excess of aniline yields successively sulphocarbaniide (phenylsulphocarbamide), sulphocarbaniide (diphenylsulphocarbamide), and triphenyl-guanidine; thus:

4. Triphenyl-guanidine is likewise produced by heating sulphocarbaniide with metallic copper, cuprous sulphide being also formed, together with greasy secondary products consisting of hydrocarbons, probably resulting from the decomposition of methylene formed in the first instance:

5. Together with phenylsulphocyanate, when sulphocarbaniide is heated to 160°–170° with concentrated hydrochloric acid (Merz a. Weith):

6. Also when an alcoholic solution of iodine is poured into a boiling alcoholic solution of sulphocarbaniide (Hofmann, *Zeitschr. f. Chem.* [2] v. 671):

7. By the action of 1 mol. phosphorus trichloride on 3 mol. carbanilide and 3 mol. aniline (Merz a. Weith):

8. By the action of 2 mol. PCl^3 and 3 mol. CO^2 on 9 mol. aniline:

(Merz a. Weith, *Zeitschr. f. Chem.* [2] vi. 160).

Triphenyl-guanidine is susceptible of three isomeric modifications, viz.,

The base obtained by the methods above given is the α modification; this is shown for example by its formation from sulphocarbaniide and aniline; thus:

Moreover, this base when heated with potash yields nothing but aniline and potassium carbonate, whereas the bases β and γ should yield diphenylamine and ammonia:

Hofmann's carbotriphenyltri-amine, obtained by the action of aniline on carbon tetrachloride, is regarded by Merz a. Weith as different from their triphenyl-guanidine; but the published descriptions of the two products do not exhibit any essential difference of properties. Moreover, Hofmann's reaction should yield a symmetrically constituted triamine identical in structure with that obtained from sulphocarbaniide by the methods above described. This may be seen from the following equation, in which the 4 hydrogen-atoms removed from the 3 aniline molecules to combine with the chlorine are printed for distinction in *italics*:

α Triphenyl-guanidine is nearly insoluble in boiling water, dissolves in 22 pts. of absolute alcohol at 6°, much more easily in the hot liquid, and crystallises therefrom in white needles on cooling. The pure base melts at 143°, but the melting point is considerably lowered by the presence of small quantities of foreign substances. It is not volatile without decomposition. At 250° it gives off a liquid containing aniline, and from 280° upwards a gelatinous liquid smelling like bitter almond oil and solidifying to a hard vitreous mass, while a carbonaceous residue is left.

α Triphenyl-guanidine exhibits some remarkable colour-reactions with oxidising agents. A dilute solution of its hydrochloride, mixed with about 1½ pt. *potassium chlorate* and a little *hydrochloric acid*, acquires a yellowish and after a while a greenish colour.

and deposits dark-coloured flocks, which dissolve in alcohol with a fine violet colour; thin layers of this solution exhibit a fine garnet-red colour by transmitted light; thicker layers are opaque. When a larger quantity of potassium chlorate is used, the tints of the alcoholic solution incline more to red, afterwards to yellowish. Triphenyl-guanidine heated with a very large quantity of potassium chlorate deposits white flocks which become coloured by prolonged boiling, and form compact brick-red to madder-red particles, which are also dissolved by alcohol with violet-red colour. Hypochlorites and other oxidising agents react in the same manner with triphenyl-guanidine. Chlorine-water produces, even in very dilute solutions of the hydrochloride, an immediate whitish turbidity, which becomes flesh-coloured or lilac-coloured on heating the liquid. In concentrated solutions, or on agitation, the cloudy precipitate collects into flocks, probably consisting of chlorinated triphenyl-guanidine. The products obtained by all the processes above described exhibited exactly the same colour-reactions, down to the minutest detail.

Triphenyl-guanidine in alcoholic solution precipitates various metallic salts, e.g. ferrous and ferric salts, but not lead salts. In a stream of hydrochloric acid gas it becomes very hot and absorbs the gas, forming the hydrochloride $C^6H^3N^3.HCl$, which crystallises from water or alcohol with 1 mol. water. The nitrate $C^6H^3N^3.HNO^3$ forms nacreous laminae, which, as well as the hydrochloride, have a distinct alkaline reaction. The sulphate $C^6H^3N^3.H^2SO^4$ crystallises from a hot solution containing free sulphuric acid in broad colourless needles having a strong acid reaction. The oxalate $C^6H^3N^3.C^2H^2O^4$ forms nacreous laminae, also having an acid reaction, but only slightly soluble.

Triphenyl-guanidine heated to 160° – 170° in a sealed tube with a large excess of carbon bisulphide is converted into sulphocarbaniide and phenylsulphocyanate:

and when hydrogen sulphide is passed through it while fused at 170° , aniline distils over abundantly, and sulphocarbaniide remains behind:

As carbon bisulphide, hydrogen sulphide, and triphenyl-guanidine are the final products obtained by the action of heat on sulphocarbaniide, it is easy to see that during this decomposition the carbon bisulphide and hydrogen sulphide will act upon the triphenyl-guanidine in the manner shown by the equations just given, thereby greatly diminishing the quantity of triphenyl-guanidine ultimately obtained; in fact, 90 p. c. of the sulphocarbaniide remains undecomposed (Merz & Weith, *Zeitschr. f. Chem.* [2] vi. 72).

Triphenyl-guanidine is decomposed in a similar manner by heating it to about 250° and passing carbon dioxide through it, the products being carbaniide, aniline, and pungent vapours (perhaps carbaniil). Heated with water to 170° – 180° , it also yields carbaniide and aniline (Merz & Weith).

An alcoholic solution of triphenyl-guanidine absorbs large quantities of cyanogen-gas, and the saturated solution after some time deposits yellowish-white crystals of a base, $C^6H^3N^3$, which in contact with hydrochloric acid assumes a deep yellowish-red colour, due to the formation of a salt. This salt cannot, however, be isolated, being quickly resolved, with evolution of ammonia, into yellow crystals of oxalyl-triphenyl-guanidine, $C^6H^3N^3O^2 = N^3[C^6(C^2O)^2(C^6H^3)]$, formed according to the equation:

This last compound boiled with alcohol and hydrochloric acid yields aniline and diphenyl-parabanic acid, the latter body being ultimately resolved into aniline, oxalic acid, and carbon dioxide (Hofmann, *Berichte d. deutsch. chem. Gesellschaft*, 1870, p. 761).

A base having the composition $C^6H^3N^3$, but differing in properties from the above, is produced by the action of cyanogen on aniline. (See PHENYLTAMINES.)

Tritolyl-guanidine, $C^6H^3N^3 = N^3[C^6(C^6H^3)H^2]$, is obtained by reactions exactly similar to those which yield triphenyl-guanidine, e.g. by fusing sulphocarbaniide (ditolyl-sulphocarbamide, $N^2(CS)^2(C^6H^3)H^2$) with metallic copper, or by heating it alone or with hydrochloric acid. It dissolves in 13.5 pts. alcohol at 0° , more easily in hot alcohol or ether, and crystallises from alcohol in tufts of long satiny needles, resembling theine; very slightly soluble in boiling water. It melts at 122° , and usually solidifies to a transparent vitreous mass; leaves a carbonaceous residue when distilled. Its alcoholic solution has a strong alkaline reaction, and precipitates ferric, cupric, and lead salts.

Sup.

The salts of tritoly-guanidine crystallise with remarkable facility, and are on the whole much less soluble than those of triphenyl-guanidine. The *hydrochloride* $C^{22}H^{23}N^3.HCl + H^2O$ crystallises from cold alcohol by slow evaporation in large transparent prisms; from hot water in more tabular crystals. The *platinochloride* $C^{22}H^{23}N^3.HCl.PtCl^4$ forms slender yellow or orange-coloured needles, sparingly soluble in hot water. The *nitrate* $C^{22}H^{23}N^3.HNO^3$ crystallises on adding nitric acid to a hot solution of the base in aqueous alcohol, in white slender needles; from boiling water in prisms. Dissolves in 1,400 pts. water at 0° . The sulphate $(C^{22}H^{23}N^3)^2H^2SO^4$ crystallises from hot water in iridescent laminae having a neutral reaction and moderately soluble in water (Merz a. Weith).

Tritoly-guanidine is decomposed by carbon bisulphide and by hydrogen sulphide in the same manner as a triphenyl-guanidine. *Diphenyl-tolyl-guanidine* heated with carbon bisulphide yields as chief products, sulphocarbaniide and tolyl-sulphocyanate (Merz a. Weith):

GUARANA or *Uarana*, the fruit of *Paulinia sorbilis*, has been analysed by Peckolt (*Jahresb.* 1866, p. 709). The seed-shells contain 2.443 p. c. caffeine; the shelled seeds, 4.813 p. c.; the pulp, 4.288 p. c.

GUM. Gum-arabic heated to 150° with 2 pts. of acetic anhydride swells up to a mass which, when washed with boiling water and then with alcohol, leaves a white amorphous insoluble powder, which is saponified by alkalis with reproduction of soluble gum. This substance is diacetyl-arabin, $C^8H^8(C^2H^3O)^2O^2$. If the gum be heated to 180° for five or six hours, with excess of acetic anhydride, triacetyl-arabin similar to the former is produced (Schützenberger a. Naudin, *Compt. rend.* lxxviii. 814).

Ritthausen (*J. pr. Chem.* xcii. 321; *Jahresb.* 1867, p. 747) has obtained from the grain of rye a kind of gum soluble in dilute alcohol. It resembles vegetable mucilage, and is obtained by digesting rye-flour with cold alcohol of 50 p. c., and mixing the clear extract with a large quantity of strong alcohol. Theropy voluminous conglum thereby separated dries up over sulphuric acid, after washing with strong alcohol, to a loose colourless mass, which (after deduction of ash) consists of $C^9H^{10}O^2$. When dried and finely pulverised, it forms with 25–30 pts. water, or with 30–40 pts. aqueous alcohol, a thickish solution difficult to filter, which dries up to a yellowish residue resembling gum-arabic. Cupric sulphate and potash form with the solution a light blue precipitate insoluble in excess of potash; lead acetate, neutral or basic, and mercurous nitrate do not precipitate it. The aqueous or alcoholic solution of the gum has no action on polarised light, but by prolonged boiling with dilute sulphuric acid it is converted into dextroglucose.

Chagual gum, a variety brought from St. Jago de Chile, resembles gum-senegal. The portion of it, amounting to about 75 p. c., which is soluble in water, has the composition $C^{12}H^{11}O^{11}$, is not thickened by borax, is precipitated by neutral lead acetate, but not by potassium silicate, and when treated with dilute sulphuric acid is completely converted into dextroglucose (Pribram, *Jahresb.* 1867, p. 747).

On the precipitation of dextrin gum by alcohol from solutions containing vegetable mucilage, see Günsberg (*Bull. Soc. Chim.* v. 526; *Jahresb.* 1863, p. 571).

GUMMIC ACID. This name was given by Reichardt to a crystalline acid, $C^6H^{12}O^{10}$, which he obtained by oxidising glucose with cupric oxide in alkaline solution (ii. 956). It has since been examined by Felsko (*Ann. Ch. Pharm.* cxlix. 358; *Zeitschr. f. Chem.* [2] v. 228), working under Reichardt's direction, who finds that the syrupy light yellow liquid which remains on evaporating a solution of the acid over calcium chloride, has the composition $C^6H^{10}O^{10}$; this he designates as *hydrated gummie acid* (*Gummisäurehydrat*), and represents by the formula $3HO.C^6H^8O^{10} + 6HO$ or $3H^2O.C^6H^{10}O^{10} + 6H^2O = \frac{(C^6H^{10}O^7)^{11}}{H^4} O^6 + 6aq.$, according to which it is a sexbasic acid. It has an intensely sour taste, mixes in all proportions with water and alcohol, turns the plane of polarisation to the left. It is precipitated directly by lime-water, and after neutralisation, by calcium chloride, the precipitate being soluble in acetic acid, insoluble in ammonia; ferric chloride produces, after addition of alcohol, a yellow-brownish precipitate. The acid easily reduces platinum and silver salts. The syrupy acid, after standing for a considerable time, deposits rhombic prisms of gummie anhydride, $C^6H^{10}O^{10}$, which dissolves easily in alcohol and water, and reacts like the acid. The solution is levogyrate. The anhydride does not give off water below 110° ; emits acid empyreumatic vapours between

110° and 120°; melts at 140°-150°; and blackens, with increased emission of empyreumatic vapours, between 160° and 190°.

Gummic acid forms crystallisable salts containing 4 and 6 atoms of univalent metal, 2 or 3 at. of bivalent metal: thus there are two sodium salts containing respectively $C^8H^{10}O^{12}Na^2 + 2aq.$ and $C^8H^{10}O^{12}Na^4H^2 + 2aq.$; a solio-potassic salt, $C^8H^{10}O^{12}Na^2K^2H^2$; and two barium salts containing $C^8H^{10}O^{12}Ba^2 + 6aq.$ and $C^8H^{10}O^{12}.Ba^2H^2$ (Felsko).

Gummic acid has also been examined by A. Claus (*Zeitschr. f. Chem.* [2] v. 152), according to whose analysis it is a bibasic acid, $C^8H^4O^8$, identical or isomeric with oxymalonic acid. Its barium and calcium salts have the composition $C^8H^4O^8Ba$ and $C^8H^4O^8Ca$. Gummic or oxymalonic acid is not, however, the chief product of the oxidation of glucose by alkaline cupric solutions, being formed, indeed, only in small quantity, together with oxalic, formic, and acetic acids, and the gum obtained by Reichardt.

Orygummic acid, $C^8H^{10}O^{11}$, produced by oxidation of gummic acid, is described in vol. iv. p. 312.

GUMMIDES. See GLUCOSIDES (p. 636).

GUN-COTTON. Pelouze and Maurey (*Ann. Ch. Phys.* [4] iii. 186) assign to this substance the formula $C^{24}H^{36}O^{18}.5N^2O^5$; Blondeau (*Compt. rend.* lxi. 378) gives the formula $C^{24}H^{36}O^{18}.5N^2O^5$. Abel, however (*Phil. Trans.* 1866, p. 269; 1867, p. 181; *Chem. Soc. J.* [2] v. 310, 505), has shown, by a series of very carefully conducted experiments, that when Lenk's directions for the cleansing and nitration of the gun-cotton are exactly carried out, uniform products are obtained, whose composition, with the exception of slight variations due to admixtures to be presently noticed, is represented by the formula of trinitrocellulose, $C^{24}H^{14}O^{72}.3N^2O^5$ or $C^8H^{11}(NO_2)^3O^8$ (iv. 777). This result, deduced from numerous analyses, is also in accordance with the increase of weight which the cotton undergoes by nitration. The slight differences between the observed results and those required by the formula of trinitrocellulose are due partly to the presence of a small quantity (0.75 to 1 p. c.) of a yellow acid nitro-compound soluble in alcohol, which is produced by the action of the nitric acid on foreign substances still present in the purified cotton, and partly to the presence of 1 to 1.5 p. c. of the lower nitro-derivatives of cellulose. (See PYROXYLIN, iv. 782.)

Well-prepared gun-cotton exposed to diffused daylight or direct sunshine gradually gives off a little gas, but without undergoing any essential alteration. Pelouze and Maurey found indeed that gun-cotton undergoes rapid decomposition even at temperatures below 100°, giving off nitrous vapours and sometimes exploding; but according to Abel, neither trinitrocellulose nor the less nitrated products just mentioned are affected when pure by a temperature near 100°, and the easy decomposability of gun-cotton sometimes observed is due to the presence of nitro-derivatives of foreign organic substances (the incrusting matter of the cellular tissue), which when heated, quickly decompose, with formation of free acid. This tendency to decomposition may be arrested by impregnating the finished gun-cotton with sodium carbonate. Gun-cotton may be preserved for any length of time by immersing it in water, or saturating it with moisture sufficiently to render it unflammable. In this condition it is less dangerous than gunpowder can be rendered by any process whatever, may be transported as safely as raw cotton, and is less prone than the latter to gradual deterioration by mouldiness and putrefaction.

The normal firing temperature of gun-cotton is about 150°, but under peculiar circumstances it may take fire at 136°, or when very loose masses are slowly heated, not till 205°. When the temperature is very gradually raised, the gun-cotton decomposes without taking fire, and is converted into a brown non-explosive substance (Abel). According to W. L. Scott (*Bull. Soc. Chim.* [2] ix. 383), gun-cotton explodes instantly in contact with the alkali-metals (but not with their amalgams) even when all friction is avoided. Other metals do not act in this way; pulverised arsenic however induces the explosion on percussion.

On the explosion of gun-cotton under the influence of detonating substances, such as fulminating silver and mercury, chloride of nitrogen, &c., see COMBUSTION (pp. 486-488).

GUNPOWDER. Abel, in connection with his experiments on gun-cotton (PYROXYLIN, iv. 779), has also examined the behaviour of gunpowder when heated in rarefied air. When small quantities (4 grains) under an air-pump receiver exhausted to a pressure of 15 to 51 millim., are touched with a fine platinum wire heated to redness, the grains nearest to the wire fuse, give off sulphur-vapours with ebullition, and at last take fire, scattering at the same time the rest of the unignited

powder. Under a pressure of 76 millim. complete ignition takes place after about four seconds. The same phenomena are exhibited in an equally rarefied atmosphere of nitrogen or of oxygen; in the latter case the combustion is somewhat more brilliant. After combustion under very low pressure (below 38 millim.), the atmosphere of the combustion-chamber was always found to contain nitrous acid, and a sulphuretted compound having an odour of horseradish (*Proc. Roy. Soc. xiii. 204*). Similar results have been obtained by Heeren (*Dingl. pol. J. clxxx. 286*).

The products of the combustion of gunpowder under different circumstances have recently been examined by Fedorow (*Zeitschr. f. Chem. [2] v. 12*), who finds, in accordance with Craig (*Dingl. pol. J. clxi. 482*), but contrary to Karolyi (iv. 958), that these products vary in composition according to the mode of combustion. The powder-residue was prepared by firing a pistol within a glass tube 4 feet long, and by firing a 9-pounder copper cannon, using 3 pounds (Russian) of powder for each charge.

Composition of the Powder and of the Charcoal contained in it.

Powder.				Charcoal.			
Potassium Nitrate	.	.	74.175	Carbon	.	.	72.5
Charcoal	.	.	14.835	Hydrogen	.	.	2.9
Sulphur	.	.	9.890	Oxygen	.	.	22.3
Water	.	.	1.100	Ash	.	.	2.3
			100.000				100.0

The residue was dissolved in water, the carbon and sulphur separated by filtration, and the filtrate agitated for several days with cadmium carbonate. The amount of sulphur in the potassium sulphide was calculated from the cadmium sulphate; the potassium hyposulphite was determined by precipitation with silver nitrate; the potassium sulphocyanate was estimated by the calorimetric method (Bunsen's); the carbonate by precipitating with manganese chloride and weighing the resulting manganese oxide, Mn_2O_3 . The amount of potassium nitrate was calculated from the difference. The following results are the mean of several closely agreeing analyses:

Composition of Powder-residue calculated on 100 pounds of dry substance.

	Blank cartridge with:				Cannon-shot with 3-lb. charge	
	0.75 grm.		1.5 grm.			
K^2SO^4	48.25	47.61	40.83	43.28	15.00	15.15
K^2CO^3	23.44	24.13	30.96	31.90	37.00	36.20
$K^2S^2O^8$	16.53	17.03	19.32	17.74	8.28	7.44
K^2S	0.97	0.54	2.49	1.67	38.18	39.55
KNO^3	5.81	5.66	2.79	1.73	—	—
KCNS	0.54	0.54	0.56	0.56	0.33	0.33
S.	4.38	4.49	3.05	2.90	0.22	0.09
C.	4.08	—	—	—	—	1.02
Sand, CuO	—	—	—	—	0.82	0.22
$(NH^4)^2CO^3$	—	traces	—	—	—	—

These analyses show decidedly that an increase of the charge is attended with a more complete combustion of the powder. The higher the pressure attending the explosion, the smaller is the quantity of undecomposed powder ($KNO^3 + C + S$) in the residue, and the greater the amount of potassium sulphide and carbonate in this residue, the sulphate diminishing in the same proportion. At high pressures the quantity of hyposulphite likewise diminishes. Retarded combustion, such as may be obtained by admixture of fatty matter with the powder, acts in the same manner as increased pressure. With a blank charge of 1.5 grm. of a mixture of 100 pts. meal-powder and 0.5 pt. stearic acid, a residue was obtained containing

K^2SO^4	$K^2S^2O^8$	K^2CO^3	K^2S	KCNS	C	S
31.57	22.25	39.09	2.01	0.74	4.02	0.32 = 100.

The proportion of hyposulphite was therefore increased, and that of sulphate diminished.

In the experiments with the cannon, 100 pts. of anhydrous powder yielded 49.61 pts. of dry residue, whence it may be calculated that 1 grm. of powder would yield in

this case 0.039 grm. aqueous vapour, and 258.7 c.c. gases (= 82.6 c.c. N + 162.1 c.c. CO² + 14 c.c. SO² and O). Nearly all the carbon was therefore converted into CO².

The preceding results lead to a theory of gunpowder different from that deduced from the experiments of Bunsen and Schischkoff (ii. 958).

In the combustion of gunpowder several successive reactions take place. First the sulphur takes fire and potassium sulphate is formed; then the excess of oxygen burns the carbon to CO², which escapes with the nitrogen, while the excess of carbon reduces the potassium sulphate, forming potassium carbonate, hyposulphite, and free carbon dioxide (or monoxide); thus:

If the proportion of sulphur in the powder does not correspond with the normal composition $2\text{KNO}_3 + \text{S} + 3\text{C}$, as in Russian powder or in the sporting powder used in the experiments of Bunsen and Schischkoff, K₂CO₃ is formed in the first stage of the reaction as well as K₂SO₄.

In combustion in an open tube, the two reactions indicated by the above equations are the only ones that take place; but in combustion under pressure the free carbon exerts a further action on the hyposulphite; thus:

In this case also the free sulphur may act upon the potassium carbonate formed as in equation II. The hyposulphite is also decomposed at a high temperature. The sulphur acts upon the potassium carbonate essentially in the manner shown by the equation:

Brugère (*Compt. rend.* lxi. 716) describes a kind of gunpowder prepared by mixing 54 pts. ammonium picrate with 46 pts. nitro. In the combustion of this powder the whole of the charcoal is burnt, and the residue consists entirely of potassium carbonate:

The volume of gas produced by the explosion is about 2½ times as great as that which is formed by the combustion of an equal weight of ordinary gunpowder. The new powder takes fire when touched with a burning body, but not by percussion. At 150° it assumes an orange-red colour, but undergoes no further alteration; at 190° the ammonium picrate begins to volatilise; at 300° the nitro melts, and at 310° the powder explodes. By prolonged contact with water it is resolved into potassium picrate and ammonium nitrate.

White Gunpowder.—This name is applied to an explosive material for fire-arms and for blasting, invented by E. Schultze (*Dingl. pol. J.* clxxv. 453), and consisting of nitrated woody fibre impregnated with salts rich in oxygen. To prepare it, finely divided wood or sawdust is first freed from acids and soluble substances by boiling it with a weak solution of sodium carbonate, and washing in running water, then dried, exposed to a current of steam to separate albuminous substances, again washed, bleached with chlorine, and finally washed, first with cold, then with hot water, and dried. The woody fibre thus purified is nitrated by maceration for some hours in a mixture of nitric and sulphuric acids, then washed with weak alkaline ley and with water, and dried. The product is a feebly explosive material which leaves a considerable carbonaceous residue when burnt; in this state it may be preserved and transported with safety. When required for use, it is steeped in a solution of potassium nitrate or of mixed potassium and barium nitrates, and dried at 32°–44°. This powder is said to be considerably more powerful than ordinary gunpowder as a blasting agent, and to produce little or no smoke; but it does not appear to be well adapted for fire-arms.

Respecting other explosive mixtures proposed as substitutes for gunpowder, see *London Journal of Arts*, 1864, pp. 29, 87; *Chem. News*, xi. 19; *Dingl. pol. J.* clxxii. 229, 236; clxxxiii. 248, 251, 344; *Bull. Soc. Chim.* [2] ii. 391; v. 234; *Jahresh.* 1864, p. 795; 1866, p. 859; also Richardson and Watts's *Chemical Technology*, pt. iv. 435; pt. v. p. 385). Respecting the methods of estimating the force of gunpowder, see the last-mentioned work, pt. iv. p. 474.

GUTTA-PERCHA. The alterations which this substance undergoes in course of time have been carefully studied by W. A. Miller (*Chem. Soc. J.* [2] iii. 273). These alterations depend upon oxidation (ii. 982), which takes place especially when

the gutta-percha is exposed to light and to the alternate action of air and water. Gutta-percha kept under pure water or sea-water retains its original properties for a long time; but if exposed in sunshine to the alternate action of air and water, it gradually increases in weight, becomes brittle, resinous, more soluble in alcohol and in dilute alkalis. Pure milk-white gutta-percha, perfectly soluble in benzol, ether, and carbon bisulphide, has the composition of a hydrocarbon, $C^{20}H^{30}$. Heated to 100° it softens and gradually takes 4.4 p. c. oxygen, becoming brown, resinous, and brittle; the oxidised portion is insoluble in benzol. Commercial gutta-percha, such as is used for the manufacture of cables, becomes liquid at 100° , and contains, together with the pure hydrocarbon and mechanically enclosed water, a considerable quantity of the resinous oxidation-product, as shown by the following analysis:

Hydrocarbon	Resin	Woody fibre	Water	Ash
79.70	15.10	2.18	2.5	0.52 = 100.

After drying at 100° it exhibited the composition A; the oxidised portion soluble in alcohol had the composition B; the portion soluble in benzol, and precipitable therefrom by alcohol, had the composition C:

	Carbon	Hydrogen	Oxygen	
A . . .	84.66	11.15	4.19	= 100.
B . . .	76.15	11.16	12.69	= 100.
C . . .	87.22	12.04	0.74	= 100.

Commercial gutta-percha, if excluded from light, may also be kept for months or even years under water or in air; but when it is exposed to light in the open air, the portions on which the light falls quickly assume the composition above given.

H

HÆMATEIN. See HÆMATOXYLIN (*infra*).

HÆMATIN. See BLOOD (p. 355).

HÆMATOÏDIN. This substance, originally found in blood and afterwards in bile (iii. 3), is most easily obtained, according to Hulm (*Bull. Soc. Chim.* [2] viii. 60), from the *Corpus luteum* of the cow. According to Piccolo a Lieben, however, the dichroic crystals obtained from the latter source are not identical with hæmatoïdin. These chemists also consider it most probable that hæmatoïdin is identical with bilirubin, and propose to designate the new substance from the *Corpus luteum* as luteohaematoïdin or haemolutein (p. 497). Jaffé (*Jahresb.* 1862, p. 537) finds that hæmatoïdin (from the brain of an apoplectic patient) exactly resembles bilirubin in its reaction with nitric acid, becoming first green, then blue, violet, &c.

HÆMATOXYLIN. $C^{16}H^{14}O^6$.—A solution of this substance, or paper saturated with it, is recommended by Wildenstein (*Zeitschr. anal. Chem.* ii. 9) as a test-paper, especially for the detection of ammonia, the fixed alkalis, alkaline earths, and certain metals (iii. 5). Swedish filtering paper thus prepared has a yellowish colour when dry, and is coloured red, violet, or violet-blue by the smallest trace of an alkali.

As hæmatoxylin reduces silver salts, it may be used, like pyrogallie acid, for developing photographic pictures. A solution for the purpose may be prepared with 0.5 pt. hæmatoxylin, 80 pts. distilled water, and 22 pts. acetic acid: a little glycerin may also be advantageously added (Tabensky, *Zeitschr. f. Chem.* [2] v. 386).

Hæmatein may be quickly prepared by passing air containing ammonia, by means of an aspirator, into a bottle containing hæmatoxylin suspended in water, the delivery-tube terminating just above the surface of the liquid: by this arrangement, an excess of ammonia is avoided, which would produce a brown amorphous substance. When a considerable quantity of hæmatoxylin is used, it may be simply drenched with ammoniacal water. The process yields a solution having a fine violet colour, and forming with acid ammonium sulphite a precipitate soluble at the boiling heat (Tabensky).

According to Schützenberger a. Paraf (*Jahresb.* 1862, p. 495), the violet solution of hæmatoxylin in ammonia is decolorised by heating to 100° for 48 hours in an exhausted tube, a colourless pasty mass being formed, which the authors designate as hæmatinamide; on exposure to the air it quickly takes up oxygen, and turns

violet. It is slightly soluble in water, easily in alcohol, ether, and hydrochloric acid, and is precipitated from the latter by ammonia in white flocks.

HÆMIN.**HÆMOGLOBIN.**

} See BLOOD (pp. 352, 356).

HÆMOGLOBIN.

} See CORPUS LUTEUM (p. 497).

HAGEMANNITE. A fluoride occurring at Arksutflord in Greenland, together with cryolite and pachnolite. It is opaque, has an ochre-yellow or wax-yellow colour, and uneven fracture; hardness = 3 to 3·5; sp. gr. 2·59 to 2·60. Contains:

Al	Fe	Ca	Mg	Na	F	Si	H ² O	Insol.

(Shepard & Hagemann, *Sill. Am. J.* [2] xli. 119).

HEAT. THERMOMETRY.—A convenient form of *air-thermometer*, for the approximate measure of temperatures above 300°, has been contrived by Berthelot (*Ann. Ch. Phys.* [4] xiii. 144, and xv. 413). It consists of a cylindrical bulb of glass or silver, with thin sides, of about 4 cubic centim. capacity, communicating at the upper end with a capillary tube of uniform bore, about 1·2 metre long and 0·2 mm. in diameter. At a distance from the bulb of about 200 mm. this capillary stem is bent so as to become horizontal, and at about 250 mm. further on it is bent downwards at a right angle, and, after proceeding vertically downwards for a length of about 730 mm., it is again bent up, and terminates in a wide open bulb. A double graduation is attached to the vertical part of the stem: on one side a scale of millimetres, and on the other a scale of thermometric degrees. These two scales are both divided upon a flat strip of wood, which is supported so as to be capable of being moved a short distance up or down the stem, and then clamped in any required position. The bulb and stem having been made thoroughly dry, a small quantity of pure dry mercury is poured into the bulb at the lower end of the stem, and by means of an air-pump the pressure in the bulb is reduced to 20 or 25 centim. of mercury; in this way part of the air is removed from the thermometer, and on restoring the atmospheric pressure, mercury is driven up towards the top of the vertical part of the stem. If the thermometer is to be used for indicating temperatures near 500°, the quantity of air removed ought to be such that a difference of temperature of 1°, at ordinary atmospheric temperatures, makes a difference of about 1 mm. in the height of the mercury in the stem. The thermometer is graduated empirically by marking on the scale the points at which the mercury stands in the stem when the bulb is surrounded by ice, and by the vapours of boiling water, boiling mercury, and boiling sulphur respectively. These points being marked 0°, 100°, 350°, and 440°, the intermediate temperatures, as well as temperatures below 0° and above 440°, are supplied by inter- and extrapolation. It is evident that the four fixed points must be determined when the barometric pressure is sensibly constant. Berthelot does not admit greater variations than 1 mm. of mercury. When the instrument is used to indicate unknown temperatures, the barometric pressure will in general be different from that under which it was graduated; but the requisite adjustment can be made by immersing the bulb in pounded ice, and pushing the graduated scale up or down the stem until the zero-mark agrees with the extremity of the mercury-column.

The action of the apparatus is easily understood by reference to the laws of the expansion of air. With the dimensions of bulb and stem that have been indicated, the changes of volume of the air in the thermometer consequent on the mercury standing at different heights may be neglected without sensible error; hence, if H_0 be the pressure (measured in millimetres of mercury) which the air supports at 0°, and $H_0 + h$ the pressure supported by it at t° , we have the equation (comp. iii. 49)

$$H_0 + h = H_0(1 + \alpha t),$$

whence

$$1 + \frac{h}{H_0} = 1 + \alpha t,$$

or

$$t = \frac{h}{H_0 \alpha},$$

which shows that the temperature indicated is proportional to the depression h of the mercury-column from the position occupied by it when the thermometer is at 0°, since the denominator $H_0 \alpha$ of the expression for t is constant. This calculation, however, is only approximate, as the expansion of the bulb, the expulsion of some air from the bulb into the stem, and the effect of variation of temperature in the part of the stem

occupied by air, are not taken into account. The effect of these circumstances would be to make the length of a degree upon the stem get gradually less and less as the temperature rises; but with the dimensions indicated this occurs to a very small extent, and the mode of graduation by actually fixing the position of four known temperatures on the scale almost entirely eliminates the errors which might otherwise arise from these causes. Berthelot concludes that the possible error, even at temperatures near 500° , cannot exceed 2 or 3 degrees.

For measuring the temperature of the ocean at great depths, where an ordinary thermometer would give wrong indications in consequence of the pressure supported by the bulb, a Six's thermometer (v. 768) with its bulb enclosed in a second or outer bulb sealed round the neck of the stem, the intermediate space being partially filled with alcohol, was suggested by Professor W. A. Miller (*Proc. Roy. Soc.* xvii. 482), and has been used with success by Dr. W. B. Carpenter (*ibid.* xviii. 408).

Siemens's Resistance Thermometer (iii. 23).—A description and diagram of this instrument will be found in Poggendorff's *Annalen*, vol. cxxix. p. 647; and another form of it, in which the ratio of the resistances of the two coils is indicated by a differential voltmeter, is described in the *Proceedings of the Royal Society*, vol. xix. p. 443.

Specific Heat. Methods of Observation.—A detailed account of Regnault's method of experimenting in the case of solids or liquids, with a full discussion of all the needful corrections, is given in *Pogg. Ann.* cxxii. 269. A modification of the same method, whereby it becomes possible for a single experimenter to perform every part of the process without the help of an assistant, is described in full by Pfandlner (*Pogg. Ann.* cxxix. 108; *Ann. Ch. Phys.* [4] vii. 253). A simplification of Regnault's method of experimenting is also described by Kopp (*Ann. Ch. Pharm. Supplementb.* iii. 25; *Phil. Trans.* 1865, p. 71; *Chem. Soc. J.* xix. [N. S. iv.] 169), but in the way in which he employed it, it does not seem capable of giving very exact results; a more accurate method of carrying out the same process has, however, been given by Bettendorff n. Wüllner (*Pogg. Ann.* cxxiii. 293).

For a description of Bunsen's method, by means of his ice-calorimeter, see *Pogg. Ann.* cxli. 1; *Phil. Mag.* [4] xli. 161; *abstr. Chem. Soc. J.* xxiv. [N. S. ix.] 180; and for the method employed by Julius Thomsen, depending on the observation of the change of temperature caused by the heat given out in the combustion of a constant volume of hydrogen, see *Pogg. Ann.* cxlii. 337.

Numerical Results.—The most important determinations of specific heat that have been made known between the publication of vol. iii. and the end of 1869, with a few still more recent, are collected in the following tables.

The variation of specific heat with temperature has been investigated by Bède (*Mém. couronnés de l'Acad. de Bruxelles*, xxvii. 1; Wüllner's *Lehrbuch der Experimentalphysik*, ii. 241), who finds that the mean specific heat between 0° and any other temperature t° , may be represented by an expression of the form

$$c = k + at,$$

in which k and a are constants depending on the nature of the metal, the former denoting the specific heat at 0° , and the latter the increment of the specific heat per degree above 0° . The following table gives the values which he found for these coefficients for the metals examined, namely:

Copper	$k = 0.0910$	$a = 0.00023$

The specific heats of alcohol and benzene at different temperatures have been determined by Schüller (*Pogg Ann., Ergänzungsbd.*, v. 116). For the mean specific heats of these liquids between 0° and any other temperature t° , his experiments lead to the following results:

Alcohol $0.5585 + 0.00093195t + 0.0000003463t^2$.
Benzene $0.3798 + 0.00072t$.

Values having reference to much higher temperatures have been given by Hirn (*Ann. Ch. Phys.* [4] x. 63) for alcohol, ether, sulphide of carbon, bichloride of carbon, and oil of turpentine.

The specific heat of various aqueous solutions has been investigated by Schüller (*Pogg. Ann.* cxxxvi. 70 and 235) and Thomsen (*Zeitschr. f. Chem.* 1870, p. 729); the following tables give the principal results:

If, when a salt is dissolved in water, both the water and the salt retain the same specific heat that they possess when separate, the specific heat C_p of a solution containing p parts of the salt in 100 parts of water would be represented by the formula

$$C_p = \frac{100 + pk}{100 + p},$$

where k is the specific heat of the salt in the separate state. It appears, however, from Schüller's experiments that, in the cases investigated by him, the relation between the specific heat of a solution and the specific heats of its constituents is less simple than that expressed by this formula. He finds that the specific heat of a solution may be represented by

$$C_p = r \frac{100 + pk}{100 + p},$$

where r is a coefficient (in the cases examined always less than unity) which may either be sensibly constant* or, as is more commonly the case, may vary with the strength of the solution. Hence, in order to calculate the specific heat of a solution of given strength, we require to know the values of r and k , which correspond to the salts employed. Schüller deduces from his experiments the values of r given in the next table; the values of k are in some cases those resulting from his own experiments, and in others they are taken from Regnault's or Kopp's determinations:

* It is clear that, as the proportion of salt diminishes, the specific heat of a solution must approach indefinitely near to unity: hence, as Thomsen points out, the above formula with $r = \text{const.}$ is inapplicable to very dilute solutions.

Name of Salt	t	r
Potassium Chloride . .	·1729	$1 - 0\cdot003194p + 0\cdot000036p^2$
Sodium Chloride . .	·214	$0\cdot9624$
Ammonium Chloride . .	·373	$1 - 0\cdot003996p + 0\cdot0000497p^2$
Sodium Sulphate . .	·2291	$1 - 0\cdot00096p + 0\cdot000046p^2$
Sodium Iodide . .	·0881	$0\cdot9925$
Sodium Nitrate . .	·2671	$1 - 0\cdot00025p + 0\cdot000012p^2$
Potassium Nitrate . .	·2387	$0\cdot98905 - 0\cdot000255p$

The specific heat of mixtures of alcohol and water in various proportions has been examined by Dupré and Page (*Phil. Trans.* 1869, p. 591); the following table gives an epitome of their results:

Specific Heat of Aqueous Alcohol.

Percentage of Absolute Alcohol by Weight	Specific Heat	Percentage of Absolute Alcohol by Weight	Specific Heat
5	1·0150	50	·9063
10	1·0358	60	·8433
20	1·0436	70	·7844
30	0·0260	80	·7169
40	0·9681	90	·6574
45	0·9419	100	·6043

The most remarkable result of this investigation is that when alcohol is added to water, the specific heat of the mixture increases until the proportion by weight of alcohol amounts to 20 per cent., when the specific heat has the maximum value 1·0436; beyond this point, it diminishes as more alcohol is added, until, with a mixture containing nearly 35 per cent. of alcohol, the specific heat is equal to that of pure water. Closely accordant results have been obtained by Schüller (*Pogg. Ann., Ergänzungsbd.* v. 116, 192), who has also determined the specific heats of various mixtures of alcohol, sulphide of carbon, chloroform, and benzene.

Comparison of the Specific Heats of Gases under Constant Pressure and Constant Volume (iii. 40).—The following table gives the values found by various experimenters for the ratio of the specific heat of air under constant pressure to its specific heat when kept at a constant volume:

Ratio	Experimenter
1·4196	Masson (<i>Ann. Ch. Phys.</i> [3] liii. 269).
1·4025	Weisbach (quoted by Zeuner, <i>Wärmetheorie</i> , 1860, p. 38).
1·41	Cazin (<i>Ann. Ch. Phys.</i> [3] lxvi. 243).
1·3845	Hirn (<i>Théorie mécanique de la Chaleur</i> , 1865, p. 69).
1·302	Kohlrausch (<i>Pogg. Ann.</i> cxxvi. 618).
1·41	Jamin and Richard (<i>Compt. rend.</i> lxxi. 336).

All these results, except the last, are deduced from observations of the change of temperature which a mass of air undergoes when it is subjected to a sudden change of density, work being at the same time done either by it or upon it. Jamin and Richard compared the rise of temperature produced by a given quantity of heat (generated by an electric current traversing a metallic wire) in a quantity of air allowed to expand under constant pressure, with the rise of temperature caused in air which was not allowed to expand.

The values given for the corresponding ratio in the case of some other gases are as follows:

Name of Gas	Ratio of Specific Heat	Experimenter
Oxygen	1.41	Cazin (<i>loc. cit.</i>).
Nitrogen	1.41	—
Hydrogen	$\left\{ \begin{array}{l} 1.41 \\ 1.376 \end{array} \right.$	Masson (quoted by Cazin).
Carbonic oxide	1.41	Jamin and Richard (<i>loc. cit.</i>).
Ammonia	1.328	Cazin.
Carbonic acid	$\left\{ \begin{array}{l} 1.291 \\ 1.30 \end{array} \right.$	—
Nitrous oxide	1.285	Masson.
Sulphurous acid	1.262	Jamin and Richard.
Marsh gas	1.257	Cazin.
Ether vapour	1.079	—

Expansion by Heat. *General Formulæ relating to Expansion.*—If the volume of a given body at 0° be represented by V_0 , and the volume of the same body at t° by V , the increase of bulk between 0° and t° , expressed as a fraction of the volume at 0° , will be represented by

$$\frac{V - V_0}{V_0} = e;$$

this quantity may be conveniently called the *expansion* of the body between 0° and t° . Similarly, if the volume at any other temperature t'° be denoted by V' , the expansion between 0° and t'° will be represented by

$$\frac{V' - V_0}{V_0} = e'.$$

These formulæ give the following for the relations between V_0 , V , and V' :

$$V = V_0(1 + e) \quad V' = V_0(1 + e') \quad V' = V \frac{1 + e'}{1 + e}.$$

The last of these expressions may be written in a simpler form; for if e be small compared with unity (as it always is in reality), the value of the fraction will not be sensibly changed if we subtract e from both numerator and denominator: this gives:

$$V' = V(1 + e' - e) \text{ nearly.}$$

If we divide the expansion between 0° and any other temperature t° by the number of degrees within which it takes place, the quotient is the *average expansion, or average increase of bulk of unit volume, per degree, between 0° and the temperature in question.* This quantity is called the *mean coefficient of expansion* between 0° and t° . Thus if Δ and Δ' are the mean coefficients of expansion between 0° and the temperatures t° and t'° respectively, we have

$$\Delta = \frac{e}{t} = \frac{V - V_0}{V_0 t}, \text{ and } \Delta' = \frac{e'}{t'} = \frac{V' - V_0}{V_0 t'}.$$

In general, the values of Δ and Δ' are not equal except for the permanent gases, but if the temperatures t° and t'° lie near together, their difference may be neglected. Within limits where this is allowable, the relations between the volumes at 0° , t° , and t'° may be written

$$V = V_0(1 + \Delta t) \quad V' = V_0(1 + \Delta' t') \\ V' = V \frac{1 + \Delta' t'}{1 + \Delta t} = V[1 + \Delta(t' - t)] \text{ nearly.}$$

The fraction of its volume at 0° by which a given mass of any substance would expand when heated from the temperature t° to the temperature $(t + 1)^\circ$, if it continued to expand at a constant rate for one degree, is called the *coefficient of expansion at t°* . It is the limit towards which the value of the expression $\frac{V' - V}{V_0(t' - t)}$, or $\frac{e' - e}{t' - t}$, approaches as the interval of temperature $t' - t$ gets smaller and smaller.

Expansion of Mercury.—If the mean coefficient of expansion of mercury between 0° and a series of other temperatures, differing from each other by a constant amount, be calculated from the numbers resulting from Regnault's experiments (iii. 55, 56), the value obtained is found to increase uniformly as the temperature for which it is calculated rises. Hence, if a be the value of the mean coefficient of expansion between 0° and 1° , and b be the increment in the value of the mean coefficient corresponding to a rise of one degree in the higher limit of the interval for which it is calculated, we may write as general expressions for the mean coefficients of expansion between 0° and any other temperatures t° and t'°

$$\Delta = a + bt \text{ and } \Delta' = a + bt'.$$

The values of a and b may be found by introducing into the general formula the values of Δ given by experiment for any two values of t , and then solving the two resulting equations for a and b successively. The values calculated by Regnault, from a discussion of all his experiments, are

$$a = 0.000179006 \text{ and } b = 0.000000252316.$$

Expressing the expansion of mercury between 0° and any two temperatures t° and t'° in terms of these constants, we have

$$e = \Delta t = at + bt^2 \text{ and } e' = \Delta t' = at' + bt'^2;$$

consequently for the mean coefficient of expansion between t° and t'° , we get

$$\Delta_{t-t'} = \frac{e' - e}{t' - t} = a + b(t' + t).$$

But if the temperatures t° and t'° are indefinitely near to each other, we have $t' + t = 2t$, and hence the coefficient of expansion of mercury at t° is expressed by

$$\Delta_t = a + 2bt = 0.000179006 + 0.000000504632t.$$

The mean coefficient of expansion of mercury between 0° and 100° has been re-determined by Matthiessen (*Phil. Trans.* 1866, p. 244), by weighing mercury in water at various temperatures. His experiments give the value

$$0.0001812.$$

Expansion of Water (iii. 52).—The rate of expansion of water by heat has been investigated by Matthiessen (*Phil. Trans.* 1866, p. 231) and by Rossetti (*Ann. Ch. Phys.* [4] x. 461; xvii. 370). The method employed by Matthiessen was to determine first the coefficient of linear expansion of glass,* by direct measurement upon a long glass rod, to calculate the coefficient of cubical expansion of the glass by multiplying the linear coefficient by 3, and finally to determine the weight of a piece of the same glass in water at various temperatures. Rossetti's method consisted in ascertaining the weight of water which occupied a known volume at various temperatures, the volume being found by observing the height at which the water stood in a graduated capillary stem connected with a large bulb like that of a thermometer, the capacity of the bulb and of each division of the stem, as well as the coefficient of expansion, having been previously found (apparently by weighings of the instrument when filled to different points with mercury at known temperatures). These determinations therefore depend upon Regnault's measurement of the coefficient of expansion of mercury; Matthiessen's experiments, on the other hand, are of importance as being the only accurate series of observations made by a method which does not presuppose a knowledge of the expansion of mercury. The following table gives the density and volume of water for each degree between -10° and 100° , as calculated by Rossetti from his own experiments and those of Kopp, Pierre, Despretz, Hagen, Matthiessen, Weidner (*Pogg. Ann.* cxxix. 300; *Jahresb.* 1866, p. 100), and Kremers. The columns headed d_t and v_t give the density and volume at t° compared with the density and volume at 0° taken as unity; in the columns headed D_t and V_t the comparison is with the density and volume at 4° . Two columns are added giving a few of the special values found by Weidner, Matthiessen, and Rossetti.

* The approximate composition of the mixture from which the glass was made was '3 parts sand, 2 lead, and 1 alkali.' The mean coefficient of linear expansion was found = 0.00000729 .

Expansion of Water.

100	.95878	1.04300	.95865	1.04312	1.04316	1.04312

The numbers in the above table show that the expansion-curve for water is not symmetrical on the two sides of the point of greatest density, but that the expansion caused by a given fall of temperature from that point is perceptibly greater than that caused by an equal rise of temperature.

The following table gives the temperature at which solutions of chloride of sodium of various strengths possess the greatest density, as well as the densities of the solutions at these temperatures, and their freezing points, as determined by Rossetti (*loc. cit.*):

Maximum Density of Solutions of Salt.

Chloride of Sodium in 100 parts of water. p	Density at 0° . ρ	Density at maximum. d_T	Temperature of maximum density. T	Depression of temperature of maximum density. A	Depression of freezing point. C	$\frac{A}{p}$	$\frac{C}{p}$
			0°	0°	0°		
0	1.000000	1.000130	+ 4.00	0.00	0.00	—	—
0.5	1.003925	1.003988	+ 3.00	1.00	0.32	2.00	0.64
1	1.007634	1.007666	+ 1.77	2.23	0.65	2.23	.65
2	1.015366	1.015367	— 0.58	4.58	1.27	2.29	.63
3	1.023530	1.023583	— 3.24	7.24	1.90	2.41	.63
4	1.030669	1.030890	— 5.63	9.63	2.60	2.41	.65
6	1.045975	1.046952	— 11.07	15.07	3.91	2.51	.65
7	—	—	— 13.69	17.69	4.60	2.53	.65
8	—	1.063102	— 16.62	20.62	5.12	2.58	.64
Water of the Adriatic collected in June	1.026699	1.026774	— 3.21	7.21	1.90		
Water of the Adriatic collected in November	1.028141	1.028261	— 3.90	7.90	2.10		

These results show that (up to a concentration of 8 parts in 100) the depression of the freezing point caused by the solution of common salt in water is strictly proportional to the quantity of salt present, but that the depression of the point of maximum density increases rather more rapidly than the quantity of salt. In these respects Rossetti's experiments entirely confirm the earlier experiments of Depretz (iii. 60) and Rüdorff (iii. 80).

Expansion of other Liquids.—The expansion of water and of several other liquids at temperatures above their usual boiling points has been examined by Hirn (*Ann. Ch. Phys.* [4] x. 32); his results lead to the numbers given in the next table:

Expansion of Liquids at High Temperatures.

<i>t</i>	Water	Alcohol	Sulphide of Carbon	Bichloride of Carbon	Oil of Turpentine
0	—	1·00000	1·00000	1·00000	1·00000
30	—	—	—	1·03489	—
40	—	—	1·04946	—	1·03401
50	—	1·05429	—	—	—
70	—	—	—	1·08909	—
80	—	—	1·10608	—	1·07667
100	1·04315	1·12735	—	1·15310	—
110	—	—	—	—	—
120	1·05992	—	1·17515	—	1·12453
140	1·07949	—	—	—	—
150	—	1·21074	—	1·23296	—
160	1·10149	—	1·26572	—	1·17836
180	1·12678	—	—	—	—
200	1·15900	1·47665	—	—	—

The limits of temperature employed in the experiments from which the above values were deduced were—for *water*, 101°·7 and 181°·95; for *alcohol*, 19°·09 and 151°·3; for *sulphide of carbon*, 22°·39 and 145°·66; for *chloride of carbon*, 31°·29 and 140°·67; for *oil of turpentine*, 17°·99 and 161°·45°. In the case of water, the volume at 100° was assumed to be 1·04315 as compared with that at 4° taken as unity, on the authority of Depretz's experiments.

Experiments on the expansion of benzene and some of its homologues have been made by Louguinine (*Ann. Ch. Phys.* [4] xi. 453), for the results of which see pp. 278, 279.

Expansion of Solids.—The expansion of a considerable number of carefully purified metals and alloys has been determined by Matthiessen (*Phil. Trans.* 1866, p. 861; *Pogg. Ann.* cxxx. 50; abstract in *Proc. Roy. Soc.* xv. 220), by weighing the substances under examination in water at various temperatures. His principal results are given in the table on the following page, where the numbers given in the columns headed *a* and *b* respectively are the values of the coefficients which enter into the formula

$$V_t = V_0 (1 + at + bt^2),$$

expressing the relation between the volume at the temperature t° and the volume at 0° .

The method of experiment adopted by Matthiessen did not admit of his employing higher temperatures than 100°: hence this temperature marks the limit up to which the above numbers may be taken as expressing the results of actual observation. It results from these measurements that the expansion of an alloy is sensibly equal to the sum of the expansions of its constituents, each multiplied by the fraction which represents the proportion by volume in which it enters into the composition of the alloy.

The expansion of a great number of crystallised substances has been examined by Fizeau (*Ann. Ch. Phys.* [4] viii. 335; *Pogg. Ann.* cxxviii. 564; *Compt. rend.* lxii. 1101, 1133; lxiv. 314, 771; *Pogg. Ann.* cxxxii. 292; *Compt. rend.* lxvii. 1005, 1072; *Pogg. Ann.* cxxxv. 372; *Compt. rend.* lxviii. 1125; *Pogg. Ann.* cxxxviii. 26), by a method depending upon the accuracy with which extremely minute movements can be appreciated by observing the changes they produce in a system of 'Newton's rings.' He found, as a general result, that the coefficient of expansion of the substances examined by him is not constant, but is greater at high than at low temperatures; the rate of change of the coefficient with change of temperature, however, he found to be constant. Hence if α be the mean coefficient of expansion for the interval of temperature t° to t'° , α_1 the mean coefficient for the interval t_1° to t'_1 , and $\theta = \frac{t + t'}{2}$ and $\theta_1 = \frac{t_1 + t'_1}{2}$ respectively the mean temperatures of the two intervals, the ratio of the difference of the two coefficients to the difference of the two mean temperatures, namely

$$\frac{\alpha - \alpha_1}{\theta - \theta_1} = \frac{\Delta\alpha}{\Delta\theta},$$

has a constant value for the same substance. Further, if α_0 be the coefficient for any

x x 2

interval of which the mean temperature is θ° , the coefficient a_τ for an interval the mean temperature of which is $\tau^\circ = (\theta \pm n)^\circ$ will be given by the formula

$$a_\tau = a_\theta \pm n \frac{\Delta a}{\Delta \theta}.$$

Hence the expansion of any substance can be expressed completely by means of the two constants a_θ and $\frac{\Delta a}{\Delta \theta}$, and it is the values of these constants that are given in the following tables of Fizeau's results. The relation between the formulæ of expansion expressed by means of these coefficients and those commonly employed will be understood clearly by noticing that the length at t° of a body which measures l_t at t° is given by the formula

$$l_t = l_t [1 + a_\tau (t' - t)] = l_t \left[1 + \left(a_\theta \pm n \frac{\Delta a}{\Delta \theta} \right) (t' - t) \right],$$

where τ is the mean temperature of the interval $t' - t$, and n the number of degrees by which it differs from θ , the temperature for which the value of a is given in the tables; and by observing further that the values of the coefficients in the ordinary formula $l_t = l_0 (1 + at + bt^2)$ are given by the equations $a = a_0$ and $2b = \frac{\Delta a}{\Delta \theta}$.

In the majority of solid substances, the linear expansion which takes place in consequence of a given change of temperature is not the same in different directions, so

that an indefinite number of different values might be found for the coefficient of expansion of the same substance, by measuring it in as many different directions. These different rates of expansion may however in all cases be referred to *three* principal rates of expansion in three directions at right angles to each other, so that the expansion in any given direction may be regarded as the resultant expansion due to three independent components, each of which takes part in the resultant expansion to an extent proportional to the length of the projection upon its own direction of a line parallel to the direction of the resultant expansion. Hence if α , α' , and α'' are the three primary coefficients of expansion, the coefficient of expansion in any direction making the angles δ , δ' , and δ'' respectively with the directions of the three primary directions of expansion may be represented by

$$D = \alpha \cos^2 \delta + \alpha' \cos^2 \delta' + \alpha'' \cos^2 \delta'' \quad . \quad . \quad . \quad (1).$$

But, since the angles δ , δ' , and δ'' are the angles made by the same straight line with three axes at right angles to each other, they fulfil the relation

$$\cos^2 \delta + \cos^2 \delta' + \cos^2 \delta'' = 1 \quad . \quad . \quad . \quad (2).$$

In the case of *amorphous* substances, and those which crystallise in forms belonging to the *cubical* system, the three coefficients of expansion are equal, or $\alpha = \alpha' = \alpha''$: hence formula (1) becomes $D = \alpha (\cos^2 \delta + \cos^2 \delta' + \cos^2 \delta'') = \alpha$. That is to say, the expansion of such substances is the same in all directions.

In crystallised substances belonging to the *quadratic* and *hexagonal* systems, the coefficient of expansion has a special value corresponding to the direction of the principal crystallographic axis, but the coefficients for all directions equally inclined to the principal axis are the same. Hence the expansion of such crystals can be represented by making $\alpha' = \alpha''$ in formula (1), which then becomes $D = \alpha \cos^2 \delta + \alpha' (\cos^2 \delta' + \cos^2 \delta'')$; or, since by formula (2) $\cos^2 \delta' + \cos^2 \delta'' = 1 - \cos^2 \delta = \sin^2 \delta$, the expansion may be expressed by $D = \alpha \cos^2 \delta + \alpha' \sin^2 \delta$. For all directions perpendicular to the axis, $\delta = 90^\circ$, and consequently $\cos \delta = 0$, and $\sin \delta = 1$; hence for all such directions $D = \alpha'$.

In crystals belonging to the *right prismatic system* the three principal axes of expansion are parallel to the crystallographic axes, but the coefficients of expansion corresponding to them are all unequal. The expansion of *monoclinic* crystals corresponds also to three unequal coefficients in directions at right angles to each other, but the relation between the positions of the crystallographic axes and those of the axes of expansion cannot be stated in general terms.

In all cases the coefficient of *cubical* expansion is equal to the sum of the three coefficients of linear expansion, or

$$\alpha_c = \alpha + \alpha' + \alpha'' \quad . \quad . \quad . \quad (3),$$

a relation which becomes $\alpha_c = 3\alpha$ when applied to amorphous substances or to crystals belonging to the regular system, and becomes $\alpha_c = \alpha + 2\alpha'$ when applied to substances crystallised in forms belonging to the quadratic or hexagonal systems. In all cases also the coefficient of *mean linear* expansion is given by the expression

$$\alpha_m = \frac{1}{3} (\alpha + \alpha' + \alpha'') = \frac{1}{3} \alpha_c.$$

The mean linear or the cubical expansion may thus be deduced from the measurement of one, two, or three coefficients of linear expansion, according to the crystalline system to which the substance belongs. It may however be obtained from a single measurement of the coefficient of expansion in a direction equally inclined to the three axes of expansion; for if in equation (1) we make $\delta = \delta' = \delta''$, we get $D = (\alpha + \alpha' + \alpha'') \cos^2 \delta$. But, under these conditions, equation (2) gives $\cos^2 \delta = \frac{1}{3}$, or $\delta = 54^\circ 44'$, and therefore $D = \frac{1}{3} (\alpha + \alpha' + \alpha'') = \alpha_m$.

In the following tables of results, the letters A, B, and C denote the coefficients of expansion parallel to the three principal axes of expansion respectively, M denotes the coefficient of mean linear expansion obtained by direct measurement in a direction inclined at $54^\circ 44'$ to the axes, and M_1 the same coefficient calculated by the formula $\alpha_m = \frac{1}{3} (\alpha + \alpha' + \alpha'')$, or when two coefficients are equal, $\alpha_m = \frac{1}{3} (\alpha + 2\alpha')$. The numbers in the first table are given chiefly by way of illustration of the above-mentioned relations between expansion and crystalline form:

In order to save room, and to make the table easier to read, six or seven ciphers are left out before each of the numbers giving the values of $\frac{\Delta\alpha}{\Delta\theta}$, and a comma is used to mark the *eighth* decimal place: thus the numbers for plate-glass, namely 1,58 and 4,74, are to be read 0.000000158 and 0.000000474 respectively.

The values given above for α_{40} and $\frac{\Delta\alpha}{\Delta\theta}$ in the case of *diamond* indicate that this substance has a minimum volume (or maximum density) at $-42^{\circ}3$, and that below this temperature it expands as the temperature falls. In like manner, a maximum density is indicated for *cuprous oxide* at $-4^{\circ}3$, and for *emerald* at $-4^{\circ}2$. On the other hand, a maximum volume, or minimum density, is indicated for fused *silver iodide* at about -60° .

Fusion and Solidification. The latent heat of fusion of *water* has been determined by Bunsen (*Pogg. Ann.* cxli. 30) by means of his ice-calorimeter. In two experiments he obtained the values 80.01 and 80.01: mean 80.025. He has also determined the *specific gravity of ice* at 0° by a new process, and obtained in three experiments the values

$$0.91682, 0.91673, 0.91667; \text{ mean } 0.91674.$$

Solubility of Salts.—According to Nordenskiöld (*Pogg. Ann.* cxxvii. 309), the effect of temperature in modifying the solubility of such salts as crystallise from aqueous solution without water, even at low temperatures, can be expressed by the following formula:

$$\log_{10} S = a + bt + ct^2,$$

or

$$S = 10 (a + bt + ct^2),$$

in which S is the quantity of a salt which can be dissolved by 1 part of water at the temperature t without forming a supersaturated solution, and a , b , and c are constants depending on the nature of the salt. The values of these constants have been calculated by Nordenskiöld for several substances, with the following results:

Sodium chloride . . .	$\log S = -0.4484 + 0.0105 \left(\frac{t}{100}\right) + 0.0319 \left(\frac{t}{100}\right)^2$
Potassium chloride . . .	$= -0.5345 + 0.379 \left(\frac{t}{100}\right) - 0.09 \left(\frac{t}{100}\right)^2$
Ammonium chloride . . .	$= -0.5272 + 0.5483 \left(\frac{t}{100}\right) - 0.1732 \left(\frac{t}{100}\right)^2$
Barium chloride . . .	$= -0.5084 + 0.3413 \left(\frac{t}{100}\right) - 0.658 \left(\frac{t}{100}\right)^2$
Sodium nitrate . . .	$= -0.1364 + 0.3892 \left(\frac{t}{100}\right) - 0.003 \left(\frac{t}{100}\right)^2$
Potassium nitrate . . .	$= -0.8755 + 0.2003 \left(\frac{t}{100}\right) - 0.7717 \left(\frac{t}{100}\right)^2$
Barium nitrate . . .	$= -1.2793 + 1.2495 \left(\frac{t}{100}\right) - 0.4307 \left(\frac{t}{100}\right)^2$
Potassium chlorate . . .	$= -1.4776 + 1.7834 \left(\frac{t}{100}\right) - 0.5555 \left(\frac{t}{100}\right)^2$
Potassium sulphate . . .	$= -1.1061 + 0.8117 \left(\frac{t}{100}\right) - 0.3245 \left(\frac{t}{100}\right)^2$
Potassium chromate . . .	$= -0.2219 + 0.1741 \left(\frac{t}{100}\right) - 0.0445 \left(\frac{t}{100}\right)^2$

The general law expressed by these formulæ may be thus stated: the rate at which the power of water at any given temperature to dissolve a salt varies with variation of temperature is inversely proportional to its power of dissolving the salt at that given temperature.

Vaporisation and Condensation. *Tension of Vapours.*—The relation between pressure, volume, and temperature may be represented, in the case of perfect gases, by the equation (iii. 45)—

$$\frac{pv}{a+t} = \text{constant},$$

where $a + t$ denotes the temperature counted from the absolute zero. It is known, however, from Regnault's experiments (cf. iii. 48), that the law expressed by this

equation does not apply with absolute strictness to any known gas; but the same experiments have also proved that it represents with a very close approach to accuracy the behaviour of the permanent gases at moderate pressures. In the case of vapours, on the other hand, the relation between pressure, volume, and temperature differs very considerably from this law, though the difference becomes smaller and smaller as the temperature is raised and the pressure is diminished—that is to say, as the vapour is farther removed from the state of saturation. In the case of several vapours, the passage from the state of complete saturation to that of an approximately perfect gas has been made the subject of a detailed investigation by Herwig (*Pogg. Ann.* cxxxvii. 19 and 592; also cxli. 84). The general result of his observations may be thus stated: at any given temperature t , the product of the pressure p into the volume v , which is just sufficient to allow a given mass of a substance to evaporate (so that the whole exists as saturated vapour), bears a constant ratio to the square-root of the absolute temperature at which the evaporation takes place: that is,

$$pv = \kappa \sqrt{a + t},$$

if a is the absolute temperature of melting ice and κ a constant coefficient. But since, as has just been said, the product of pressure into volume gets more and more nearly constant at a given temperature as the vapour is farther removed from the state of saturation, or as its volume becomes greater, if we represent by PV the sensibly constant value which this product assumes at the temperature t , when the vapour is sufficiently expanded, we get, by combining the last equation with the expression $PV = \kappa(a + t)$ representing the law of perfect gases,

$$\frac{PV}{pv} = c \sqrt{a + t},$$

c again being a constant numerical coefficient. Herwig found that this coefficient has a constant value, not only in relation to a given vapour at various temperatures, but that it has the same value, namely 0.0595, for all the vapours examined by him, which were *alcohol, chloroform, sulphide of carbon, ether, water, and bromide of ethylene*.

This law being once established, the volume occupied by a unit mass of any substance in the state of saturated vapour at a given temperature may be deduced from observations of the volume and pressure exerted at the same temperature by a known mass of the vapour when expanded sufficiently to behave as a sensibly perfect gas. Thus if s be the mass of vapour which occupies the volume v under the conditions named, we have, for the volume of the unit mass under like conditions,

$$v_1 = \frac{v}{s} = \frac{PV}{0.0595 \sqrt{a + t} \cdot p \cdot s}.$$

The numbers in the following tables, calculated by this formula from Herwig's experiments, give the volumes occupied at various temperatures by 1 gramme of each of the substances mentioned, when in the form of saturated vapour, and therefore exerting the maximum pressure corresponding to each temperature:

Pressure, Volume, and Temperature of Saturated Vapours.

Sulphide of Carbon							
t	8.5	14.2	20.1	32.0	35.9	40.0	50.0
p	183.09	234.45	294.12	461.54	531.59	614.45	856.5
v_1	1244.8	983.2	791.9	514.8	450.1	392.3	285.6

Alcohol (containing a trace of water)							
t	23.0	30.5	36.4	41.9	47.8	57.8	62.9
p	50.23	77.58	108.0	144.7	196.5	315.8	396.83
v_1	7977.9	5237.9	3798.39	2828.9	2125.0	1342.7	1076.6

Pressure, Volume, and Temperature of Saturated Vapours (continued).

Water						Chloroform		
<i>t</i>	40°0	55°0	69°8	85°0	95°0	30°4	39°8	49°8
<i>p</i>	54·95	117·81	230·23	430·55	629·59	243·08	354·77	514·07
<i>v</i> ₁	18727·3	8929·2	4700·0	2534·1	1772·2	619·5	431·0	301·6

Ether				Bromide of Ethylene		
<i>t</i>	18°2	25°0	35°0	25°0	35°0	43°0
<i>p</i>	405·16	530·16	769·73	474·8	689·5	904·0
<i>v</i> ₁	598·1	461·2	323·7	350·7	245·9	189·9

The numbers in the second line of each table represent the observed maximum pressures measured in millimetres of mercury, and those in the third line represent in cubic centimetres the corresponding volumes of 1 gramme of the several vapours.

TABLE I. (see next page).

1 Molecule of Acid; α molecules of Sodium hydrate.

4. <i>Tetrabasic acid:</i>						
Pyrophosphoric	—	144	288	—	527	546

The phenomena attending the vaporisation of liquids under very great pressure (already mentioned in vol. iii. pp. 95, 96) have been further investigated by Andrews (*Phil. Trans.* 1869, p. 575), for an account of whose results see the article CARBON OXIDES in this volume (p. 401).

Heat of Chemical Action. Numerous determinations of the heating effects of chemical action, especially in relation to the mutual action of acids and bases, have been made by Thomsen of Copenhagen (*Pogg. Ann.* cxxxviii. 65, 205, 495; cxxxix. 193; cxl. 88, 497; abstr. *Zeitschr. f. Chem.* 1870, p. 533). His principal results are contained in the tables given on this and the preceding page, the first of which gives the quantity of heat (in hundreds of grammes-degrees) produced by the action of 1 molecular proportion (in grammes) of each of the acids named upon α molecules of sodium-hydrate in aqueous solution; the second gives the quantity of heat (similarly expressed) which is produced by the action of 1 molecule of sodium-hydrate on α molecules of each acid, also in aqueous solution (200 molecules of water to 1 molecule of sodium-hydrate or of acid).

TABLE II.

1 Molecule of Sodium hydrate; α molecules of Acid.

Name of Acid	α					
	2	1	$\frac{1}{2}$	$\frac{1}{3}$	$\frac{1}{4}$	$\frac{1}{5}$
1. Monobasic acids:						
Hydrochloric	137	137	68.5			
Hydrobromic	137	137	68.5

Nitric	136	137	68			
Hypophosphorous	154	152	76			
Metaphosphoric	142	144	—			
Formic	—	132	—			
Acetic	132	132	66			
2. Bibasic acids:						
Hydrofluosilicic	—	133	133	—	—	
Sulphuric	142	146	155	—	78	
Selenic	—	148	152	—	76	
Sulphurous	—	159	145	—	73	
Selenious	—	148	135	—	69	
Hyposulphuric	—	—	135	—	—	
Chromic	—	131	124	—	63	
Phosphorous	149	148	142	96	—	
Carbonic (aqueous solution)	—	110	101	—	51	
Boric	129	111	100	68	—	34
Silicic	65	43	26	—	13.5	—
Stannic	—	—	—	—	24	—
Oxalic	138	138	141	—	71	—
Succinic	—	124	121	—	61	—
Tartaric	—	124	127	86	—	—
3. Tribasic acids:						
Citric	—	124	125	127	—	69
Orthophosphoric	147	148	135	113	—	69
Arsenic	147	150	138	120	—	62
4. Tetrabasic acid:						
Pyrophosphoric	—	144	143	—	132	91

From these results Thomsen draws the following general conclusions:

a. When 1 molecule of an acid acts upon sodium hydrate in aqueous solution, the evolution of heat is very nearly proportional to the quantity of soda, until this amounts to 1, 2, 3, or 4 molecules according as the acid is monobasic, bibasic, tribasic, or tetrabasic respectively.

b. When 1 molecule of sodium hydrate acts upon an acid in aqueous solution, the evolution of heat is very nearly proportional to the quantity of acid, until this amounts

to 1, $\frac{1}{2}$, $\frac{1}{3}$, or $\frac{1}{4}$ molecule, according as the acid is monobasic, bibasic, tribasic, or tetrabasic respectively.

c. In the case of well-characterised acids, when the quantity of alkali or acid employed is more than is required to form the normal salt, the thermal effect of the excess is inconsiderable.

The only marked exceptions to these rules are presented by silicic acid (which gives no indication of possessing a definite basicity), boric acid, orthophosphoric acid, and arsenic acid.

The heat produced by the combination of several acids with potash, soda, and ammonia, in presence of excess of water, has been redetermined by Andrews (*Trans. Roy. Soc. Edinb.* xxvi. 85). His results are given in the following table, side by side with those which he obtained from similar measurements published in 1841, and are expressed in gramme-degrees of heat produced by the reaction of 1 molecular proportion of each alkali taken in grammes:

Heat produced by Acids and Alkalis (Andrews).

Acid	Potash		Soda		Ammonia	
	1870	1841	1870	1841	1870	1841
Sulphuric . . .	16701	16330	16580	16483	14710	14135
Nitric . . .	14800	15076	14480	14288	12683	12440

Oxalic . . .	15124	14771	15032	14796	13088	12684
Acetic . . .	13805	14257	14000	14046	12316	12195
Tartaric . . .	13508	13612	13400	13135	11744	11400

The quantity of heat generated by the combustion of *hydrogen*, or, more exactly, the quantity absorbed when 1 gramme of hydrogen at 0° and under 760 mm. pressure is produced by the decomposition of water at 0°, has been measured by Kiechl (*Jahresb.* 1869, p. 143), by comparing the heat evolved by an electric current in a voltmeter during the decomposition of a known quantity of water, with that simultaneously evolved by the same current in a wire of resistance equal to that of the voltmeter (comp. iii. 114). As the mean of nine determinations he obtained the number

33,591,

or, leaving out of account two results which differed considerably from the rest,

33,653.

From experiments on the direct combustion of hydrogen, Thomsen (*Zeitschr. f. Chem.* 1871, p. 181) finds 34,034 gramme-degrees to be the quantity of heat due to the formation of 18 grammes of water weighed *in vacuo*.

Determinations of the heat of combustion of various articles of food have been made by Frankland (*Phil. Mag.* [4] xxxii. 182; *Chem. Soc. J.* [2] vi. 33) by burning them under water with potassium chlorate, and deducting from the observed evolution of heat the amount corresponding to the decomposition of the chlorate. (See NUTRITION.)

Mechanical Equivalent of Heat. Several new determinations of the mechanical equivalent of heat have been made within the last eight or ten years. We give here a short statement of the physical principles involved in the various measurements, followed by a comparative table of the results.

Hirn's Determinations.—Four separate series of experiments for the determination of the mechanical equivalent of heat are described by G. A. Hirn (*Théorie mécanique de la Chaleur*, 1^{re} partie, pp. 55–75; Paris, 1865).

1. The first series depended on the measurement of the quantity of heat produced by the expenditure of a known amount of work in overcoming the friction of liquids. The apparatus employed consisted of two concentric cylinders of brass, the inner one being 1 metre long and 0.3 metre in diameter, and the outer one large enough to leave everywhere between it and the smaller one a distance of 0.03 metre. The liquid to be experimented upon was caused to flow slowly through the cylindrical space thus formed, and the heat produced was estimated by measuring the change of temperature undergone by a known mass of the liquid during its passage through the

apparatus, proper allowance being of course made for the quantities of heat lost by radiation and conduction, or absorbed by the solid parts of the apparatus. The work expended was estimated by ascertaining the weight with which it was necessary to load friction-levers pressing against the ends of the outer cylinder in order to prevent it from being carried round by the force of friction acting between the liquid and the solid surfaces when the inner cylinder was made to turn at a known speed.

2. In the second series of experiments water was allowed to escape by a small opening from a cylinder where it was subject to a very high pressure, namely, 452,820 kilogrammes per square metre, and the elevation of temperature in the water was noted. In this experiment the actual energy with which the water escaped was very small, and was very quickly converted into heat in the receiving vessel, so that the work spent in heating each portion of the escaping water was that due to the fall of an equal mass through a height equal to that of the column of water required to produce the actual pressure employed.

3. In the third series the quantities measured were (a) the heat produced when a piece of lead was crushed by a blow, and (b) the mechanical energy spent in the blow.

4. The experiments of the fourth series consisted in observations of the change of pressure in a gas which was suddenly expanded without gaining or losing heat. Under these circumstances, the simultaneous changes of pressure and volume in a perfect gas are such as to fulfil the following equation:

$$\frac{p_1}{p_2} = \left(\frac{v_2}{v_1}\right)^k \quad (1),$$

where p_1 and v_1 represent the initial pressure and volume of the gas, p_2 and v_2 its final pressure and volume, and k the ratio of the specific heat under constant pressure to the specific heat under constant volume. During the change of volume, however, heat is either produced or absorbed; consequently the temperature of the gas changes, and the final pressure p_2 is different from what it would have been if the temperature had remained constant. Let p' be the pressure corresponding to the final volume, supposing the temperature to have remained what it was at first: we then have, by Boyle's law—

$$\frac{v_2}{v_1} = \frac{p_1}{p'} \quad (2),$$

and, substituting this value in equation (1), we get $\frac{p_1}{p_2} = \left(\frac{p_1}{p'}\right)^k$, whence

$$k = \frac{\log p_1 - \log p_2}{\log p_1 - \log p'}.$$

The value of k obtained by Hirn, as the result of about forty experiments with air on this principle, has been already given (p. 669). This being known, the value of the mechanical equivalent is given by the formula

$$J = \frac{H\alpha}{Dc(1 - \frac{1}{k})}$$

(comp. iii. 121), where α is the coefficient of expansion of air, c the specific heat of unit mass of air, and D the mass of unit volume of air at 0° under the pressure H —quantities each of which is known from Regnault's experiments.

Joule's Determination (*Brit. Assoc. Rep.* 1867, pt. i. p. 512).—Joule has determined the value of the mechanical equivalent of heat by measuring the quantity of heat produced in a known time by an electric current of known strength traversing a metallic conductor of known resistance. The principle of the measurement is expressed by the formula

$$J = \frac{C^2 R t}{Q},$$

where Q is the quantity of heat produced in the time t by a current of the strength C in a conductor of resistance R , both C and R being expressed in absolute electromagnetic measure. (See pp. 569–574.)

Viollé's Determination (*Ann. Ch. Phys.* [4] xxi. 64).—When a conducting disc is made to revolve between the poles of a magnet, so that its plane of motion is perpendicular to the line joining the poles, electric currents are produced in the disc; and since these currents do not give rise to any external work, the energy represented by them is entirely converted into heat in the disc. At the same time, the induced currents and the magnet exert upon each other forces which oppose the motion of the disc, and consequently work must be continuously expended in order to keep up a constant speed of rotation. These phenomena have been made to serve as the basis of a determination of the mechanical equivalent of heat by Viollé.

Regnault's Experiments (*Compt. rend.* lxxvi. 209).—Besides the experiments above mentioned, which were undertaken for the special purpose of measuring the mechanical equivalent of heat, Regnault's recently published experiments on the velocity of sound in air may be mentioned here, since they give the data for fixing the ratio of the two specific heats of air, and hence the value of the mechanical equivalent. These experiments gave 330·3 metres per second as the velocity of sound in dry air at 0°, and consequently we have for the value of k (see iii. 41)—

$$k = v^2 \frac{s}{H g \sigma} = 1.393,$$

v being the velocity of sound in metres, g the acceleration due to gravity, σ the weight of unit-volume of mercury, and s the weight of unit-volume of air at 0° under a pressure equal to that of H metres of mercury.

The following table contains the results of the several investigations above mentioned:

Value of the Mechanical Equivalent of Heat.

Experimenter	Result	Method
Hirn . . .	432	Friction of water and brass.
" . . .	433	Escape of water under pressure.
" . . .	441·6	Specific heats of air.
" . . .	425·2	Crushing of lead.
Joule . . .	429·3	Heat produced by an electric current.
Violle . . .	{ 435·2 (copper)	Heat produced by induced currents.
	{ 434·9 (aluminium)	
	{ 435·8 (tin)	
	{ 437·4 (lead)	
Regnault . .	437	Velocity of sound.

It will be remarked that, with one exception, all these values are perceptibly higher than that obtained by Joule from his experiments on the friction of water, and the single process which gave a result almost identical with the number commonly adopted on the strength of Joule's experiments is one which can hardly be made to give a very accurate value. As to the number deduced by Hirn from his experiments on the expansion of air (441·6), he points out that it is certainly too great, on account of the unavoidable errors of the method. Joule's new result is the lowest of three values obtained in distinct sets of observations, but it is adopted by him as the result of the investigation in consequence of more complete precautions to ensure accuracy having been taken in the set of experiments from which it was deduced than in the other two sets. These, however, were closely accordant with each other, and would lead to 431·5 as the value of the mechanical equivalent. Of the numbers obtained by Violle, the one in which he places the greatest confidence is that obtained by the experiments with a copper disc, and he places next the number obtained with a disc of aluminium.

Radiant Heat.

Emissive Power.—The following table gives the comparative emissive powers of the substances enumerated in it at 150°, according to Magnus's experiments (*Pogg. Ann.* cxxxix. 437).

<i>Radiating Substance.</i>	<i>Emissive power at 150°.</i>
Blackened silver	100
Glass 2 mm. thick	64
Fluor-spar 10 mm. "	45·5
Sylvin 3 mm. "	17
Rock-salt 3 mm. "	13
Polished silver 1 mm. "	9·7

When a plate of rock-salt was placed in front of a polished silver plate, either in contact or at a distance of 1 mm. from it, the radiation from both together was considerably more than the sum of their separate radiations (being as much as 41 per cent. of the radiation from the blackened silver plate when they were in contact). The cause of this effect was found to be the reflection by the silver plate of the heat radiated from the second surface of the rock-salt, for it was found to be greatly diminished when the silver plate was blackened and placed at the same distance from the rock-salt. Hence, as Magnus points out, the great importance, in all experiments

upon the nature or amount of the radiation from diathermic substances like rock-salt, of avoiding as far as possible the presence of anything that can radiate or reflect heat through the substance under examination.

The difference between the radiating powers of the same substance, according as its surface is rough or polished, has been investigated by Magnus (*Pogg. Ann.* xl. 337), whose experiments have proved that platinum which has been strongly hammered has the same emissive power as platinum which has been most carefully annealed, and also that when platinum-foil is passed, under great pressure, between a pair of rollers, one of which is smooth and the other covered with fine lines, the emissive power of the two surfaces of the foil is the same. Hence Magnus concludes that the power of emitting radiant heat has no direct connection with the greater or lesser density of the radiating surface (see v. 49). On the other hand, the radiating power of annealed platinum-foil may be doubled by scratching the surface with fine emery-paper; and by coating it with platinum-sponge, its radiating power may be increased sevenfold. In order to account for these results, Magnus supposes that, even in the case of metals, the origin of the heat radiated outwards is not only the geometrical surface, but also that the internal parts of the mass very near to the surface take part in the process; and that the greater radiating power of a rough surface, as compared with that of a smooth surface of the same material, is due to the fact that the irregularities of outline which constitute the roughening diminish in some manner the proportion of rays incident upon the outer surface from the interior which are there reflected back again into the mass.

Reflection.—The proportion in which the heat given out by various diathermic substances at 150° is reflected by surfaces of the same or of different kinds, and under various angles of incidence, has been investigated by Magnus (*Pogg. Ann.* cxxxix. 583). In these experiments, as well as in those to be mentioned presently, under the head *Transmission* (see p. 690), the substance which was employed as the source of the radiation was heated by being suspended by fine platinum wire in a current of heated air, so arranged with reference to a thermo-electric pile that not the smallest effect was produced upon the galvanometer except when a solid radiator was introduced into the current. The principal results of the investigation are given in the following table:

Reflection of Radiant Heat.

		RADIATING SUBSTANCES				
		Lamp-black* on silver	Glass	Rock-salt	Sylvin	Fluor-spar
Direct radiation, without reflection		124.5	119.8	21.5	35.5	63.0
Reflecting surface	Angle of Incidence	Percentage of total incident heat reflected				
Polished Silver . . .	0°	93.6	88.8	84.8	83.3	82.5
	33	94.4	89.4	89.4	92.6	86.0
	45	93.6	94.2	96.9	99.0	87.3
Glass	62	—	7.5	7.0	6.7	—
	33	—	8.6	9.3	9.2	11.0
	45	—	14.8	13.9	13.5	15.0
Rock-salt	62	—	7.6	6.0	6.5	4.9
	33	—	8.3	8.4	8.1	10.0
	45	—	12.9	12.8	10.8	11.7
Sylvin	62	—	2.6	4.6	2.7	2.7
	33	—	3.6	3.5	6.0	5.4
	45	—	8.5	10.7	8.9	10.8
Fluor-spar	62	—	7.2	23.0	15.4	6.5
	33	—	8.6	8.8	24.2	18.1
	45	—	14.3	33.5	24.3	12.4

* The coating of lampblack was necessarily thin, as a thicker one did not adhere; it was probably not thick enough for the lampblack to produce its full effect.

It will be observed that, of the substances whose behaviour is given in this table, fluor-spar is the only one of which the reflecting power varies to any great extent with the nature of the source from which the heat comes. When the angle of incidence is 45° , the proportion of heat reflected varies —

With Silver, between 86 and 94.4 per cent.

"	Glass,	"	8.4	"	11	"
"	Rock-salt,	"	8.2	"	10	"
"	Sylvin,	"	3.5	"	6	"

whereas fluor-spar reflects only 8.8 and 8.6 per cent. respectively of the heat radiated by lampblack and by glass, but as much as 24.2 per cent. of the heat from rock-salt, and 18.1 per cent. of that from sylvin.

Refraction.—The refraction of solar heat by sylvin (native potassium-chloride) has been compared by Knoblauch (*Pogg. Ann.* cxxvi. 66) with its refraction by rock-salt. A beam of solar rays was allowed to pass through two slits, each 2 millim. wide, placed at a distance of 0.93 metre apart, and then through a prism, set at the angle of least deviation, 0.1 metre from the second slit, after which it fell upon a thermoelectric pile, with a linear opening 3 mm. wide. The following table gives the galvanometer-deflections produced by this arrangement of apparatus with a prism of sylvin of refracting angle = 50° , compared with the deflections obtained with a prism of rock-salt of refracting angle = 45° :

Refraction by Sylvin and Rock-salt.

	Sylvin prism of 50°	Rock-salt prism of 45°
In the first zone beyond the Violet (up to the limit)	0.00	0.00
" Violet	0.50	0.30
" Indigo	0.55	0.35
" Blue	0.60	0.45
" Green	0.65	0.50
" Yellow and Orange	1.00	1.00
" Red (as far as the limit)	2.00	2.00
" first zone beyond the Red	2.83	2.50
" second " " " " " "	1.75	1.25
" third " " " " " "	0.50	0.25
" fourth " " " " " "	0.00	0.00

In both cases the greatest heating effect occurs in the part of the spectrum which is less refrangible than the visible red.

The distribution of heating power in a solar spectrum produced by using a silver heliostat mirror and lenses and prisms of rock-salt has also been studied by P. Dessains (*Compt. rend.* lxx. 985). The apparatus used gave an angular separation of about $3^\circ 48'$ between the ends of the visible spectrum, and the greatest heating effect was found on an average at an angular distance of $51'$ from the bright red: sometimes, at eight in the morning, the maximum of heat was at $46'$ only from the red; in other cases, at noon, it was as much as $54'$ from the red. Possibly this difference is owing to the absorption of a considerable part of the least refrangible heat by the water existing in the atmosphere in the liquid state, as mist, which is commonly more abundant in the morning than it is at noon. The first table on p. 690 gives an analysis of the heat-spectrum for about 11 o'clock in the forenoon of April 20, 1870.

If a curve were drawn with abscissæ proportional to the numbers in the first column of this table, and ordinates proportional to the corresponding numbers in the third column, the area enclosed by any part of the curve, the ordinates of its extremities, and the axis of abscissæ would express the total heating effect of the part of the spectrum represented by the corresponding part of the axis of abscissæ. Compared in this way, the total heating effect of the visible spectrum is found to be about $\frac{1}{4}$ of the heating effect of the whole spectrum.

Distribution of Heat in the Solar Spectrum.

Angular Distance	Colour	Comparative Heating Power
0'	Extremity of the Violet	0
30'	Violet	5
2° 18'	Blue	10
3° 0'	Greenish Yellow	23
3° 30'	Bright Carmine	39
3° 48'	Extreme Red	51
4° 0'	} Beyond visible Red }	81
4° 18'		100
4° 24'		94
5° 0'		20
5° 12'		8
6° 0'		0

Transmission.—The transmission of radiant heat from various sources through various media has been examined by Magnus with special reference to the properties of rock-salt (*Pogg. Ann.* cxxxix. 431). The mean results of his most important measurements are given in the following table:

Substances through which the Heat was transmitted	Thickness	Sources of Heat (temperature in all cases, 150°)						
		Rock-salt			Sylvia	Fluor-spar	Silver Chloride	Silver Bromide
		2·5 to 3 mm. thick	15 mm. thick (not quite clear throughout)	18 mm. thick (quite clear throughout)	3 to 4 mm. thick (clear)	3·8 mm. thick (clear, colourless)	2·5 mm. thick	1 mm. thick
Air	mm.	100	100	100	100	100	100	100
Rock-salt	1	53·2	68·1	54·4	—	—	—	—
"	2	41·6	60·3	52·8	61·4	80·5	71·6	70·6
"	5	30·5	50·6	43·3	—	—	—	—
"	20	20·0	40·2	24·7	59·2	70·8	72·1	73·3
"	80	20·9	39·4	16·6	—	—	—	—
Sylvia	3	55·16	70·7	64·8	49·6	88·9	73·7	66·2
"	10	44·0	—	—	—	—	—	—
"	20	36·5	56·4	47·8	28·4	85·1	65·2	60·9
"	29·5	—	48·4	39·8	—	—	—	—
Fluor-spar	2·8	8·3	17·3	3·3	58·7	19·2	51·6	53·1
"	10	8·3	15·6	2·8	54·5	9·1	43·6	48·3
Silver chloride	0·6	64·0	62·0	62·5	67·8	67·8	59·3	53·9
"	3	47·4	47·4	48·7	36·7	54·6	41·3	37·0
Silver bromide	0·3	68·8	68·0	68·0	70·5	72·2	69·4	65·3
"	2·75	45·3	44·4	44·1	43·7	45·1	41·8	37·5
Selenium	2·5	13·3	15·0	16·9	9·53	21·3	13·7	10·9

These numbers afford a striking illustration of the previously known fact (see v. 60), that diathermic substances absorb most readily rays omitted by other portions of the same substances; but they also bring out in a very remarkable manner the thermochroic character of *rock-salt*. This is best seen by examining the results relating to the thickest piece (18 mm.) of that material, the thickness and perfect purity of which caused the heat given out by it to exhibit the special characters peculiar to the substance in the highest degree. Of this heat, little more than one-half was able to pass through a plate of rock-salt 2 millimetres thick, and only one-sixth could pass through 80 millimetres of rock-salt; while nearly the whole of it (96·7 per cent.) was stopped by a plate of fluor-spar 2·8 millimetres thick. Hence, as Magnus

pointed out, the characteristic properties exhibited by rock-salt in connection with radiant heat (see v. 62, 63, 66, 67) are not the result of its being really *athermochroic*, as was thought by Melloni, but of its being *monothermochroic*, that is to say, of its having the power to emit and to absorb (at temperatures not above about 160°) rays solely or nearly of one kind, and of these rays having been present only in very small proportions in the heat from the sources employed by Melloni and most other experimenters who have studied its action. It has already been pointed out that the heat given out by rock-salt is reflected to an exceptionally great extent by fluor-spar; this property, together with the very small proportion in which it is transmitted by fluor-spar, forms a marked difference between the thermal characters of rock-salt and those of sylvin, which in many respects they so closely resemble.

Polarisation.—1. *By Emission.* It was shown in 1849 by De la Provostaye and Desains that not only luminous heat emitted obliquely is polarised at right angles to the plane of emission, but that this is the case also with heat emitted by platinum at temperatures as low as about 230° (*Jahresb.* 1849, p. 48). Magnus in 1866 (*Pogg. Ann.* cxxvii. 600; *Fortschr. d. Phys.* xxii. 328) confirmed this result, so far as regards polished platinum, but found that the heat emitted by platinumised platinum is not polarised. More recently (1868) Magnus examined the heat emitted by various surfaces at 100° (*Pogg. Ann.* cxxxiv. 45; *Ann. Ch. Phys.* [4] xv. 467), and found that the proportion of heat polarised at right angles to the plane of emission, contained in the total radiation in a direction making an angle of 35° with the surface, could be represented by the numbers given in the following table:

Radiating surface	Percentage of polarised heat	Radiating surface	Percentage of polarised heat
Tin-plate	27.6	Colza oil	5.64
Copper	22.4	Melted rosin	7.26
Aluminium	28.5	White wax	7.3
Mercury	32.0	Glycerin	5.61
Glass, transparent . .	10.4	Paraffin	5.0
Glass, black	12.4		

The analyser employed in these experiments was a black glass reflector set at an angle of 35° to the axis of the incident beam.

2. *By Reflection.* By employing as polariser a pile of 4 plates of rock-salt, each from 3 to 4 mm. in thickness and having about 50 square centim. of superficial area, and a similar pile as analyser, Desains (*Compt. rend.* lxiv. 1246; *Pogg. Ann.* cxxxiv. 472) succeeded in polarising the heat radiated by copper at 160° . When the planes of incidence of analyser and polariser were parallel, the galvanometer connected with the thermoelectric pile which received the heat from the analyser showed a deflection of 12° ; when the planes of incidence were at right angles to each other, the deflection was 7° .

Conduction of Heat. The laws of the conduction of heat by *liquids* have been investigated by Guthrie (*Phil. Trans.* 1869, p. 637) by a method in which one of the chief causes of uncertainty in previous experiments on the same subject is got rid of. His apparatus consisted essentially of an air-thermometer with a conical reservoir of sheet brass; the base of the cone, formed by a flat plate of platinum, was placed uppermost, and a calibrated and graduated glass tube, open at both ends, was fitted into the apex of the cone by means of a cork. The lower end of this tube dipped into coloured water contained in a wide open vessel, and the motion of the water in the tube indicated the changes of temperature in the air in the conical reservoir. A similar brass cone with a flat platinum base was placed, base downwards, with its axis in the same vertical line as that of the thermometer-cone, with its base facing the base of the latter at a distance which could be accurately adjusted and measured by means of a micrometer screw. The apparatus being set so that the bases of the two cones were exactly horizontal, the upper one was brought down to within the required distance (usually 1 or 2 millimetres) of the lower one, and the flat cylindrical space between the two platinum faces was filled by means of a pipette with the liquid to be examined. By this arrangement a uniform layer of liquid was obtained, the vertical sides of which were not in contact with any solid material which could either help or hinder the passage of heat from one surface to the other. Heat was applied to the upper surface of this layer of liquid, by causing a stream of warm water of known

temperature to flow through the upper cone; and the passage of heat through it was judged of by comparing the resulting depression of the coloured water in the thermometer-tube with the depression which occurred, under otherwise like conditions, when the faces of the two cones were close together, contact between them being made more perfect by wetting them with mercury. The numbers in the following table express the relative resistances to the passage of heat through the various liquids examined by him, which Guthrie deduced from the results of his experiments made under the following conditions: namely, temperature of the air 20.17° , temperature of water in the upper cone 30.17° , thickness of layer of liquid 1 millim., duration of each experiment 1 minute:

Liquid	Thermal resistance	Liquid	Thermal resistance
Water	1.0	Amylic acetate	10.00
Glycerin	3.84	Amylamine	10.14
Acetic acid (glacial)	8.38	Amylic alcohol	10.23
Acetone	8.51	Oil of turpentine	11.75
Ethyllic oxalate	8.85	Butylic nitrate	11.87
Sperm oil	8.85	Chloroform	12.10
Alcohol	9.09	Bichloride of carbon	12.92
Ethyllic acetate	9.09	Mercury-amyl	12.92
Nitrobenzene	9.86	Bromide of ethylene	13.16
Amylic oxalate	10.00	Amylic iodide	13.27
Butylic alcohol	10.00	Ethyllic iodide	14.20 (?)

It can hardly be supposed that the method employed in these experiments could give strictly accurate numerical results, though the sources of error cannot have been such as to cause any great error in simply comparative measurements. Hence we do not reproduce here the numbers calculated by Professor Guthrie to express the 'number of heat-units arrested in 1 minute by 1 square decimetre 1 millim. in thickness' when the temperature of the lower surface of the layer of liquid is 20.17 , and that of the upper surface 10° higher. One of the most important results of this investigation is that the conducting power of liquids for heat is greater at high temperatures than at low ones.

Conducting Power of Metals.—Some confusion exists in the statements in vol. v. (pp. 69–72) with regard to the conducting power of metals, caused partly by the variety of units adopted by different experimenters for the purpose of expressing their results. It will therefore be useful to repeat the statement of some of the numerical values in such a way as to prevent the possibility of further error. In the first place, however, it is needful to correct a statement made in p. 69 (vol. v.) to the effect that coefficients of conducting power are expressed by the same number, whether they are referred to the *kilogram*, *millimetre*, and *square metre*, or to the *gram*, *centimetre*, and *square centimetre*, as units of mass, thickness, and area respectively. If we denote by Q the quantity of heat which would pass per second through a plate 1 mm. thick and 1 square metre in area, with a given difference of temperature between the surfaces, the quantity which would pass under like conditions through each square centimetre of a plate 1 centim. thick would be $\frac{Q}{10 \times 10,000}$, since the thickness, in the second case, would be ten times as great, and the area 10,000 times as small, as in the first case; but if this smaller quantity of heat is expressed in gram-degrees instead of in kilogram-degrees, the number representing it will be 1,000 times as great: hence it appears that, in order to convert coefficients of conductivity expressed in *kilogram-degrees*, per *square metre*, per *millimetre*, per *second*, into *gram-degrees*, per *square centimetre*, per *centimetre*, per *second*, we must multiply by $\frac{1,000}{10 \times 10,000} = 0.01$. Further, if the *minute* be taken as the unit of time, instead of the *second*, we must multiply again by 60, so that to pass from kilogram-degrees, per square metre, per millim., per second to gram-degrees, per centimetre, per minute, we must multiply by 0.6. We pass now to the statements of experimental results.

Péclet (*Traité de la Chaleur*, 3rd edit. vol. i. pp. 390, 391) gives the following as the result of a determination of the absolute conducting power of lead: the quantity of heat which would pass in 1 hour through a plate of lead 1 sq. metre in area and 1 metre thick, with a difference of 1° between the temperature of its surfaces, is 13.83

kilogram-degrees. This result, reduced to what it would be for a plate 1 millim. thick and for 1 second of time, would become (compare v. 69)

$$13.83 + \frac{1,000}{3,600} = 3.84.$$

Ångström (*Pogg. Ann.* cxiv. 527) gives, as the results of his experiments on copper and iron, the numbers 61.62 and 9.77 respectively as the numbers of gram-degrees which would pass per second through each square centim., of plates 1 centim. thick, and at a mean temperature of from 51° to 52°, if the temperature of the surfaces differed by 1 degree. From the context, however, it appears that 1 second here is a mistake for 1 minute. In a subsequent paper (*Pogg. Ann.* cxviii. 429) Ångström gives the following values for the conductivities of copper and iron at the temperature t°:

61.63 (1-0.00214t)	copper (first specimen).
58.94 (1-0.001519t)	" (second specimen).
11.927 (1-0.002874t)	iron.

Neumann (*Ann. Ch. Phys.* [3] lxvi. 185) takes as his units of time and length 1 minute and 1 Paris line, and, as unit of heat, the quantity required to raise the temperature of 1 cubic line of water 1 degree, and adds that to reduce his values to the units employed by Péclot or to those employed by Ångström, they must be multiplied by 0.0848 or by 0.0509 respectively. The following are the results which he gives:

Copper	1306
Brass	356
Zinc	362
German silver	129
Iron	193

These various results, expressed according to the same units, are collected in the following table, where the numbers in the columns headed A are referred to 1 gram-degree as the unit of heat, 1 centimetre as the unit of length, and 1 minute as the unit of time, whereas for the columns headed B the units are 1 kilogram-degree, 1 millimetre, 1 square metre, 1 second:

	Ångström		Neumann	
	A	B	A	B
Copper . . .	{ 61.63 (1-0.00214t) 58.94 (1-0.001519t)	{ 102.7 (1-0.003567t) 98.23 (1-0.002532t)	66.48	110.75
Zinc	18.43	30.70
Brass	18.12	30.19
Iron . . .	11.927 (1-0.002874t)	19.88 (1-0.00479t)	9.82	16.37
German silver	6.67	10.94
Lead . . .	(A) 2.30; (B) 3.84 Péclot.			

The numbers given at p. 72, vol. v., as the result of Neumann's experiments on several non-metallic substances refer to the units employed in the columns B of the above table. G. C. F.

HELENIN. According to Hoyer (*Vierteljahrs. pr. Pharm.* xiii. 544), the formula of this substance is $C^{18}H^{14}O$, which, however, requires 12.8 p. c. carbon and 0.8 p. c. hydrogen more than the formula $C^{17}H^{13}O$, deduced by Gerhardt (iii. 138) from several closely agreeing analyses. According to Hoyer, helenin melts at 75°; according to Gerhardt, at 72°.

HELIANTHUS. The seeds of the sunflower (*H. annuus*) yield 21.8 p. c. of fixed oil (Cloeys, *Bull. Soc. Chim.* [2] iii. 41).

The tubers of Jerusalem artichokes (*H. tuberosus*) gathered in September yield a juice which is strongly lavogyrate, is only partially thrown into alcoholic fermentation by beer-yeast, and when left to itself solidifies to a curdy mass, with separation of inulin. The juice expressed therefrom deposits a further quantity of inulin on addition of alcohol; after the separation of the inulin it is optically inactive, and ferments with yeast without becoming optically active. The tubers taken up in March or April

yield a dextrogyrate juice, which is free from inulin, and yields by fermentation a considerable quantity of alcohol. After evaporation it yields, on addition of alcohol, a gummy precipitate, the aqueous solution of which is optically inactive, and ferments without alteration of this property (*vid. inf.*). The alcoholic solution separated from this gummy substance is dextrogyrate, and undergoes, under the influence of acids or of yeast, the same transformation as cane-sugar, yielding inverted sugar, with a rotatory power varying according to temperature. The alcoholic solution when evaporated leaves a syrup, from which, by treatment with baryta and decomposition of the resulting precipitate with carbonic acid, crystallisable cane-sugar is obtained. The tubers gathered in September yield neither sugar nor a saccharate when thus treated. Hence it appears that the inulin formed in the early stage of growth is afterwards converted into crystallisable cane-sugar and an uncrystallisable optically inactive sugar (Dubrunfaut, *Compt. rend.* lxiv. 764).

Ville a. Joulis (*Bull. Soc. Chim.* [3] vii. 262), by repeatedly treating the juice of Jerusalem artichoke tubers with alcohol, obtained a substance which they designate as levulin; it resembles dextrin, has a sweetish taste, is soluble in water, reduces alkaline cupric solutions only after boiling with acids, is optically inactive, but becomes strongly lævogyrate by treatment with hydrochloric acid.

HELICIN. $C^{12}H^{16}O^7$.—This compound, the glucoside of salicylol, is converted by digestion in aqueous solution with excess of sodium-amalgam into salicin, $C^{12}H^{16}O^7$ (Lesonsko, *Zeitschr. Chem. Pharm.* 1864, p. 577). According to Swarts (*Institut.* 1865, p. 325), helicin thus treated yields helicoidin, $C^{22}H^{30}O^{14} = 2C^{12}H^{16}O^7 + H^2$.

Helicin treated with chlorides of acid radicles yields substitution-products (Schiff, *Zeitschr. f. Chem.* [2] v. 1). Acetyl chloride decomposes it even at ordinary temperatures; and if the action be allowed to go on for 24 hours, the mixture then heated to 60° and mixed with ether, *tetracetyl-helicin*, $C^{12}H^{12}(C^2H^3O)^4O^7$, is dissolved, and may be obtained by crystallisation from alcohol in shining prisms. Boiled with absolute alcohol, it yields ethyl acetate. By boiling it with water and magnesia, the whole of the acetyl is removed as magnesium acetate.

Helicin heated to 60° with benzoyl chloride, is converted into *benzoyl-helicin*, $C^{12}H^{12}(C^7H^5O)^4O^7$, which separates as a white crystalline powder, insoluble in ether, slightly soluble in water and in alcohol, and converted by treatment with water and sodium-amalgam containing a small proportion of sodium, into populin (benzoyl-salicin). Helicin heated with benzoyl chloride to 150° – 170° yields *tetrabenzoyl-helicin*, $C^{12}H^{12}(C^7H^5O)^4O^7$, coloured brown by secondary products, and difficult to purify. It is soluble in alcohol and ether, nearly insoluble in water, and when heated in a sealed tube with hydrochloric acid, gives up the whole of its benzoyl as benzoic acid.

Helicin reacts with organic bases like an aldehyde, exchanging an atom of its oxygen for an imidogen group in which the hydrogen is replaced by an alcohol-radicle, e.g. $(NC^2H^3)^+$, $(NC^2H^3)^-$, &c. Amylamine and aniline act upon it at ordinary temperatures, toluidine only at the boiling heat. The *phenyl-derivative* $C^{12}H^{21}NO^6 = C^{12}H^{16}O^6(NC^6H^5)^1$ is prepared by gently heating helicin with aniline, treating the product several times with acetic acid to remove the excess of aniline, dissolving the yellow residue in alcohol, adding an equal volume of ether, filtering, evaporating, dissolving in absolute alcohol, and pouring the filtered solution into excess of cold water. The aniline derivative of helicin, $C^{12}H^{21}NO^6$, then separates as a yellow powder, which turns green on exposure to the air, is insoluble in water, very soluble in alcohol, and forms with concentrated acids, scarlet solutions which are decomposed by water. The hydrochloric solution does not yield a platinumchloride. By boiling with acids or alkalis it is resolved into glucose and salhydranilide, $C^8H^8O(NC^6H^5)$, which latter is then further resolved into its constituents. The *toluidine-derivative* of helicin is similar in every respect to the aniline derivative (Schiff, *Zeitschr. f. Chem.* [2] iv. 638).

The acetyl and benzoyl derivatives of helicin gently heated with aniline and toluidine yield similar derivatives. *Tetracetohelicinanilide*, $C^{12}H^{12}(C^2H^3O)^4O^6(NC^6H^5)^1$, separates from solution in hot alcohol as a white crystalline powder. A similar compound is formed with toluidine. The anilide heated to about 160° with toluidine yields *tetracetohelicinanilotoluide*, $C^{12}H^{12}(C^2H^3O)^4O^6(NC^6H^5)(NC^6H^7)^1$, and with aniline a similar compound containing 2 at. NC^6H^5 . Both these compounds are amorphous, and when boiled with water and magnesia give up 2 at. acetyl in the form of magnesium acetate, while the other two are separated as acetanilide and acetotoluide. Benzoyl-helicin and tetrabenzoyl-helicin yield analogous compounds with aniline and toluidine (Schiff, *ibid.* [2] v. 51).

HELLEBORIN, $C^{12}H^{12}O^6$, and **HELLEBOREIN**, $C^{12}H^{14}O^{13}$ (Husemann a. Marmé, *Ann. Ch. Pharm.* cxxxv. 56).—Two glucosides existing in the roots of *Helleborus niger* and *H. viridis* and determining their physiological action. Helleborin, which occurs but very sparingly in black, more abundantly in green hellebore, is identical with the supposed azotised body *helleborine*, obtained in an impure state from black hellebore by Bastick (iii. 140). Helleboresin is much more abundant in black than in green hellebore, but occurs in considerably larger quantity than helleborin, even in the latter.

To prepare helleboresin, the aqueous decoction of the root is precipitated with basic lead acetate; the concentrated filtrate is freed from excess of lead by sodium sulphate and phosphate; the precipitate, after being repeatedly pressed, is stirred up with alcohol and levigated litharge, dried therewith, and exhausted with boiling alcohol; and the helleboresin is precipitated from the strongly concentrated extract by ether. After repeated solution in alcohol and precipitation with ether, it crystallises gradually from the former in transparent nodular groups of microscopic needles, which on exposure to the air crumble to a yellowish-white hygroscopic powder. It has a sweetish taste, is very soluble in water, somewhat less soluble in alcohol, and quite insoluble in ether. The aqueous solution, which scarcely reddens litmus, dries up to an amorphous yellowish mass, which loses its water at 110° – 120° , and then exhibits the composition above given, becomes straw-yellow above 160° , brown at 220° – 230° , viscid at 280° , and then carbonises. Strong sulphuric acid dissolves it, with brown-red colour, gradually changing to violet. Alkalis and alkaline earths have no action upon it. By boiling with dilute acids, it is resolved into helleboretin, $C^{12}H^{12}O^6$, which separates as a dark violet-blue precipitate, and glucose, which remains dissolved:

Helleboretin when dried forms a grey-green, amorphous, inodorous, and tasteless powder melting above 200° , insoluble in water and ether, but easily soluble, with violet colour, in alcohol. From the brown-red solution in strong sulphuric acid it is precipitated by water in its original state.

Helleborin, $C^{12}H^{12}O^6$, is best prepared from old roots of green hellebore. The hot-prepared and strongly concentrated alcoholic extract is repeatedly agitated with boiling water; the liquid freed from supernatant fatty oil is evaporated; and the helleborin which separates on cooling is washed with water and purified by recrystallisation from alcohol. It forms shining, white, concentrically grouped needles, insoluble in cold water, slightly soluble in ether and in fixed oils, easily soluble in boiling alcohol and chloroform; decomposes when heated above 260° . The smallest trace of it may be detected by its reaction with strong sulphuric acid, which first colours it deep red, and then dissolves it with the same colour. It is a stronger narcotic than helleboresin, and its alcoholic solution has a very acid burning taste. It is resolved by boiling with dilute acids, or more completely with a concentrated solution of zinc chloride, into glucose and helleboresin, $C^{12}H^{14}O^{13}$:

The helleboresin separates as a resinous body which is insoluble in water, slightly soluble in ether, easily soluble in boiling alcohol, and is separated therefrom by water as a white flocculent precipitate.

HEMIPINIC ACID, $C^{10}H^{10}O^8$.—This acid is produced by oxidising opianic acid ($C^{12}H^{14}O^8$) with chromic acid mixture (Matthiessen, *Proc. Roy. Soc.* xvii. 341). It crystallises in different forms with $\frac{1}{2}$, 1, or $2\frac{1}{2}$ mol. water; the first and second of these hydrates crystallise in the monoclinic system (Matthiessen a. Foster, *ibid.* xvi. 40). Respecting its reactions with hydriodic and hydrochloric acids, see iii. 142. It is not reduced to opianic acid or meconin by any reducing agents; neither have experiments to form opianic acid by the union of hemipinic acid and meconin been successful; nor has hemipinic acid been oxidised to any other compound. Heated to 170° it gives off water and leaves an anhydride, $C^{10}H^8O^8$, which may be crystallised unaltered from absolute alcohol, but when treated with ordinary spirit of 80 p. c. it forms ethyl-hemipinic acid, $C^{12}H^{16}(C^2H^5)O^8$ (Matthiessen a. Wright, *ibid.* xvii. 341).

HEMP. See CANNABIS.

HEPTANE, *Septane*, *Heptyl Hydride*, C^7H^{16} .—The properties of this hydrocarbon, obtained from various sources, and of its derivatives $C^7H^{15}Cl$, $C^7H^{15}Br$, &c., have been examined by Schorlemmer (*Proc. Roy. Soc.* xiv. 164, 464). The specific gravities and boiling points are given in the following table:

Formula		Heptyl-compounds from :			
		Petroleum	Azelaic acid	Ethyl-amyl	Methyl-hexyl
C^7H^{16}	Boiling point Sp. gr.	98° (91°) 0.7149 at 15.5°	100.5° 0.6840 at 20.5°	90.5° 0.6819 at 18.5°	90° 0.6789 at 19°
C^7H^{14}	Boiling point Sp. gr.	96° 0.7383 at 17.5°	96° 0.7026 at 19°	94° 0.7060 at 12.5°	
$C^7H^{13}Cl$	Boiling point Sp. gr.	149° 0.8965 at 19°	152° 0.8737 at 18.5°	147° 0.8780 at 18.5°	
$C^7H^{12}O$	Boiling point Sp. gr.	164.5° 0.8749 at 16°	165.6°? 0.8286 at 19.5°	164° 0.8291 at 13.5°	
$C^7H^{15} \left. \begin{matrix} \\ \\ \end{matrix} \right\} O$ $C^7H^{10} \left. \begin{matrix} \\ \\ \end{matrix} \right\} O$	Boiling point Sp. gr.	180° 0.8868 at 19°	181° 0.8605 at 16°	179° 0.8707 at 16.5°	

The ethyl-amyl C^7H^{12} , C^7H^{11} was prepared by decomposing a mixture of ethyl and amyl iodides with sodium, treating the product with a mixture of nitric and sulphuric acids, and rectifying over sodium. The *heptyl chloride*, $C^7H^{13}Cl$, prepared from it, was resolved (like that obtained from petroleum heptane, iii. 146), by heating to 160°–180° with potassium acetate and acetic acid, into heptylene and heptyl acetate. The *heptyl alcohol*, $C^7H^{14}O$, prepared from this acetate, dissolves in strong sulphuric acid, with slight browning, and formation of a sulpho-acid whose barium and calcium salts are not crystallisable. By oxidation with chromic acid mixture, it yields *enanthylic acid*, together with a little *enanthol*: hence it is a primary alcohol. Heptane prepared by heating azelaic acid with baryta, $C^7H^{16}O_4 = C^7H^{16} + 2CO_2$ (Dale, *Chem. Soc. J.* [2] ii. 258), yields by a similar series of reactions, a primary alcohol boiling at 94°. The portion of American petroleum boiling below 100° yields, together with the heptane boiling at 98°, another isomeric hydrocarbon boiling at 90°–92° (see also Warren, *Jahresb.* 1865, p. 516). The heptanes from azelaic acid and ethyl-amyl are regarded by Schorlemmer as distinctly isomeric. The former is probably the normal compound $CH^3-(CH^2)^4-CH^3$; the latter, if prepared from ordinary amyl-iodide (p. 111), must be supposed to contain the group $CH(CH^3)^2$: hence its constitutional formula is probably $CH^3-(CH^2)^3-CH(CH^3)^2$.

Phthalic and terephthalic acids heated with 80 pts. of saturated hydriodic acid yield heptane boiling at 91°–93°:

Toluene, C^7H^8 , similarly treated, is completely converted into heptane; benzoic acid also yields the same hydrocarbon as normal product, together with hexane, C^6H^{14} , in consequence of the previous splitting up of part of the benzoic acid into benzene and carbon dioxide (Berthelot, *Jahresb.* 1867, pp. 346, 350). Toluidine and paratoluidine heated with 60 pts. hydriodic acid are almost wholly resolved into ammonia and heptane (Berthelot, *Compt. rend.* lxxiii. 606): $C^7H^7N + 10HI = NH_3 + C^7H^{16} + 5I_2$.

Heptane boiling at 97.8° is found, together with heptylene, C^7H^{14} , amongst the hydrocarbons produced by the dry distillation of the lime-soap of Menhaden oil (Warren a. Storer, *Zeitschr. f. Chem.* [2] iv. 231).

HEPTENE or *Septine*, C^7H^{12} , also, but inappropriately, called *Enanthydene*.

—A hydrocarbon homologous with ethino or acetylene, first obtained by Limpricht (*Jahresb.* 1857, p. 464); more completely examined by Rubien (*Ann. Ch. Pharm.* cxlii. 224). It is obtained by boiling heptylene chloride, $C^7H^{14}Cl^2$ (iii. 148), with 2 vol. concentrated alcoholic potash for twelve hours in a retort with upright condenser, treating the product with water, rectifying, collecting the chloroheptylene, $C^7H^{13}Cl$, which distils above 120°, and repeatedly heating it to 150° in sealed tubes, with alcoholic potash. On subjecting the portion of the oily product which boils below 120° to repeated fractional distillation, heptene is ultimately obtained as a transparent, colourless, mobile liquid, boiling at 106°–108°. It has an intensely alliaceous odour, is lighter than water, burns with a smoky flame, and dissolves easily in alcohol, ether, and benzol. Bromine acts violently on it in diffused daylight, forming the dibromide $C^7H^{12}Br^2$; with excess of bromine in sunshine the tetrabromide $C^7H^{12}Br^4$ is produced,

which, when purified, is a yellowish oil, smelling like fennel, not volatile without decomposition, easily soluble in ether and benzol, sparingly in alcohol. Heated with sodium it decomposes and takes fire. On boiling it with alcoholic potash, potassium bromide is slowly deposited, and an oil is formed having a faint alliaceous odour.

HEPTYLIDENE. C^7H^{14} .—A diatomic radicle related to heptylene in the same manner as ethylidene to ethylene. Several diamines containing it have been obtained by Schiff (*Ann. Ch. Pharm. Suppl.* iii. 343). *Triheptylidene-diamine*, $C^7H^{14}N^2 = (C^7H^{14})^3N^2$, is formed, with separation of water, &c., on passing dry ammonia gas into anhydrous cenanthol: $3C^7H^{14}O + 2NH^3 = 3H^2O + (C^7H^{14})^3N^2$. It is a yellow aromatic oil, which distils undecomposed above 400° , and does not unite either with acids or with chlorides. It is also formed on agitating cenanthol with aqueous ammonia, or heating it with ammonium carbonate and acetate. *Dianthylidene-diamyl-diamine*, $C^{14}H^{30}N^2 = (C^7H^{14})^2(C^5H^{11})^2N^2$, produced by mixing cenanthol with amylamine, is an oily liquid which distils with partial decomposition. Several phenyl-diamines containing heptylidene are described under PHENYLAMINES (iv. 458).

HERACLEUM. The volatile oil obtained from the fruits of the cow-parsnep (*Heracleum sphondylium*, L.) by distillation with water (80 lb. of the fresh ripe fruits yielding about 120 grms. of the oil) is light green, mobile, has a sp. gr. of 0.864 at 20° , a faint, not unpleasant odour, and a sharp burning taste. It consists mainly of octyl acetate, $C^8H^{16}O^2 \cdot C^8H^{17}$, which may be obtained pure by continued fractionation of the portion of the oil passing over between 200° and 212° . This ether yields by saponification a primary octyl alcohol, $C^8H^{18}O$, boiling at 190° – 192° , and yielding, by oxidation with chromic acid, an acid, $C^8H^{16}O^2$, identical or isomeric with the capric acid of natural fats. (See OCTYL ALCOHOLS.)

The portion of the crude oil distilling between 190° and 195° consists mainly of the same octyl alcohol. The higher fractions yield by continued fractional distillation an ethereal liquid boiling between 268° and 271° , and consisting mainly of octyl caproate, $C^8H^{18}O^2 \cdot C^8H^{17}$. The acid $C^8H^{16}O^2$ obtained from this ether by saponification is identical with the caproic acid obtained from natural fats. The acid water obtained in the distillation of the fruits contains acetic and caproic acids (Ziucke, *Ann. Ch. Pharm.* clii. 1).

HERSCHELITE. According to V. von Lang (*Phil. Mag.* [4] xxviii. 506), the crystals of this mineral, hitherto regarded as hexagonal (iii. 150), are polysynthetic, being composed of six individuals belonging to the rhombic system and united by the faces αP .

HESSENBERGITE. A silicate of unknown composition, occurring in very small tabular crystals on the so-called 'Eisenrosen' from the Fibin on the St. Gothard. According to Kennigott (*Jahresb.* 1863, p. 802), they belong to the rhombic system; according to Hessenberg (*ibid.* 1866, p. 924), they are monoclinic.

HEXADECYL. $C^{16}H^{34}$.—Syn. with CETYL.

HEXAHENE. C^6H^8 .—A hydrocarbon obtained, together with others, by heating naphthalene with excess of silver oxide (Maumené, *Bull. Soc. Chim.* [2] vii. 72).

HEXAMETHYLENAMINE. See METHYLENE-COMPOUNDS.

HEXANE, SEKTANE, or HEXYL HYDRIDE. C^6H^{14} , is produced by the action of hydriodic acid at 280° on benzene: $C^6H^6 + 8HI = C^6H^{14} + 4I^2$ (Berthelot, *Jahresb.* 1867, p. 345); also by heating suberic acid with lime or baryta: $C^6H^{14}O^4 = C^6H^{14} + 2CO^2$. The latter product has the same specific gravity as the β hexyl hydride of Wanklyn & Erlensmeyer (*Dale, Chem. Soc. J.* [2] ii. 258). Hexane is also found among the hydrocarbons of Menhaden oil (p. 696). Hexane, like all the paraffins, is but slowly attacked by potassium permanganate, yielding a mixture of fatty acids apparently containing caproic acid (Berthelot).

HEXINE. C^6H^{10} . *Sextine. Hexylene.*—A hydrocarbon, homologous with acetylene, and isomeric with diallyl (p. 92), produced by heating bromhexylene, $C^6H^{14}Br$, to 150° – 160° in sealed tubes with alcoholic potash. It is a colourless liquid, having a pungent alliaceous odour, sp. gr. 0.71 at 13° , and boiling at about 80° . Vapour-density 2.8372 (obs. 2.7938). With bromine it behaves like valerylene (v. 981), forming a liquid dibromide, $C^6H^{12}Br^2$, or a crystallisable tetrabromide, $C^6H^{10}Br^4$, according to the proportion of bromine used (Caventou, *Compt. rend.* lix. 449. Reboul & Truchot, *ibid.* lxx. 73).

Formula		Heptyl-compounds from :			
		Petroleum	Azelaic acid	Ethyl-amyl	Methyl-hexyl
C^7H^{16}	Boiling point Sp. gr.	93° (91°) 0·7149 at 15·5°	100·5° 0·6840 at 20·5°	90·5° 0·6819 at 18·5°	90° 0·6789 at 19°

The ethyl-amyl C^7H^{13} . C^7H^{11} was prepared by decomposing a mixture of ethyl and amyl iodides with sodium, treating the product with a mixture of nitric and sulphuric acids, and rectifying over sodium. The *heptyl chloride*, $C^7H^{13}Cl$, prepared from it, was resolved (like that obtained from petroleum heptane, iii. 146), by heating to 160°–180° with potassium acetate and acetic acid, into heptylene and heptyl acetate. The *heptyl alcohol*, $C^7H^{13}O$, prepared from this acetate, dissolves in strong sulphuric acid, with slight browning, and formation of a sulpho-acid whose barium and calcium salts are not crystallisable. By oxidation with chromic acid mixture, it yields *œnanthyllic acid*, together with a little *œnanthol*: hence it is a primary alcohol. Heptane prepared by heating azelaic acid with baryta, $C^7H^{16}O^4 = C^7H^{16} + 2CO_2$ (Dale, *Chem. Soc. J.* [2] ii. 258), yields by a similar series of reactions, a primary alcohol boiling at 94°. The portion of American petroleum boiling below 100° yields, together with the heptane boiling at 98°, another isomeric hydrocarbon boiling at 90°–92° (see also Warren, *Jahresb.* 1865, p. 516). The heptanes from azelaic acid and ethyl-amyl are regarded by Schorlemmer as distinctly isomeric. The former is probably the normal compound $CH^2-(CH^2)^5-CH^3$; the latter, if prepared from ordinary amyl-iodide (p. 111), must be supposed to contain the group $CH(CH^3)^2$: hence its constitutional formula is probably $CH^2-(CH^2)^4-CH(CH^3)^2$.

Phthalic and terephthalic acids heated with 80 pts. of saturated hydriodic acid yield heptane boiling at 91°–93°:

Toluene, C^7H^8 , similarly treated, is completely converted into heptane; benzoic acid also yields the same hydrocarbon as normal product, together with hexane, C^6H^{14} , in consequence of the previous splitting up of part of the benzoic acid into benzene and carbon dioxide (Berthelot, *Jahresb.* 1867, pp. 346, 350). Toluidine and paratoluidine heated with 60 pts. hydriodic acid are almost wholly resolved into ammonia and heptane (Berthelot, *Compt. rend.* lxxviii. 606): $C^7H^9N + 10HI = NH^3 + C^7H^{16} + 5I^2$.

Heptane boiling at 97·8° is found, together with heptylene, C^7H^{14} , amongst the hydrocarbons produced by the dry distillation of the lime-soap of Menhaden oil (Warren a. Storer, *Zeitschr. f. Chem.* [2] iv. 231).

HEPTINE or *Septine*, C^7H^{12} , also, but inappropriately, called *œnanthylidene*.—A hydrocarbon homologous with ethine or acetylene, first obtained by Limpricht (*Jahresb.* 1857, p. 465); more completely examined by Rubien (*Ann. Ch. Pharm.* cxlii. 224). It is obtained by boiling heptylene chloride, $C^7H^{11}Cl^2$ (iii. 148), with 2 vol. concentrated alcoholic potash for twelve hours in a retort with upright condenser, treating the product with water, rectifying, collecting the chloroheptylene, $C^7H^{11}Cl$, which distils above 120°, and repeatedly heating it to 150° in sealed tubes, with alcoholic potash. On subjecting the portion of the oily product which boils below 120° to repeated fractional distillation, heptine is ultimately obtained as a transparent, colourless, mobile liquid, boiling at 106°–108°. It has an intensely alliaceous odour, is lighter than water, burns with a smoky flame, and dissolves easily in alcohol, ether, and benzol. Bromine acts violently on it in diffused daylight, forming the dibromide $C^7H^{12}Br^2$; with excess of bromine in sunshine the tetrabromide $C^7H^{12}Br^4$ is produced,

If the product of the action of zinc-ethyl on acetyl chloride be treated with water immediately, instead of being first left to itself for some days, it yields *propyl-methyl ketone*, $\text{CO} \cdot \text{C}^6\text{H}^7 \cdot \text{CH}^3$, instead of the tertiary alcohol; and the product obtained with butyryl chloride and zinc-methyl, if immediately treated with water, yields *propyl-ethyl ketone*, $\text{CO} \cdot \text{C}^6\text{H}^7 \cdot \text{C}^2\text{H}^5$ (Buttlerow, *Bull. Soc. Chim.* [2] v. 17; *Jahresb.* 1866, p. 461).

HEXYLENE. C^6H^{12} .—This hydrocarbon admits of several isomeric modifications, accordingly as each atom of carbon is united at most with two others, or with three, or with four. (See **HYDROCARBONS**.) There are two modifications in which neither of the carbon-atoms is associated with more than two others, viz. normal hexylene, $(\text{CH}^2)^3$, homologous with ethylene; and hexylidene, $\text{CH}^2-(\text{CH}^2)^4-\text{CH}$, homologous with ethylidene. Normal hexylene does not appear to have been obtained. *Hexylidene* is produced by heating dichlorohexane (hexylidene chloride), $\text{C}^6\text{H}^{12}\text{Cl}_2$, to 90° with sodium, adding the metal by small quantities at first, and applying a stronger heat when the first violent action is over. Hexylidene and unaltered dichlorohexane then pass over together, and may be separated by fractional distillation. Hexylidene boils between 68° and 71° , has a sp. gr. of 0.702 at 0° , unites with bromine with a hissing noise, producing a heavy limpid liquid. Heated with excess of fuming hydrochloric acid to 160° , it is almost wholly converted into hexyl chloride, $\text{C}^6\text{H}^{11}\text{Cl}$, boiling between 125° and 130° , having a sp. gr. of 0.892 at 23° , and identical with that which Pelouze a. Cahours obtained by the action of chlorine on hexane from American petroleum. This chloride heated to 160° with lead acetate is converted into hexyl acetate, $\text{C}^6\text{H}^{11} \cdot \text{C}^2\text{H}_3\text{O}_2$, without a trace of hexylene; and the acetate treated with potash yields normal hexyl alcohol identical with that obtained by Pelouze a. Cahours (Geibel a. Buff, *Zeitschr. f. Chem.* [2] iv. 179; Buff, *ibid.* 730):

Hexylenes yielding secondary hexyl alcohols are obtained: α . Together with other olefines and several paraffins, by distilling amyl alcohol with zinc chloride: B. P. $60^\circ-70^\circ$ (Wurtz).— β . By decomposing secondary hexyl iodide (from mannite) with potash: B. P. $68^\circ-70^\circ$ (Wanklyn a. Erlenmeyer, iii. 155).— γ . By distilling phenose, $(\text{C}^6\text{H}^9)^2(\text{OH})^2$, or the corresponding trichlorhydrin, $(\text{C}^6\text{H}^9)^2\text{Cl}^3(\text{OH})^3$, with hydriodic acid, whereby hexylene hydriodide or secondary hexyl iodide is obtained:

Phenose

Trichlorhydrin

and heating the hydriodide thus obtained with alcoholic potash: hexylene then passes over, boiling at $68^\circ-70^\circ$ (Carius, *Ann. Ch. Pharm.* cxxvi. 323).— δ . Diallyl dihydriodide, $\text{C}^6\text{H}^{10} \cdot 2\text{HI}$, heated with sodium, or better with an alloy of tin and sodium containing a large proportion of the latter, is partly converted into hexylene boiling at $68^\circ-70^\circ$, and having a sp. gr. of 0.6937 at 0° (Wurtz, *Jahresb.* 1864, p. 612):

Hexylene prepared from mannite, or from the hexyl chloride obtained with American petroleum, is converted by careful admixture with bromine into a red liquid not volatile without decomposition, which when heated with silver acetate suspended in ether, and subsequently distilled, yields hexylene diacetate, together with a liquid boiling between 300° and 320° . Hexylene diacetate, $\text{C}^6\text{H}^{10} \cdot (\text{C}^2\text{H}_3\text{O}_2)^2$, is a colourless oily liquid, insoluble in water, having a sp. gr. of 1.014 at 0° , and boiling between 215° and 220° . By carefully treating it with recently ignited and pulverised potassium hydrate, and distilling the resulting alkaline mass, hexylene alcohol or hexylene glycol, $\text{C}^6\text{H}^{10}\text{O} = \text{C}^6\text{H}^{11}(\text{OH})^2 = \left. \begin{matrix} \text{C}^6\text{H}^{11} \\ \text{H}^2 \end{matrix} \right\} \text{O}^2$, is obtained as a thick, colourless liquid, miscible in all proportions with water, alcohol, and ether, having a sp. gr. of 0.9669 at 0° , and boiling at about 207° ; that is to say, a few degrees lower than the isomeric compound diallyl dihydrate, $\text{C}^6\text{H}^{10} \cdot 2\text{H}^2\text{O}$ (p. 94), and 20° to 25° higher than amylene glycol.

Hexylene glycol dissolves completely in very strong hydrochloric acid, forming a liquid which gradually turns brown, and from which, especially when heated, there separates a black liquid boiling between 100° and 250° , but not containing hexylene

dichloride. The hydrochloric acid solution distilled with potash yields hexylene oxide, $C^6H^{12}O$, boiling at 115° . Hexylene glycol heated to 100° with concentrated hydriodic acid yields a brown solution, from which, after neutralisation with potash, hexylene monohydriodide or secondary hexyl iodide, $C^6H^{12}.HI$ or $C^6H^{12}I$ (boiling between 165° and 170°), is obtained by distillation:

Diallyl dihydrate, $(C^3H^6O)^2 \left\{ \begin{smallmatrix} H^2 \\ (OH)^2 \end{smallmatrix} \right.$ (p. 94), isomeric with hexylene glycol, is converted by similar treatment with hydriodic acid into diallyl dihydriodide, $C^6H^{12} \left\{ \begin{smallmatrix} H^2 \\ I^2 \end{smallmatrix} \right.$. Hexylene monohydriodide treated with dry silver benzoate immediately yields a certain quantity of hexylene (Wurtz, *Ann. Ch. Phys.* [4] iii. 129; *Bull. Soc. Chim.* [2] ii. 161; *Jahresb.* 1864, p. 515).

HIPPURIC ACID, $C^9H^7NO^3$, has the composition of benzamidoglycollic acid, $C^9H^7(C^2H^3O)NO^2$, and is isomeric with acetamidobenzoic or acetoxybenzamic acid, $C^9H^7(C^2H^3O)NO^2$ (ii. 699; iv. 291). It is formed in small quantity by the action of benzamide on chloracetic acid at 150° – 160° (Jazukowitsch, *Bull. Soc. Chim.* [2] viii. 361):

According to Schulzen a. Naunyn (*Zeitschr. f. Chem.* [2] iv. 29), hippuric acid is found in the urine in considerable quantity after 2 or 3 grms. of toluene have been swallowed. According to Graebe a. Schultzen (*ibid.* iii. 417), cinnamic and mandelic acids, after passing through the organism, appear in the urine as hippuric acid; chlorobenzoic acid as chlorhippuric acid.

A dilute solution of sodium hippurate mixed with a nearly neutral solution of ferric chloride yields a cream-coloured precipitate of ferric hippurate containing $Fe^2O^3.2C^9H^7N^2O^3$, the acid liquid filtered therefrom containing free hippuric acid. The precipitate is not quite insoluble in water, especially in presence of free hippuric acid, and moderately soluble in excess of ferric chloride. On heating the recently precipitated and still moist salt just mentioned, hippuric acid separates, and a more basic salt is formed containing $2Fe^2O^3.3C^9H^7N^2O^3$. This latter is also sometimes produced, together with the former, on mixing very concentrated solutions of sodium hippurate and ferric chloride (Salkowski, *Zeitschr. f. Chem.* [2] iv. 313).

When sodium-amalgam is gradually added to a boiling aqueous solution of hippuric acid acidulated with hydrochloric acid, glycocine is formed, together with benzyl alcohol, a white crystalline compound, $C^7H^7O^2$ (identical with that which is obtained in like manner from benzoic acid, p. 307), and a gummy nitrogenous acid apparently related to hippuric acid in the same manner as hydrobenzoic to benzoic acid (M. Herrmann, *Ann. Ch. Pharm.* cxxxiii. 335). In alkaline solution, on the other hand, hippuric acid is converted by sodium-amalgam, first into hydrobenzauric acid, and by further action into hydrobenzyluric acid and glycocine (Otto, p. 703):

and

Bromhippuric acid, $C^9H^5BrNO^3$, is obtained, by treating a boiling alcoholic solution of hippuric acid with bromine, adding water, and evaporating to one half, as a crystalline deposit made up of small needles. It dissolves in hot water, alcohol, and ether, much more easily than in the same liquids when cold; gives off bromine on exposure to moist air; and when heated with lime, gives off first benzoic acid and then a violet oil. The strongly acid solution is not precipitated by calcium, barium, or copper salts. The potassium and sodium salts are not crystallisable. The calcium salt, $(C^9H^5BrNO^3)_2Ca$, forms slender needles easily soluble in hot water (J. Maier, *Sill. Am. J.* [2] xxxix. 208).

Diazohippuric acid, $C^9H^7N^2O^4$, is obtained as a nitrate by the prolonged action of nitrous acid on amidohippuric acid (iii. 160):

The nitrate $C^9H^7N^2O^4.NHO^2$, which is explosive, crystallises in white prisms, and dissolves easily in water. The aurochloride $C^9H^7N^2O^4.HCl.AuCl^2$ and the platinum-chloride are crystallisable (Griess, *Jahresb.* 1862, p. 260).

Iodhippuric acid, $C^9H^7INO^3$, is produced by the action of aqueous hydriodic acid on sulphate of diazohippuric acid, and separates in coloured crystalline masses, which may be purified by solution in ammonia, decolorisation with animal charcoal, and precipitation with hydrochloric acid. It forms laminae resembling naphthalene, easily soluble in cold alcohol and ether, moderately soluble in hot water, nearly insoluble in cold water. Its ammonium salt forms a white precipitate with silver nitrate (Griess, *Zeitschr. f. Chem.* [2] iv. 725). Another modification of this acid is obtained, like the brominated acid, by treating a boiling alcoholic solution of hippuric acid with iodine. It forms white needles which react like the brominated acid. All its salts are soluble in water excepting the silver salt (Maier). Griess regards the iodated acid obtained from diazohippuric acid as $C^9H^4(C^2H^3IO)NO^2$, and Maier's acid as $C^9H^3I(C^2H^3O)NO^2$. The iodine of the former is as difficult to replace as that of iodobenzoic acid.

Oxyhippuric acid, $C^9H^7NO^4$, is produced by heating the aqueous solution of diazohippuric sulphate to the boiling point, neutralising with ammonia as soon as the evolution of nitrogen ceases, evaporating at 100° , and precipitating with hydrochloric acid. It crystallises in colourless needles, easily soluble in hot water, alcohol, and ether, sparingly soluble in cold water. The aqueous solution is decomposed by nitric acid (Griess, *loc. cit.*).

HOPS. The bitter principle of hops (lupulite) may be obtained in the crystalline state as follows: Fresh hops are exhausted with four times their weight of ether; the blackish residue left on evaporating the ethereal solution is treated with cold alcohol of 90 p. c.; the liquid filtered from the undissolved myrcin is freed from alcohol by distillation; and the residue is redissolved in ether. The ethereal solution is agitated, first with strong potash-ley (till the latter is no longer coloured yellow), then with pure water, which dissolves out the bitter principle in combination with potash; the aqueous solution is precipitated with cupric sulphate; and the blue precipitate is washed with a little ether, then dissolved in more ether, and decomposed by hydrogen sulphide. The solution, filtered from the copper sulphide and evaporated to a syrup in a stream of carbon dioxide, gradually yields the hop-bitter as a crystalline mass, which may be freed from the brown mother-liquor by repeatedly treating it with nitrobenzol on a plate of gypsum. The pure white crystals thus obtained become soft and yellow on exposure to the air; and on recrystallising them from ether, large very brittle rhombic prisms are obtained, covered with a layer of the same substance in the amorphous state. The bitter principle is insoluble in water, but very soluble in alcohol, ether, chloroform, carbon bisulphide, benzol, and oil of turpentine; the alcoholic solution diluted with water has a pure and pleasant bitter taste and a distinct acid reaction. The potash-ley which has been shaken up with the ethereal solution in the process above described contains, besides resin, a second body, which crystallises in white needles melting above 110° , and likewise unites with cupric oxide (Lermer, *Dingl. pol. J.* clxxix. 54).

According to Leuchs (*J. pr. Chem.* ci. 137), the aqueous infusion of hops loses its bitter taste by the action of reducing agents, such as sulphurous acid, aldehyde, and formic acid.

For analyses of the ash of hops, see Lermer (*Jahresb.* 1864, p. 609), Wheeler (*J. pr. Chem.* xciv. 385; *Jahresb.* 1865, p. 636).

HORNBLENDE. For analyses of this mineral, see *Jahresb.* 1862, p. 725; 1864, pp. 836, 837; 1866, 926;—of hornblende rock: *ibid.* 1867, pp. 1014, 1017, 1026.

HYÆNIC ACID. $C^{23}H^{32}O^2$ (Carius, *Ann. Ch. Pharm.* cxxxix. 168).—The anal glandular pouches of the striped hyæna contain a pale yellow buttery mass smelling slightly like musk, and consisting of the glyceride of this acid, together with palmitic and oleic acids. The separation and purification of the acid, which is present in small quantity only, depend upon its comparatively slight solubility in alcohol, and on the fact that it is precipitated by lead acetate from a hot alcoholic solution slightly acidulated with acetic acid, sooner than palmitic acid, while the oleic acid remains entirely in solution.

Hyænic acid resembles cerotic acid more than any other acid of the series $C^mH^{2m}O^2$; it is but slightly soluble in cold absolute alcohol, and separates from solution in boiling alcohol in granules appearing under the microscope to consist of groups of very slender mostly curved needles; in ether it is very slightly soluble. When heated it assumes a soft waxy consistence long before fusion, which takes place at 77° – 78° ; at 76° it again becomes waxy, and when cooled to the ordinary temperature, hard and friable. The acid thus solidified exhibits under the microscope the same forms as the acid crystallised from alcohol. The alcoholic solution has an acid

reaction. The salts, which are insoluble in water, are not decomposed by acetic acid; the potassium and sodium salts form clear solutions only with a very small quantity of warm water, an acid salt being precipitated even on slight dilution. The insoluble hyænates are also converted into acid salts by treatment with a large quantity of water. The *calcium salt* ($C^2H^4O^2$) 2Ca is a white crystalline powder, melting at 90°, slightly soluble in hot alcohol. The *lead salt* ($C^2H^4O^2$) 2Pb is a white very bulky precipitate, likewise very sparingly soluble in hot alcohol. Whether the hyænic acid is a constituent of the fat of the hyæna in general, or peculiar to the secretion above mentioned, is a question not yet decided.

HYALOPHANE. For analyses of this mineral, see *Jahresb.* 1866, p. 928; 1867, p. 982.

HYDANTOÏC ACID, GLYCOLURIC ACID, or OXACETYL-UREA. $C^2H^4N^2O^2 = COH^2(C^2H^3O^1)N^2$.—An acid containing the elements of hydantoin plus H^2O ; produced: 1. By the action of potash or baryta-water on hydantoin (Baeyer, iii. 177).—2. Together with urea, by boiling glycoluril with baryta-water (Rheineck, v. 960):

3. By heating bromacetyl-urea with aqueous ammonia (Baeyer, *Jahresb.* 1864, p. 636):

4. By heating glycocine with a slight excess of urea (Heintz, *ibid.* 1865, p. 360):

Hydantoinic acid obtained by decomposing its barium salt with sulphuric acid crystallises in large, transparent, colourless, mostly unsymmetrically developed monoclinic prisms exhibiting the combination $\infty P . \pm P . (2P\infty) . oP$. Ratio of clinod. to orthod. to principal axis = 0.662 : 1 : 1.535. Acute angle of axes = 81° 0'. Cleavage perfect parallel to oP . All the hydantoates, even the silver salt, are easily soluble in water, and only some of them crystallise, the rest drying up to amorphous masses. The *potassium salt* $C^2H^3N^2O^2K$, evaporated over sulphuric acid, forms microscopic six-sided tables and rhombohedrons; the *sodium salt* $C^2H^3N^2O^2Na + H^2O$, extremely soluble silky needles, which do not give off water at 133°; the *ammonium salt* $C^2H^3N^2O^2(NH^4) + H^2O$, large crystals, developed like augite at one end only, and becoming opaque from loss of ammonia. The *silver salt* crystallises in small indistinct laminae, which blacken on exposure to light. The *lead salt* ($C^2H^3N^2O^2$) $^2Pb + 3H^2O$ crystallises in nodular groups of needles very soluble in water, insoluble in alcohol of 90 p. c., becoming anhydrous at 120° (Herzog, *Ann. Ch. Pharm.* cxxvi. 276).

HYDANTOÏN, $C^2H^3N^2O^2$, or *Glycolyl-urea*, $CH^2(C^2H^3O^1)N^2O$.—Produced: 1. Together with urea, by the action of hydriodic acid on allantoin.—2. Together with a small quantity of allanturic acid, by the action of hydriodic acid upon alloxanic acid (iii. 177).—3. By heating bromacetyl-urea for several hours to 100° with alcoholic ammonia:

On evaporating the liquor to dryness, washing the residue with a little cold water, boiling it with water and lead hydrate, and removing the lead from the filtrate, the hydantoin separates in colourless spicular crystals. It is neutral, has a sweet taste, dissolves easily in hot water, melts at 206° to a colourless liquid, which solidifies to a crystalline mass at 157° (Baeyer, *Jahresb.* 1864, p. 637).

Ethyl-hydantoin. $C^2H^3(C^2H^3)N^2O^2$.—Produced, together with another body sparingly soluble in alcohol, by melting ethyl-glycocine with urea:

It crystallises from water, or from ether-alcohol, in large well-defined rhombic prisms of 76° 50', which appear tabular from truncation of the acute prismatic edges (at an angle of 128° 25'); dissolves very easily in water and in alcohol, somewhat less easily in ether; reacts neutral, and does not unite either with bases or with acids. It melts at the heat of the water-bath, and solidifies again but slowly; by continued heating it sublimates as a crystalline deposit (Heintz, *Ann. Ch. Pharm.* cxxiii. 65; *Jahresb.* 1865, p. 349).

HYDRAZO-ANILINE—HYDROBENZYLURIC ACID. 703

Methyl-hydantoin, $C^3H^3N^2O^2 = C^3H^3(CH^3)N^2O^2$, is formed by heating creatinine to 100° with baryta-water:

On warming the filtered solution to expel ammonia, carefully adding sulphuric acid, again filtering, and evaporating, the methyl-hydantoin separates in limpid crystals easily soluble in water and alcohol. The concentrated aqueous solution has a strong acid reaction; the alcoholic solution is not precipitated by ether. Methyl-hydantoin melts at 145° , and sublimes in oily crystallising drops or in shining spangles. It does not unite with baryta, but its heated solution takes up considerable quantities of silver oxide, and the alkaline filtrate deposits the *silver compound* $C^3H^3AgN^2O^2$, in groups of thin lancet-shaped laminae. The *mercury compound* obtained in like manner forms nodular groups of microscopic crystals which dissolve very easily in water, the solution depositing metallic mercury when evaporated by heat (Neubauer, *Ann. Ch. Pharm.* cxxviii. 288; *Jahresb.* 1866, p. 381).

HYDRAZO-ANILINE. $C^{12}H^{11}N^4$.—A base produced by the action of sodium-amalgam on nitraniline (prepared by reduction of dinitrobenzene). It is precipitated from the filtered liquid by water, and after recrystallisation from alcohol, forms long golden-yellow needles, which melt a little above 140° , sublime for the most part undecomposed at a lower temperature, and dissolve sparingly in water, easily in alcohol and ether. The *sulphate*, $C^{12}H^{11}N^4.H^2SO^4$, formed by direct combination, is yellow, nearly insoluble in water, slightly soluble in alcohol and ether. The *hydrochloride*, $C^{12}H^{11}N^4.2HCl$, obtained in like manner, forms thin laminae resembling mosaic gold, easily soluble in water, slightly in alcohol, almost insoluble in ether. The *nitrate* forms yellow needles easily soluble in water. The *platinochloride*, $C^{12}H^{11}N^4.2HCl.PtCl^4$, is a flesh-coloured precipitate. Nitraniline prepared from nitranilides (iv. 445) is converted by sodium-amalgam into a black-brown resinous mass.

HYDRAZOBENZENE. See AZOBENZENES (p. 271).

HYDRAZOBENZOIC ACID and **HYDRAZODRACTYLIC ACID**. See AZOBENZOIC ACIDS (p. 321).

HYDRAZOSALICYLOL. See SALICYLOL.

HYDRAZOTOLUENE. $C^{11}H^{10}N^2$. See AZOTOLUENES, under BENZENE, HOMOLOGUES OF (p. 285).

HYDRINDIC ACID. Syn. with DIOXINDOL. See INDOL.

HYDROBENZAMIDE, $C^{12}H^{12}N^2$, heated with hydrocyanic and hydrochloric acids, is for the most part decomposed, with separation of benzoic aldehyde; but if the hydrobenzamide be first covered with a large quantity of alcohol, then treated with hydrocyanic and hydrochloric acids, or only with the former, and warmed, the liquid on cooling yields white granular crystals of hydrocyanobenzide, formed according to the equation:

Hydrocyanobenzide is isomeric or identical with Laurent's benzoylazotide, produced by the action of ammonia on bitter almond oil (i. 572). It melts when heated, solidifies in the amorphous state, dissolves sparingly in boiling alcohol, and is decomposed by hydrochloric acid, only in alcoholic solution, with separation of hydrocyanic acid. Heated to 100° in a sealed tube with carbon bisulphide, it dissolves, and afterwards separates in small shining crystals.

HYDROBENZOIC ACID. See BENZOIC ACID.

HYDROBENZYLURIC ACID. $C^{13}H^{12}N^2O^4$ (Otto, *Ann. Ch. Pharm.* cxxiv. 303).—An acid produced by the incomplete action of sodium-amalgam on hippuric acid in alkaline solution (p. 700). It may be separated from hydrobenzyluric acid formed at the same time, by its insolubility in ether (free from alcohol), and when purified by treatment with warm water and animal charcoal, forms a yellowish inodorous mass of the consistence of turpentine, which solidifies in the crystalline form after standing for several months. It is insoluble in water, but dissolves in all proportions of alcohol, and is dissolved without decomposition by caustic and carbonated alkalis. The solution in ammonia forms with various metallic salts precipitates which decompose at the boiling heat, with partial separation of the acid.

HYDROBENZYLURIC ACID. $C^{13}H^{12}NO^4$ (Otto, *loc. cit.*).—Formed by the complete action of sodium-amalgam on hippuric or hydrobenzyluric acid (p. 700).

When recently prepared, it is an inodorous yellowish oil, soluble in ether, alcohol, and alkalis, but insoluble in water; but when exposed to the air, either in the free state or in alkaline solution, it takes up oxygen and is gradually converted into hydroxybenzyluric acid (*q.v.*). Boiled with alkalis out of contact with the air, it is resolved into glycocine, benzyl alcohol, and hydrobenzoic acid:

HYDROCAFFEIC ACID. $C^8H^{10}O^4$ (Hlasiwetz, *Ann. Ch. Pharm.* cxlii. 353).—

Produced by heating caffeic acid with water and sodium-amalgam in a flask provided with a condenser, acidulating the liquid with dilute sulphuric acid without opening the flask more than necessary, and agitating with ether. The aqueous solution of the syrupy residue left on evaporating the ethereal extract, gradually yields colourless rhombohedral crystals of hydrocaffeic acid. It has a slightly acid taste; easily reduces cupric oxide in alkaline solution, also silver nitrate; forms with lead acetate a white precipitate, and with ferric chloride a deep green solution, changing to dark cherry-red on addition of sodium carbonate. The metallic hydrocaffiates are gummy, or when thrown down by alcohol, white precipitates, whose solutions are coloured dark blue by ferric chloride, green by an excess of the latter. The calcium salt contains $(C^2H^3O^4)^2Ca$, the barium salt $(C^2H^3O^4)^2Ba$; the lead salt $(C^2H^3O^4)^2Pb^2$. The acid is therefore tribasic.

In the action of sodium-amalgam on caffeic acid there is also formed a small quantity of a body which is coloured grass-green by a trace of alkali.

HYDROCARBONS. *Classification and Nomenclature.*—The simplest of all hydrocarbons is methane or marsh gas, CH^4 , in which the tetrad atom of carbon is united with 4 atoms of hydrogen. The compound thus formed is a saturated molecule, not capable of uniting directly with chlorine, bromine, or other monad element, but only of exchanging a part or the whole of its hydrogen for an equivalent quantity of another monad element. But it may take up any number of dyad elements or radicles, because such a radicle introduced into any group of atoms neutralises one unit of equivalence and introduces another, thereby leaving the combining power or equivalence of the group the same as before. Accordingly the hydrocarbon CH^4 can take up any number of molecules of the bivalent group or radicle CH^2 , giving rise to the homologous series of saturated hydrocarbons:

These saturated hydrocarbons may, under various circumstances, be deprived of two atoms or one molecule of hydrogen, producing a new homologous series:

These are unsaturated molecules, having two units of equivalency uncombined, and therefore acting as bivalent radicles.

The first term of this last series cannot give up 2 atoms of hydrogen without being reduced to the atom of carbon; but the remaining terms may give up 2 atoms of hydrogen and thus give rise to the series

each term of which is a quadrivalent radicle.

And in like manner, by successive abstraction of H^2 , a number of homologous series may be formed, whose general terms are

The individual series, as far as C^6 , are given in the following table, together with the names proposed for them by Hofmann (*Proc. Roy. Soc.* xv. 57):

CH^4	C^2H^2			
Methane.	Methene.			
C^2H^6	C^2H^4	C^2H^2		
Ethane.	Ethene.	Ethine.		
C^3H^8	C^3H^6	C^3H^4		
Propane.	Propene.	Propine.	Propone.	
C^4H^{10}	C^4H^8	C^4H^6	C^4H^4	C^4H^2
Quartane.	Quartene.	Quartine.	Quartone.	Quartene.
C^5H^{12}	C^5H^{10}	C^5H^8	C^5H^6	C^5H^4
Quintane.	Quintene.	Quintine.	Quintone.	Quintene.
C^6H^{14}	C^6H^{12}	C^6H^{10}	C^6H^8	C^6H^6
Sextane.	Sextene.	Sextine.	Sextone.	Sextene.

These names, proposed by Hofmann in 1863, have not been generally adopted; but a systematic nomenclature for the hydrocarbons, which are the fundamental compounds of organic chemistry, is a great desideratum, and it would not perhaps be easy to devise a better system than that above given. It is true that these names do not carry us beyond the fifth term of each isologous series; but they suffice for most of the hydrocarbons at present known, and it would be easy to extend them by the use of double vowels.

The hydrocarbons of the second homologous series, the olefines C^sH^{2s} , are generally designated by names ending in *ylene*, and these names are perhaps too well established to be altered, but the shorter names without the *yl* are more systematic, and their adoption would be an improvement in our nomenclature.

The formulæ in the preceding table represent hydrocarbons, all of which are capable of existing in the separate state, and many of which have been actually obtained. They are all derived from saturated molecules, C^sH^{2s+2} , by abstraction of one or more pairs of hydrogen-atoms.

But a saturated hydrocarbon, CH^4 for example, may give up 1, 2, 3, or any number of hydrogen-atoms in exchange for other elements: thus, marsh gas, CH^4 , subjected to the action of chlorine under various circumstances, yields the substitution-products

which may be regarded as compounds of chlorine with the radicles

and in like manner each hydrocarbon of the series C^sH^{2s+2} may yield a series of radicles of the forms

each of which has an equivalent value, or combining power, corresponding with the number of hydrogen-atoms abstracted from the original hydrocarbon. Those of even equivalence contain even numbers of hydrogen-atoms, and are identical in composition with those in the table above given; but those of uneven equivalence contain odd numbers of hydrogen-atoms, and are incapable of existing in the separate state, except, perhaps, as double molecules.

These hydrocarbon radicles of uneven equivalence are designated by names ending in *yl*, those of the univalent radicles being formed from methane, ethane, &c., by changing the termination *ane* into *yl*; those of the trivalent radicles by changing the final *e* in the names of the bivalent radicles, methane, &c., into *yl*; and similarly for the rest. The names of the entire series as far as C^7 will therefore be as follows:

CH^4 Methane.	$(CH^3)'$ Methyl.	$(CH^2)''$ Methene.	$(CH)'''$ Methenyl.						
C^2H^6 Ethane.	$(C^2H^4)'$ Ethyl.	$(C^2H^2)''$ Ethene.	$(C^2H)'''$ Ethenyl.	$(C^2H^2)^{iv}$ Ethine.	$(C^2H)^v$ Ethynyl.				
C^3H^8 Propane.	$(C^3H^6)'$ Propyl.	$(C^3H^4)''$ Propene.	$(C^3H^2)'''$ Propenyl.	$(C^3H)^{iv}$ Propine.	$(C^3H)^v$ Propynyl.	$(C^3H^2)^{vi}$ Propone.	$(C^3H)^{vii}$ Proponyl.		

General Properties of the Hydrocarbons.

First Series. C^sH^{2s+2} . *Paraffins*.—The name paraffin, signifying chemical indifference (*parum affinis*), has long been applied to a colourless crystalline fatty substance found native in the coal-measures and other bituminous strata, and separable from the least volatile portions of native petroleum, tar, &c. This substance is a hydrocarbon or a mixture of hydrocarbons of the series C^sH^{2s+2} (iv. 344, and *infra*); and the liquid members of the same series are now known commercially as paraffin oils: the name paraffin may therefore be conveniently used as a generic term for the whole series. The names of the first six members, proposed by Hofmann, are contained in the first column of the table above given; the following terms are named *septane*, *octane*, *nonane*, *decane*, *undecane*, *dodecane*, &c.

All the members of the series above the first, CH^4 , may be regarded as derived from

$$\begin{array}{c} \text{Z Z} \\ \text{Sup.} \end{array}$$

that compound by replacement of one of the hydrogen-atoms by a univalent hydrocarbon radicle of the series C^nH^{2n+1} ; thus :

The paraffins are formed : 1. By the simultaneous action of zinc and water on the alcoholic iodides, compounds derived from these same hydrocarbons by the substitution of one atom of iodine for hydrogen.

This reaction, which appears to be applicable to the formation of the whole series of paraffins, is represented by the general equation :

2. By heating the alcoholic iodides with zinc alone. Generally speaking, however, two of these hydrocarbons are obtained together, the first product of the reaction being a paraffin containing twice as many carbon-atoms as the alcoholic iodide employed; and this compound being then partly resolved into the paraffin containing half this number of carbon-atoms and the corresponding olefine, (C^nH^{2n}); thus :

3. By the electrolysis of the fatty acids $C^nH^{2n}O^2$. For example, a solution of potassium acetate divided into two parts by a porous diaphragm, yields pure hydrogen, together with potash, at the negative electrode, and at the positive electrode (if of platinum) a mixture of carbon dioxide and ethane gases :

The general reaction is

4. Some of the paraffins are obtained from acids of the series $C^nH^{2n}O^2$ and $C^nH^{2n-2}O^4$, by the action of alkalis, which abstract carbon dioxide from those acids, the hydrocarbon thus eliminated containing one atom of carbon less than the acid from which it is produced :

In this manner methane (marsh gas) is obtained by heating potassium acetate with excess of potassium hydrate (p. 178) :

Also, sextane and octane, by similar treatment of the potassium salts of suberic acid, $C^8H^{14}O^4$, and sebacic acid, $C^{10}H^{18}O^4$:

Generally speaking, however, a further decomposition takes place, resulting in the

formation of hydrocarbons containing a smaller proportion of hydrogen than the paraffins.

5. The paraffins may also be produced from the olefines, C^aH^{2a} , by combining the latter with bromine, and heating the resulting compound, $C^aH^{2a}Br_2$, with a mixture of potassium iodide, water, and metallic copper. The bromine-compound is then decomposed, and the hydrocarbon, C^aH^{2a} , is partly reproduced in the free state, partly converted, by the addition of hydrogen, into a paraffin, C^aH^{2a+2} .

6. Several of the paraffins are produced by the dry or destructive distillation of butyrates and acetates.

7. They are also found amongst the products of the dry distillation of coal, especially Boghead and Cannel coal, and they constitute the principal portion of many mineral oils, formed by the gradual decay or decomposition of vegetable matter beneath the earth's surface (iii. 181; iv. 385).

8. Quintyl alcohol, or amyl alcohol, $C^5H^{12}O$, distilled with zinc chloride, yields quintane, C^5H^{12} , and several of its homologues, together with olefines and other hydrocarbons containing still smaller proportions of hydrogen.

9. Methane, CH^4 , is produced synthetically by passing a mixture of hydrogen sulphide and vapour of carbon bisulphide over red-hot copper:

Properties and Reactions.—Methane, ethane, propane, and quartane are gaseous at ordinary temperatures; most of the others are liquids, regularly increasing in specific gravity, viscosity, boiling point, and vapour-density, as their molecular weight becomes greater; those containing 20 carbon-atoms or more are crystalline solids. The specific gravities and boiling points of the paraffins obtained from American petroleum are given in the table on p. 181, vol. iii.

The paraffins are especially distinguished by their chemical indifference, exhibiting more completely perhaps than any other class of compounds the characters of perfectly saturated and indifferent molecules, incapable of uniting directly with anything else. With bromine and chlorine they form substitution-products. Methane, CH^4 , exposed to the action of chlorine in diffused daylight, forms chloromethane or methyl chloride, CH^3Cl , which by the further action of chlorine in sunshine may be converted into CH^2Cl_2 , $CHCl_3$, and CCl^4 ; and ethane, by a series of processes described under ethyl chloride (ii. 530), may be made to yield the compounds C^2H^5Cl , $C^2H^4Cl_2$, $C^2H^3Cl_3$, $C^2H^2Cl_4$, C^2HCl_5 , and CCl^6 ; similarly with propane, quartane, &c.

Solid paraffin has sometimes been supposed to belong to the olefine series. Analysis will not decide the question, for it is evident that the percentage composition of a hydrocarbon of the series C^aH^{2a+2} or $CH^{2+\frac{2}{n}}$ approaches more nearly to that of an

olefine, C^aH^{2a} or CH^2 , as the value of n becomes greater. The olefines contain 85·7 p. c. carbon and 14·3 hydrogen. In solid paraffin melting at 56° , Gill & Meusel (*Chem. Soc. J.* [2] vi. 466) found 85·5 carb. and 14·9 hydr., the formula $C^{80}H^{122}$ requiring 85·5 carb. and 14·5 hydr. The same chemists have shown that solid paraffin heated to 50° – 100° in hydrochloric acid gas does not unite with it or suffer any alteration of melting point. On exposing it to sunshine in contact with bromine and water, the bromine disappears, half of it being found in the water as hydrobromic acid, showing that a substitution-product has been formed. This accords with the reaction of paraffin with chlorine, as observed some time ago by Bolley and by Brodie (iv. 344). Moreover, paraffin is not attacked by dilute hypochlorous acid, whereas cetene, $C^{26}H^{52}$, combines with that acid, producing rise of temperature. All these reactions show that solid paraffin belongs to the series C^aH^{2a+2} , not to the olefine series C^aH^{2a} , a result which is consistent with its constant occurrence in mineral oils consisting mainly of the liquid homologues of marsh gas, but not containing any well-characterised member of the olefine series.

The paraffins are scarcely attacked by oxidising agents at ordinary temperatures; when heated therewith, they are either wholly burnt to water and carbon dioxide, or they yield in addition comparatively small quantities of other oxidation-products, acetic acid, for example, when oxidised by chromic acid. Fuming nitric acid scarcely attacks them in the cold, even after several months, but acts very violently at a gentle heat. Nitric acid of sp. gr. 1·4 yields the same products, but acts less strongly. Sextane and octane (from petroleum) and decane (diamyl) heated with acid of this strength as long as red fumes are evolved, are converted into crystalline succinic acid, together with a nitrogenised yellow oil, and small quantities of fatty acids and nitriles; decane, for example, appears to yield capronitrile, $C^{10}H^{19}N$, and acids and valerianic acids (Schorlemmer, *Proc. Roy. Soc.* xvi. 373). Berthelot (*Jahresb.* 1867, p. 336) found that a few decigrams of

sextane required two months' treatment with potassium permanganate to oxidise it completely, yielding a mixture of fatty acids apparently containing caproic acid. Solid paraffin, melting at 56°, boiled for three or four days with sulphuric acid and potassium dichromate, with addition of a little manganese dioxide (which greatly facilitates the reaction), is converted mainly into cerotic acid, $C^{22}H^{44}O_2$, melting at 78°. The same paraffin heated with 5 or 6 vol. nitric acid diluted with $1\frac{1}{2}$ vol. water, yielded a mixture of solid fatty acids, melting after purification at about 76°, and probably therefore containing cerotic acid, also volatile fatty acids, the most abundant of which was cenanthylic acid, while the nitric acid solution contained hydrocyanic acid, succinic acid, and an acid agreeing in composition and melting point with anchoic acid (Gill a. Meusel, *loc. cit.*).

Isomerism in the Paraffin Series.—These hydrocarbons are sometimes regarded as hydrides of the univalent alcohol-radicles C^nH^{2n+1} —methane, for example, as methyl-hydride, $H.CH^3$; ethane as ethyl hydride, $H.C^2H^3$. This view of their constitution is suggested by their formation by the action of water on the zinc-compounds of the same radicles; *e.g.*,

and by the facility with which they give up one atom of hydrogen in exchange for chlorine and bromine, whereas the replacement of the remaining hydrogen-atoms is much more difficult. On the other hand, all these hydrocarbons, except methane, may be regarded as compounds of two atoms or half-molecules of alcohol radicles, C^nH^{2n+1} ; thus

This latter view appears to accord with their formation by the action of zinc on the iodides of the alcohol-radicles, which is similar to that of hydrogen by the action of zinc on hydriodic acid; thus:

The first three hydrocarbons of the series however, viz. CH^4 , C^2H^6 , C^3H^8 , exhibit exactly the same physical and chemical properties in whatever way they may be prepared; and indeed the constitutional formulæ of these bodies, viz.,

show that they are not susceptible of isomeric modifications, inasmuch as there is but one way in which the carbon-atoms in either of them can be grouped; in ethane each carbon-atom is directly combined with three hydrogen-atoms and the other carbon-

atom; and whether we regard it as ethyl hydride, $\begin{array}{c} CH^3 \\ | \\ H-CH^3 \end{array}$, or as dimethyl, H^3C-CH^3 ,

this arrangement remains the same. In propane, C^3H^8 , each carbon-atom is directly combined with at most two other carbon-atoms, and there is no other way in which the atoms can be arranged.

But if we look at the formula of the 4-carbon paraffin, C^4H^{10} , we see that it may be written in either of the following forms:

in the first of which neither of the carbon-atoms is directly united with more than two others, whereas in the second one of the carbon-atoms is directly combined with three others. The first may be represented, either as *propyl-methane*, $C \begin{Bmatrix} CH^2CH^2CH^2 \\ H^2 \end{Bmatrix}$ = $C \begin{Bmatrix} CH^2CH^2H^2 \\ H^2 \end{Bmatrix}$ = $C \begin{Bmatrix} CH^2CH^2H^2 \\ H^2 \end{Bmatrix}$, or as *diethyl*, $HC^2.C^2H^2$, according to the manner in which we may suppose it to be divided; the second as *trimethyl-methane*, $C \begin{Bmatrix} (CH^2)^3 \\ H^2 \end{Bmatrix}$, or *isopropyl methane*, $C \begin{Bmatrix} CH(CH^2)^2 \\ H^2 \end{Bmatrix}$.

From recent observations by Schorlemmer (*Proc. Roy. Soc.* xvi. 34, 367), it appears that all the paraffins may be divided into four groups, viz.: 1. Those in which each carbon-atom is directly associated with at most two other carbon-atoms.—2. Those in which one carbon-atom is associated with three carbon-atoms, or which contain the group isopropyl once.—3. Those which contain this group twice, such as di-isopropyl, or tetramethyl-ethane, C^2H^{14} = $C^2 \begin{Bmatrix} H(CH^2)^2 \\ H(CH^2)^2 \end{Bmatrix}$, produced by the action of zinc on isopropyl iodide; this compound may be represented by the constitutional formula:

4. Those in which one carbon-atom is associated with four others, as in dimethyl-diethyl-methane, or carbodimethyl-diethyl, $C \begin{Bmatrix} (CH^2)^2 \\ (C^2H^2)^2 \end{Bmatrix}$, a compound produced by the action of zinc-ethyl on dimethyl-dichloromethane, $C \begin{Bmatrix} (CH^2)^2 \\ Cl^2 \end{Bmatrix}$, the transformation being effected by the substitution of 2 at. methyl for 2 at. chlorine:

The boiling point of a paraffin containing a given number of carbon-atoms is found to be lower in proportion as its structure is more complex. The paraffins of the first group, *e.g.* sextane or hexane (from suberic acid, mannite, and petroleum, iii. 153), and heptane or heptane from azelaic acid (p. 696), boil at higher temperatures than their isomerides in either of the other groups. The difference in their boiling points for a difference in composition of CH^2 is 31° . The paraffins of the second group (amyl-hydride 30° , ethyl-butyl 62° , ethyl-amyl 91° , octyl hydride from octyl alcohol 124°) likewise exhibit for a difference of CH^2 a difference in boiling point equal to 31° . The paraffins of the third group (di-isopropyl 58° , dibutyl 58° , butyl-amyl 132° , diamyl 158°) exhibit for each difference of CH^2 a difference in boiling point equal to 25° . Of the fourth group, the only known member is dimethyl-diethyl-methane, which boils at 86° (Schorlemmer).

Second Series. C^2H^{14} . Olefines.—The hydrocarbons of this series are polymeric, as well as homologous, with one another, inasmuch as their formulæ are all exact multiples of that of the lowest, CH^2 . The lower members of the series are gaseous at ordinary temperatures, the higher members are solid, and the intermediate compounds liquid. The names and formulæ of the known members of the olefine series are given in the following table, together with their melting and boiling points:

Name			Formula	Melting point	Boiling point
Ethene	or	Ethylene	C^2H^4	—	—
Propene	"	Propylene	C^3H^6	—	-17-8°
Quartene	"	Butylene	C^4H^8	—	+3°
Quintene	"	Amylene	C^5H^{10}	—	35°
Sextene	"	Hexylene	C^6H^{12}	—	68°-70°
Septene	"	Heptylene	C^7H^{14}	—	95°
Octene	"	Octylene	C^8H^{16}	—	115°-117°
Nonene	"	Nonylene	C^9H^{18}	—	140°
Decene	"	Paramylene	$C^{10}H^{20}$	—	160°
Sexdecene	"	Cetene	$C^{16}H^{32}$	—	275°
Septavigintene	"	Corotene	$C^{27}H^{54}$	57°	(?)
Trigintene	"	Melene	$C^{30}H^{60}$	62°	375° (?)

Methene, CH^2 , the lowest term of the series, does not appear to be capable of existing in the separate state; but its oxygen analogue, carbon monoxide or carbonyl, CO, is a well-known compound.

Formation of the Olefines.—1. By abstraction of the elements of water from the alcohols of the series $C^nH^{2n+2}O$, under the influence of powerful dehydrating agents, such as oil of vitriol, phosphoric oxide, or zinc chloride; thus:

Quintyl or amyl alcohol, $C^5H^{12}O$, distilled with zinc chloride, yields—besides the corresponding olefine, quintene or amylen, C^5H^{10} —a number of others polymeric with it, also quintane, C^5H^{12} , and its homologues, and hydrocarbons containing a smaller proportion of hydrogen than the olefines.

2. By passing the vapours of the haloïd compounds of the monad radicles C^nH^{2n+1} over lime at a dull red heat; e.g.,

3. By the decomposition of the paraffins at the moment of their formation by the action of zinc or sodium on the iodides of the monad alcohol-radicles C^nH^{2n+1} .

4. By the action of these same iodides on the sodium-compounds of the same radicles; for example,

5. By decomposition of the hydrates of ammonium-bases containing four atoms of a monad alcohol-radicle, these compounds when heated splitting up into a tertiary monamine and an olefine; thus:

6. Olefines are formed by the decomposition of acetates and butyrates at a red heat, distilling over together with several other products, from which they are separated by combining them with bromine, and heating the resulting bromine-compounds, $C^nH^{2n}Br^2$, to 275° with copper, water, and potassium iodide. In this manner Berthelot has obtained ethene, propene, quartene, and quintene.

7. Several of the olefines may be produced by direct synthesis from other hydrocarbons of simpler constitution.

a. Ethene is formed by the action of nascent hydrogen upon ethine or acetylene:

8. Propene, C^3H^6 , is formed by passing a mixture of methane and carbon monoxide (oxymethene) through a red-hot tube:

Also by the action of methenyl chloride (chloroform) on zinc ethide:

7. Quintene, or amylene, C^5H^{10} (or a compound isomeric with it), is formed by the action of zinc ethide on allyl iodide:

8. Sextene, or hexylene, C^6H^{12} , is obtained in combination with hydriodic acid by the action of that acid on mannite:

and this hydriodide, heated with potassium hydrate, yields the hydrocarbon:

9. Quartene, or butylene, C^4H^8 , is obtained by precisely similar reactions from erythrite, $C^4H^4(OH)^4$.

Reactions.—1. The olefines are dyad radicles, uniting with 2 atoms of chlorine, bromine, &c., and with 1 atom of oxygen.

2. The chlorides, bromides, and other haloid compounds of the olefines, treated with an alcoholic solution of *potash*, give up one atom of hydrogen and one atom of the haloid element, yielding an olefine in which 1 atom of hydrogen is replaced by chlorine, bromine, &c., together with water and a haloid salt of potassium; thus:

The resulting chlorinated, brominated, or iodated compound can, in its turn, take up 2 atoms of chlorine, bromine, or iodine, forming a body which can likewise give up hydrochloric, hydrobromic, or hydriodic acid, under the influence of alcoholic potash; the body thus formed can again take up 2 atoms of chlorine, bromine, or iodine, then give up HCl , HBr , or HI ; and thus, by a series of perfectly similar reactions, we at length arrive at bodies consisting of the primitive olefine with all its hydrogen replaced by chlorine, bromine, or iodine, and the dichlorides, dibromides, and di-iodides of these last-mentioned bodies; thus from ethene may be derived the two following series of brominated compounds:

Ethene	C^2H^4	Ethene bromide	$C^2H^4Br^2$
Bromethene	C^2H^4Br	Bromethene bromide	$C^2H^4Br \cdot Br^2$
Dibromethene	$C^2H^4Br^2$	Dibromethene bromide	$C^2H^4Br^2 \cdot Br^2$
Tribromethene	C^2HBr^3	Tribromethene bromide	$C^2HBr^3 \cdot Br^2$
Tetrabromethene	C^2Br^4	Tetrabromethene bromide	$C^2Br^4 \cdot Br^2$

3. A monochlorinated or monobrominated olefine may give up the atom of chlorine or bromine which it contains, in the form of hydrochloric or hydrobromic acid, whereby it is reduced to a hydrocarbon of the following series: C^2H^{2n-2} . This reaction may take place at 130° – 150° , under the influence of alcoholic potash, or, better, of sodium ethylate; thus:

4. Ethene bromide and its homologues, treated with silver acetate or potassium acetate, exchange their bromine for an equivalent quantity of the halogenic residue of the acetate, $C^2H^3O^2$, giving rise to diatomic acetic ethers; thus:

and these ethers, distilled with a caustic alkali, yield diatomic alcohols or glycols; for example:

5. The bromides $C^2H^4Br^2$, heated to 275° with a mixture of potassium iodide, copper, and water, give up their bromine and reproduce the original olefine, together with other hydrocarbons (p. 707).

6. Some olefines, when briskly shaken up with strong sulphuric acid, unite with it, forming acid ethers of sulphuric acid, which contain the monatomic alcoholic radicles corresponding to the olefines; thus:

and these acid ethers distilled with water reproduce sulphuric acid and the monatomic alcohol corresponding to the olefine:

With fuming sulphuric acid (which contains sulphuric oxide in solution) the olefines yield sulpho-acids which are isomeric with the preceding, but are not decomposed by water with formation of an alcohol.

7. Olefines unite with hydrochloric, hydrobromic, and hydriodic acids; and the resulting compounds treated with silver oxide in presence of water give rise to two different reactions which go on simultaneously, one part of the compound exchanging its halogen element for hydroxyl, and thereby producing an alcohol, while another portion gives up hydrochloric, hydrobromic, or hydriodic acid, reproducing the original olefine:

8. Ethene agitated with a strongly alkaline solution of potassium permanganate is oxidised to oxalic acid, ($\text{C}^2\text{H}^4 + \text{O}^3 = \text{H}^2\text{O} + \text{C}^2\text{H}^2\text{O}^4$), which is partly resolved into formic acid and carbon dioxide. Propene similarly treated yields malonic acid, ($\text{C}^3\text{H}^6 + \text{O}^3 = \text{H}^2\text{O} + \text{C}^3\text{H}^4\text{O}^4$), with acetic, oxalic, formic, and carbonic acids as secondary products. Quintene or amylene appears to yield pyrotartaric acid, $\text{C}^5\text{H}^8\text{O}^4$, together with succinic, malonic, and oxalic acids, and volatile acids of the series $\text{C}^n\text{H}^{2n}\text{O}^2$. In all cases the primary and normal product of the oxidation of an olefine appears to be the corresponding bibasic acid $\text{C}^n\text{H}^{2n-2}\text{O}^4$, the other acids formed at the same time resulting from the decomposition and oxidation of this primary product (Berthelot, *Compt. rend.* lxiv. 35; *Jahresb.* 1867, p. 335).

Many olefines are oxidised by aqueous chromic acid to aldehydes or ketones. Ethene gas is slowly attacked at 120° , and converted into aldehyde $\text{C}^2\text{H}^4\text{O}$. Propene C^3H^6 is oxidised much more readily and almost at ordinary temperatures, yielding acetone, $\text{C}^3\text{H}^6\text{O}$. Amylene is violently attacked at ordinary temperatures, with formation of complex products, doubtless derived from a ketone, $\text{C}^5\text{H}^{10}\text{O}$ (Berthelot, *Compt. rend.* lxviii. 334).

9. Saturated aqueous hydriodic acid converts olefines even in the cold, and more quickly at 100° , first into the corresponding mono-iodated paraffins, then into the paraffins themselves; e.g.,

and

Isomerism in the Olefine Series.—These hydrocarbons may exist in two modifications, one saturated, the other bivalent, according to the manner in which the carbon-atoms are linked together; ethene, C^2H^4 , for example, may exhibit the two following modifications:

Ethene in the free state is probably represented by the first of these formulæ, but when it comes in contact with bromine, chlorine, &c., the union of the two carbon-atoms becomes loosened (as in the case of benzene, p. 196), and the molecule assumes the constitution represented by the second formula, in which state it is ready to take up Br^2 , Cl^2 , O , &c.

They likewise exhibit in some of their compounds another kind of isomerism, depending upon the relative position of the hydrogen-atoms, which does not affect their equivalent value. Thus the dichlorides of the olefines are isomeric with the monochlorinated chlorides of the alcohol-radicles $\text{C}^n\text{H}^{2n+1}$; for example:

Both these compounds, when treated with alcoholic potash, yield the same product, viz. vinyl chloride, C^2H^3Cl , but they differ in boiling point, the former boiling at 85° , the second at 64° . Again, the oxides of the olefines are isomeric with the corresponding aldehydes; e.g.,

These compounds contain the radicles ethene or ethylene, CH^2-CH^2 , and ethylidene, CH^2-CH , respectively, both of which are bivalent; the latter is not known in the free state.

In the higher terms of the series a greater number of isomeric modifications may occur; thus of the third term, C^3H^4 , the following modifications are conceivable:

The first of these is normal propylene in combination; the second is propylidene, homologous with ethylidene; the third is perhaps propylene in the free state.

Quartene or butylene, C^4H^6 , and its higher homologues may also exhibit modifications similar to those occurring in the paraffins, and depending on the presence of the radicle propyl or isopropyl in the molecule; thus the molecule C^4H^6 may exhibit nine modifications. (See BUTYLENE, p. 375.) In the higher terms still greater variety of constitution is of course possible; indeed, if it be remembered that every olefine is derived from the corresponding paraffin by abstraction of 2 at. hydrogen, and that these two hydrogen-atoms may be taken from the same group CH^2 or CH^2 , or one from each of two such groups, it is easy to see that very numerous modifications may arise. Only a small number of these modifications have however been observed in any case. (See HEXYLENE, p. 699.)

Third Series. C^2H^{2n-2} .—Five of these hydrocarbons are known, viz.,

Ethine or Acetylene,	C^2H^2
Propine „ Allylene,	C^3H^4
Quartine „ Crotonylene,	C^4H^6
Quintine „ Valerylone,	C^5H^8
Sextine „ Diallyl,	C^6H^{10}

The only general method of preparing these bodies consists in heating the monobrominated derivatives of the olefines, $C^2H^{2n-1}Br$, with sodium ethylate to $130^\circ-150^\circ$:

Ethine and propine, which are gaseous at ordinary temperatures, are separated from the alcohol vapour with which they are mixed, by passing the gas into an ammoniacal solution of cuprous chloride, whereby an explosive compound is precipitated, containing copper, carbon, hydrogen, and oxygen; and this precipitate, treated with hydrochloric acid, yields the hydrocarbon in the pure state.

The other hydrocarbons of the series, which are liquid, do not form any precipitate with ammoniacal cuprous chloride; but they may be separated from the excess of alcohol by addition of water, and further purified by distillation.

The hydrocarbons of this series should exhibit three isomeric modifications: saturated, bivalent, and quadrivalent, according to the manner in which the carbon-atoms are united; thus, for the compound C^2H^2 :

and they do in fact form compounds with 2 and 4 atoms of bromine, chlorine, and

other monad elements. When agitated with hydrobromic or hydriodic acid, they take up one or two molecules of the acid, forming compounds isomeric with the dibromides and di-iodides of the olefines; thus:

Respecting their other properties, see the individual compounds, ACETYLENE, ALLYLENE, &c.

Fourth Series. $\text{C}^6\text{H}^{2n-4}$.—The known hydrocarbons of this series are quintone or valylene, C^6H^4 , produced by abstraction of hydrogen from quintine or valerylene; and the volatile oils called terpenes or camphenes, having the composition $\text{C}^{10}\text{H}^{16}$, and existing ready-formed in plants. The former, quintine, is sexvalent and quadrivalent; the terpenes are quadrivalent and bivalent. (See VALYLENE, v. 982; CAMPHENES, i. 724; and TURPENTINE OIL, v. 920.)

Fifth Series. $\text{C}^6\text{H}^{2n-6}$.—These are the aromatic hydrocarbons already fully described under BENZENE and its homologues (pp. 259–304).

Sixth Series. $\text{C}^6\text{H}^{2n-8}$.—The only known hydrocarbons of this series are phenylene, C^6H^4 , and cinnamene or styrol, C^6H^2 , with its isomerido meta-cinnamene (p. 465). Of phenylene very little is known. A liquid having the composition C^6H^4 was found by Church (*Chem. Soc. J.* [2] i. 76) among the products of the decomposition of chlorobenzene by sodium-amalgam. It is probably also formed, together with benzene, when diphenyl, $\text{C}^{12}\text{H}^{10}$, is passed through a red-hot tube, $\text{C}^{12}\text{H}^{10} = \text{C}^6\text{H}^6 + \text{C}^6\text{H}^4$, but is subsequently converted by polymerisation into chrysene, $\text{C}^{18}\text{H}^{12}$.

Seventh Series. $\text{C}^6\text{H}^{2n-10}$.—The only known member of this series is cholesterolone, $\text{C}^{26}\text{H}^{42}$, formed by dehydration of cholesterolin, $\text{C}^{26}\text{H}^{44}\text{O}$. Another might perhaps be formed by heating bromocinnamene with sodium ethylate.

Eighth Series. $\text{C}^{10}\text{H}^{2n-12}$.—Of this series only one member is known with certainty, viz. naphthalene, C^{10}H^8 , produced in the distillation of coal (see iv. 4, and the article NAPHTHALENE in this volume). According to Chancel, two hydrocarbons isomeric or polymeric with this body are formed in the dry distillation of calcium benzoate.

Ninth Series. $\text{C}^{12}\text{H}^{2n-14}$.—Two hydrocarbons of this series are known, viz. diphenyl, $\text{C}^{12}\text{H}^{10}$, and dibenzyl, $\text{C}^{14}\text{H}^{14}$. The former is a crystalline body produced by the action of sodium on phenyl bromide, $\text{C}^6\text{H}^5\text{Br}$; by the decomposition of benzene at a red heat: $2\text{C}^6\text{H}^6 = \text{C}^{12}\text{H}^{10} + \text{H}^2$; and, together with other products, by the action of alcoholic potash on diazobenzene nitrate:

It appears also to be one of the constituents of crude anthracene, and passes over in the distillation of that substance at about 260° . (For its properties, see PHENYL, iv. 409.) Dibenzyl, $\text{C}^{14}\text{H}^{14}$, is also a crystalline solid, produced by heating benzyl chloride, $\text{C}^6\text{H}^5\text{Cl}$, or benzyldiene bromide, $\text{C}^6\text{H}^4\text{Br}^2$, with sodium (v. 870).

Tenth Series. $\text{C}^8\text{H}^{2n-16}$.—The only known member of this series is stilbene, $\text{C}^{14}\text{H}^{12}$, which is formed, together with other products, by the action of heat on benzyldiene sulphide:

It crystallises in colourless plates melting at 100° and boiling at 292° ; forms substitution-products with chlorine, bromine, and nitric acid, and unites with chlorine, forming the compound $\text{C}^{14}\text{H}^{12}\text{Cl}^2$ (v. 431).

Eleventh Series. $\text{C}^8\text{H}^{2n-18}$.—To this series belong anthracene, $\text{C}^{14}\text{H}^{10}$, and its homologues, *methylnanthracene* or *paranaphthalene*, $\text{C}^{15}\text{H}^{12}$, and *tetramethylnanthracene* or *retene*, $\text{C}^{18}\text{H}^{16}$, all of which are contained in the heavy semifluid portion of coal-tar. Anthracene is also produced by definite reactions from benzene and other hydrocarbons, and by decomposition of toluene, xylene, and cumene, at a red heat (p. 176).

Twelfth Series. $\text{C}^8\text{H}^{2n-24}$.—The only known body of this series is chrysene, $\text{C}^{18}\text{H}^{12}$, a yellow crystalline body, produced, as above mentioned, from diphenyl, also by the dry distillation of crude anthracene, and of fats and resins (p. 459).

HYDROCARBOSTYROL. $C^8H^7NO = (C^6H^5)^{\cdot\cdot} \left\{ \begin{smallmatrix} (NH) \\ (C^2H^3O) \end{smallmatrix} \right\}$ (Buchanan & Glaser, *Zeitschr. f. Chem.* [2] v. 194).—A body produced by reduction of nitrophenyl-propionic acid in the same manner as carbostyrol or carbostyryl from nitrocinnamic acid (i. 802). It has the composition of amidophenyl-propionic acid, $C^8H^{11}NO^3$, minus H^2O . To prepare it, nitrophenyl-propionic acid is treated with tin and hydrochloric acid, and the crystals which separate from the diluted and filtered liquid are recrystallised several times from alcohol. It is a very stable substance, melting at 160° , and distilling without decomposition at a higher temperature. In its chemical relations it resembles the amides. It dissolves easily in warm concentrated hydrochloric or hydrobromic acid, apparently forming definite compounds, which, however, decompose spontaneously even in the cold. Potash and soda dissolve it but slowly even at the boiling heat; it is nearly insoluble in water, moderately soluble in alcohol and ether.

HYDROCINNAMIC ACID. See CINNAMIC ACID (p. 468).

HYDROCITRIC ACID. See CITRIC ACID (p. 473).

HYDROCOMENIC ACID, $C^8H^8O^3$, is produced by the action of sodium-amalgam on comonic or bromocomenic acid. It is a yellowish, strongly acid, syrupy liquid forming a white silver salt, $C^8H^8Ag^2O^3$, easily reduced by heat (J. v. Korff, *Ann. Ch. Pharm.* cxxxviii. 191).

HYDROCOUMARIC or MELILOTTIC ACID. $C^9H^6O^3$ (Zwenger & Bodenbender, *Ann. Ch. Pharm.* cxxvi. 257; Zwenger, *ibid. Suppl.* v. 100; *Jahresh.* 1867, p. 439). This acid occurs, combined with coumarin, in the yellow melilot (*Melilotus officinalis*), forming the compound $C^{10}H^{10}O^3 = (C^9H^6O^3) \cdot (C^2H^4O)$, which may be called melilo-coumarin. (See COUMARIN, p. 499.) When the aqueous decoction of the plant, evaporated to the consistence of a thin extract, is treated with ether as long as the ether acquires an acid reaction, and the green mass which remains after distilling off the ether is repeatedly boiled with a large quantity of water, well-defined crystals of melilo-coumarin separate on cooling. The solution of these crystals (or the aqueous decoction of the extract above mentioned) is mixed with basic lead acetate, carefully avoiding an excess, which would exert a solvent action; and the precipitate which forms after long standing is collected on a filter, washed first with cold water, then with alcohol and ether to remove free coumarin, and repeatedly boiled with water, as long as the hot filtrate deposits a crystalline precipitate of lead hydrocoumarate. This precipitate decomposed by hydrogen sulphide yields hydrocoumaric acid, which may be purified by repeated precipitation with neutral lead acetate: 100 pounds of the plant yield from $1\frac{1}{2}$ to 2 ounces of the pure acid.

Hydrocoumaric acid may be produced synthetically from coumarin by gradually adding sodium-amalgam to an aqueous solution of that substance containing a little alcohol, each portion of sodium-amalgam being added only after the alkaline reaction produced by the preceding portion has nearly disappeared. By this treatment the coumarin, in the course of a few days, is almost wholly converted into hydrocoumaric acid, which may be precipitated by lead acetate. On boiling the precipitate with water, the greater part, consisting of lead hydrocoumarate, dissolves, while a small quantity of coumarate remains behind, showing that the coumarin, $C^9H^6O^2$, has first been converted, by addition of the elements of water, into coumaric acid, $C^9H^8O^2$, which has then been converted into hydrocoumaric acid by addition of 2 at. hydrogen.

Hydrocoumaric acid dissolves in 20 pts. water at 18° , in less than 1 pt. at 40° , very easily also in alcohol and ether. From a hot-saturated aqueous solution it crystallises, after long standing at ordinary temperatures, in spicular arragonitic crystals an inch long. It melts at 82° ; solidifies in the crystalline state on cooling; has a strong acid reaction, a sour astringent taste, an aromatic honey-like odour; decomposes carbonates with facility; and dissolves zinc and iron when heated, with elimination of hydrogen. Its solution in excess of ammonia, when exposed to the air, gradually acquires an indigo-blue colour, becoming reddish when the liquid is heated. On adding the aqueous solution by drops to dilute ferric chloride, a bluish coloration is produced, which gradually disappears, with formation of a yellowish precipitate. Chloride of lime colours the solution yellow and red when heated. By fusion with potash, hydrocoumaric acid is resolved, with evolution of hydrogen, into salicylic and acetic acids:

The metallic hydrocoumarates are for the most part easily crystallisable; those of the alkali-metals and alkaline earth-metals have a slight alkaline reaction, the ammonium salt and the salts of the heavy metals an acid reaction. The less soluble salts are obtained by precipitation; the more soluble by neutralisation of the corresponding

carbonates. They fuse easily, and when heated (especially the barium salt) assume first a red, then a violet colour, from liberation of hydrocoumaric anhydride; when completely decomposed at a red heat they yield phenol. The *potassium salt* $C^9H^5O^3K$ is easily soluble in water and alcohol, crystallises in radiate laminae, melts with loss of water of crystallisation at 125° , and is precipitated from its alcoholic solution by ether as an oily liquid. The *ammonium salt* is also very soluble and crystallises in slender shining needles. The *silver salt* $C^9H^5O^3Ag$ is a bulky curdy precipitate, very sensitive to light, crystallisable from water or alcohol. The *barium salt* $(C^9H^5O^3)_2Ba + 3H_2O$ forms slender nacreous laminae which give off their water at 100° . The *calcium salt* $(C^9H^5O^3)_2Ca$ is a crystalline precipitate slightly soluble in water and alcohol, easily in acetic acid. The *magnesium salt* $(C^9H^5O^3)_2Mg + 2H_2O$ forms scaly nacreous crystals, greasy to the touch, and very efflorescent. The *cupric salt* $(C^9H^5O^3)_2Cu + H_2O$ is a verdigris-green precipitate easily decomposable by heat, and crystallises from alcohol in groups resembling fibrous malachite. The *lead salt* $(C^9H^5O^3)_2Pb$ is a crystalline precipitate insoluble in water and in alcohol, but soluble in excess of basic lead acetate. The *zinc salt* $(C^9H^5O^3)_2Zn + H_2O$ is slightly soluble in cold, somewhat more soluble in hot water, and crystallises in rosettes of apparently quadratic tables, which melt below 100° .

Ethyl Hydrocoumarate, $C^9H^5O^3 \cdot C^2H_5$, formed by heating the recently precipitated silver salt with ethyl iodide, or very easily by boiling an alcoholic solution of hydrocoumaric acid with rather strong hydrochloric acid, is a syrupy liquid, which slowly solidifies at low temperatures. It crystallises from ether in large monoclinic prisms having a faint odour of cinnamon; melts at 34° , and decomposes at 273° .

Hydrocoumaric Anhydride, $C^9H^4O^2$, passes over, on distilling the acid alone, as an oily liquid which, after complete dehydration with calcium chloride, crystallises in large, hard, apparently rhombic plates, melting at 25° to a colourless strongly refracting oil, and boiling without decomposition at 272° . At ordinary temperatures it smells like coumarin; when heated, like oil of cinnamon and nitrobenzene. It dissolves in alcohol and ether, forming neutral solutions; is insoluble in cold water; dissolves partially when quickly boiled, the solution becoming turbid on cooling; and completely when slowly heated, being then converted into hydrocoumaric acid. When exposed to the air in the liquid state, it takes up water and forms the acid, which on the other hand is partially converted into anhydride when heated over the water-bath.

Dibromhydrocoumaric acid, $C^9H^4Br^2O^3$, is formed by dropping bromine on pulverised hydrocoumaric acid, and crystallises from alcohol in slender needles insoluble in cold water, easily soluble in alcohol and ether, having a strong acid reaction, melting at 115° , and distilling without decomposition. Its *barium salt* $(C^9H^4Br^2O^3)_2Ba + 5H_2O$ crystallises in shining needles, insoluble in cold water, easily soluble in warm alcohol.

Dinitrohydrocoumaric acid, $C^9H^4(NO^2)_2O^3$, is formed, together with oxalic acid, by treating hydrocoumaric acid with hot strong nitric acid. It is slightly soluble in cold water; crystallises from alcohol in honey-yellow to sulphur-yellow prisms; colours organic substances as strongly as picric acid; melts at 155° ; does not detonate; and may be volatilised for the most part without decomposition. Its ammonium salt is precipitated cinnabar-red by barium chloride, yellow by lead acetate, yellowish-red by calcium chloride and silver nitrate.

Hydrocoumaramide or *Melilotamide*, $C^9H^{11}NO^3$, formed by dissolving the anhydride in strong aqueous ammonia, or by the prolonged action of ammonia on ethylic hydrocoumarate, crystallises in long slender needles having a neutral reaction, slightly soluble in cold water, easily soluble in hot water, alcohol, and ether, melting at 70° , and decomposing at higher temperatures into ammonia and hydrocoumaric anhydride. The aqueous solution is coloured indigo-blue by ferric chloride (Zwenger).

Hydroparacoumaric Acid, $C^9H^{10}O^3$, is formed by the action of sodium-amalgam on paracoumaric acid, and separates from aqueous solution in small well-defined monoclinic crystals. It does not lose weight at 100° , melts at 125° , dissolves easily in water, alcohol, and ether, is not precipitated by lead acetate, cupric sulphate, or mercuric chloride, scarcely altered by ferric chloride, but forms a white precipitate with mercurous nitrate, and reduces alkaline cupric solutions at the boiling heat. Its ammonium salt is crystallisable; the silver salt is an amorphous precipitate (Hlasiwetz a. Malin, *Ann. Ch. Pharm.* cxlii. 358).

The formula $C^9H^{10}O^3$ includes three acids, viz. phloretic, hydrocoumaric, and hydroparacoumaric, which have the constitution of α -oxyphenyl-propionic acid, $C^9H^7\{ \begin{smallmatrix} OH \\ OCH^3 \end{smallmatrix} \} CH^2CO^2H$, their isomerism being determined, like that of the three modifications

of the acid $C^6H^4O^2$, by the relative position of the groups OH and $C^6H^4O^2$ in the benzene nucleus; thus:

Ortho-series.	Meta-series.	Para-series.
1 : 2	1 : 3	1 : 4
Oxybenzoic.	Salicylic.	Para-oxybenzoic.
Phlorctic.	Hydrocoumaric or mellitic.	Hydroparacoumaric.

Hydroparacoumaric acid has been obtained synthetically from phenyl-propionic or hydrocinnaamic acid (p. 468) as follows. This acid treated with strong nitric acid yields *nitrophenyl-propionic acid*, $C^6H^4\{NO^2\}C^3H^3O^2$ which when oxidised by chromic acid is completely converted into nitrodraeylic acid, and therefore belongs to the para-series. Nitrophenyl-propionic acid treated with tin and hydrochloric acid is converted into *amidophenyl-propionic acid*, $C^6H^4\{NH^2\}C^3H^3O^2$ (together with hydrocarbostyrol, p. 715); the hydrochloride of this amidated acid dissolved in absolute alcohol and treated with nitrous acid is converted into *diazophenyl-propionic chloride*, $C^6H^4N^2O^2.HCl$ or $C^6H^4\{N \equiv NCl\}C^3H^3O^2$; and by boiling the solution of this compound, whereby nitrogen is evolved, removing the chlorine by lead carbonate, the lead by hydrogen sulphide, and evaporating, *oxyphenyl-propionic acid*, $C^6H^4\{OH\}C^3H^3O^2$ is deposited in yellowish crystals. The acid thus obtained agrees in all its properties with the hydroparacoumaric acid obtained by Hlasiwetz a. Malin, excepting that its solution mixed with ferric chloride forms a blue liquid which soon becomes milky and deposits a resinous substance, the filtered liquid still retaining its blue colour. Its cold-saturated solution mixed with a few drops of strong nitric acid becomes red, then milky, and after a few hours deposits long needles of a nitro-compound, which dissolve in ammonia with deep red colour. The acid becomes milky when mixed with bromine-water, and reduces an alkaline cupric solution at the boiling heat (Buchanan a. Glaser, *Zeitschr. f. Chem.* [2] v. 193). See PROMONIC ACID.

HYDROCYANOBENZIDE. See HYDROBENZAMIDE (p. 703).

HYDROCYANO-ROSANILINE. See ROSANILINE.

HYDROCYANOSALIDE. See HYDROSALICYLAMIDE (p. 721).

HYDRO-EUTHIOCHROIC ACID. See DERIVATIVES OF TETRACHLORO-QUINONE, under QUINONE.

HYDROGEL. The name applied by Graham to the gelatinous hydrate of a colloidal substance. (See COLLOIDAL ACIDS, v. 1088.)

HYDROGEN. The evolution of hydrogen by the action of zinc on hydrochloric acid, or of sodium-amalgam on water, is considerably diminished when the reaction takes place under pressure, as in sealed tubes (Caillietet, *Compt. rend.* lxviii. 395). Berthelot (*ibid.* 536) regards the diminution of chemical action in this and similar cases, not as a direct consequence of the increased pressure, but as due to the formation of a layer of saturated solution on the surface of the metal, the removal of this layer by agitation or diffusion being retarded when the reaction takes place under pressure, in consequence of the diminished size of the gas-bubbles; moreover, part of the hydrogen eliminated at the beginning of the reaction remains adhering to the surface of the metal and protects it from the action of the acid, and this gaseous layer is of course less able to escape when the liquid is subject to increased pressure.

The salts of ammonia, methylamine, ethylamine, aniline, naphthylamine, and probably other amine-bases, give off hydrogen when zinc is immersed in their aqueous solutions, the reaction taking place even at ordinary temperatures, but more readily at 40° . Iron acts in the same manner, but less strongly. With zinc and iron, an ammonium salt, and free ammonia, the evolution of gas is as rapid as with zinc and dilute sulphuric acid. Ammonia nitrate, however (and probably also the nitrates of the alcoholic ammonias), forms an exception to the general rule, inasmuch as it does not evolve hydrogen, but nitrogen monoxide, when heated to 50° in contact with zinc (Lorin, *Compt. rend.* lx. 745).

On the passage of hydrogen through metals at a red heat, and its absorption by metals, especially by palladium, see GASES, ABSORPTION OF (p. 634). From the properties of the hydrogenised palladium, Graham infers that it is a true metallic alloy, and that the hydrogen enters into it as a metal, which he designates as

hydrogenium. Assuming that the hydrogen enters into the combination with the density which it would exhibit if solidified in the free state, he calculates, from the observed density of this so-called alloy of palladium and hydrogenium, and of similar alloys containing, in addition, gold, silver, or nickel, that the density of this hypothetically solidified hydrogen varies between the limits 0.711 and 0.7545: mean, 0.733.

It may, however, be doubted whether the observed modifications of the physical properties of palladium and other metals consequent on the absorption of hydrogen have any very direct bearing on the question of the metallic nature of hydrogen. What indeed is meant by the assertion that hydrogen is a metal? This element, in its chemical relations with chlorine, oxygen, and other chlorous radicles, undoubtedly exhibits striking analogies to the metals, and hence it has been inferred that if liquefied or solidified it would also exhibit the physical characters of a metal. But hydrogen in a state of combination may also be regarded as the first term of the series

and in the free state, as the first term of the series

Its chemical analogies to the several terms of the first series (the alcohol-radicles) are well known; and hence we might with equal reason suppose that, if liquefied or solidified, it would resemble the bodies of the second series (the paraffins), exhibiting the appearance of a transparent colourless liquid, or of solid paraffin, and not bearing the slightest resemblance to a metal.

In connection with this subject we may refer to the late ingenious experiments of Seeley (*Chem. News*, June 10, 1870) on the so-called ammoniacal amalgam, from which it appears that this substance when submitted to varying pressure changes its volume like a gas, and is in fact nothing but a homogeneous froth formed by the imprisonment of gas-bubbles between the pores of the mercury. Loew, by shaking together in a well-cooled vessel a mixture of mercury and 1 to 2 p. c. zinc, with an equal bulk of a solution of platonic chloride containing 10 p. c. of the solid salt, has obtained a slimy mass which, when treated with dilute hydrochloric acid, acquires a buttery consistence, and is a compound or mixture of mercury and hydrogen, designated by Loew as *hydrogenium amalgam*, and described as analogous in its properties to Graham's hydrogenised palladium. It is perhaps merely a mixture similar to the ammonium amalgam, and if the molecules of palladium were as free to move as those of the mercury, it would probably also, in absorbing hydrogen, assume the consistence of a metallic froth.

On the spectrum of hydrogen see SPECTRAL ANALYSIS.

On the coloration of the hydrogen flame by small quantities of gaseous and solid bodies, see W. F. Barrett (*Phil. Mag.* [4] xxx. 321; *Jahresb.* 1865, pp. 124, 139).

Reduction of Metallic Salts by Hydrogen.—Pure hydrogen passed for several hours through a solution of nitrate, sulphate, or acetate of silver, throws down a slight grey precipitate of metallic silver; impure hydrogen forms a brown or black precipitate, due to the foreign substances present. A solution of platonic chloride made as neutral as possible, or a solution of ammonium chloroplatinate, becomes turbid when hydrogen is passed through it, depositing a black, pulverulent, sometimes scaly, metallically lustrous precipitate; by prolonged exposure to the gas the solution becomes colourless and transparent. Palladium is precipitated with still greater facility. Iridium solutions are scarcely affected; gold solutions not at all. Solutions of mercurous nitrate and mercuric chloride are not affected under the ordinary pressure, but under a pressure of 100 atmospheres metallic mercury is deposited after 24 hours. A solution of ferric chloride treated with hydrogen for 48 hours was found to contain a small quantity of ferrous chloride (Brunner, *Pogg. Ann.* cxxii. 153; *Jahresb.* 1865, p. 124). According to Beketoff (*Ann. Ch. Pharm.* cx. 312; *Jahresb.* 1859, p. 66; 1865, p. 13), the reduction of silver from its salts by hydrogen is greatly facilitated by increased pressure. Dilute solutions of cupric nitrate and of lead salts exhibit no trace of metallic precipitation by hydrogen, even under a pressure of 40 atmospheres; but the reduction takes place in presence of platinum, not only under increased pressure, but even under ordinary pressure, if the platinum plate projects above the liquid (the tubes containing the solution and the platinum plate were filled with hydrogen and sealed up). Solutions of silver sulphate similarly treated deposited metallic silver on the platinum; lead solutions were unaffected.

On the temperatures at which different metallic oxides are reduced by hydrogen, see W. Müller (*Zeitschr. f. Chem.* [2] v. 507). Auric chloride is not decomposed by hydrogen at 200°, but above that temperature explosion occurs in consequence of the

combination of liberated chlorine with the hydrogen. Platinic chloride begins to be reduced at 85° . The chlorides of silver and lead are not affected; gold sulphide gives off sulphur at 200° (Müller).

HYDROGEN DIOXIDE. H^2O^2 .—According to H. Struve (*Zeitschr. f. Chem.* [2] v. 274), this compound occurs frequently in the atmosphere, and may be detected in snow and rain-water, by means of a solution of lead oxide in potash, with addition of a few drops of basic lead acetate, whereby, if hydrogen dioxide is present, a precipitate is formed containing lead dioxide, PbO^2 . Houzeau, on the other hand (*ibid.* iv. 375), was not able to detect hydrogen dioxide in snow or rain-water. According to Schönbein (*Jahresb.* 1864, p. 666), hydrogen dioxide may be detected in variable but always small quantity in human urine.

On the formation of hydrogen dioxide in various cases of slow oxidation, as when an amalgam of tin, lead, or bismuth is agitated with water acidulated with sulphuric acid, see Schönbein (*Pogg. Ann.* evi. 307; exxii. 445; *Jahresb.* 1859, p. 60; 1861, pp. 94, 96, 97, 156; 1862, p. 42; 1864, p. 121; 1866, p. 101).

To prepare a dilute solution of hydrogen dioxide for lecture experiments, C. Hoffmann (*Ann. Ch. Pharm.* cxxxvi. 188) adds potassium peroxide by small portions to a moderately concentrated and well-cooled solution of silicofluoric or tartaric acid, taking care not to neutralise the acid completely. The potassium peroxide is prepared for the purpose by directing a jet of air on potassium fused in a porcelain crucible.

Reactions.—The reactions of hydrogen dioxide with metals and metallic salts have been studied by Weltzien (*Ann. Ch. Pharm.* cxxxviii. 129; *Chem. News*, xiii. 159; xiv. 1, 15, 39, 50; *Jahresb.* 1866, p. 107). 1. *Metallic iron* in a solution of hydrogen dioxide becomes covered with gas-bubbles and is converted into normal ferric hydrate: $\text{Fe}^2 + 3\text{H}^2\text{O}^2 = \text{Fe}^2(\text{OH})^3$.—2. *Aluminium* is acted upon in a similar manner.—3. *Ferrous sulphate* gives a precipitate of a basic ferric salt, $\text{Fe}^2\text{SO}^2 + 8\text{H}^2\text{O}$ or $2\text{Fe}^2\text{O}^2 \cdot \text{SO}^2 + 6\text{H}^2\text{O}$, while an acid salt, $\text{Fe}^2\text{S}^2\text{O}^2$ or $\text{Fe}^2(\text{SO}^2)^2 \cdot 2\text{SO}^2$, remains dissolved:

If the solution of ferrous sulphate be mixed, first with potash, and then with hydrogen dioxide, in excess, the precipitated ferrous hydrate quickly passes into ferric hydrate, corresponding, when dried at 100° , to the formula $\text{Fe}^2\text{H}^2\text{O}^2$ or $\text{Fe}^2\text{O}^2 \cdot 2\text{H}^2\text{O}$. A solution of ferrous sulphate mixed with potassium sulphocyanate turns red on addition of hydrogen dioxide, while ferric hydrate is precipitated:

A solution of *ferrous iodide* gives with hydrogen dioxide a precipitate of ferric hydrate, with separation of the whole of the iodine:

Ferric salts are not altered by hydrogen dioxide.—4. *Magnesium* slowly forms an alkaline liquid, which, when evaporated, leaves a white mass perfectly soluble in water, the solution probably containing magnesium hydrate, MgH^2O^2 .—5. *Thallium* is converted into thallous and thallic hydrate, according to the equation:

On the other hand, thallic hydrate is slowly reduced by hydrogen dioxide to thallous hydrate, with elimination of oxygen, as already observed by Schönbein (*Jahresb.* 1864, p. 171).—6. *Silver nitrate* in ammoniacal solution is reduced by hydrogen dioxide, with brisk evolution of oxygen; probably thus:

and

7. *Potassium iodide* is decomposed by perfectly pure hydrogen dioxide (contrary to the statement of Meissner (*Jahresb.* 1863, p. 144), the liquid becoming alkaline. The reaction takes place by three stages:

- (1) $2\text{KI} + \text{H}^2\text{O}^2 = \text{K}^2\text{O}^2 + 2\text{HI}.$
- (2) $2\text{K}^2\text{O}^2 + \text{H}^2\text{O} = 2\text{KHO} + \text{O}^2.$
- (3) $2\text{HI} + \text{O} = \text{H}^2\text{O} + \text{I}^2.$

[According to Meissner (*Jahresb.* 1863, p. 144), hydrogen dioxide does not decompose potassium iodide in perfectly neutral solution; according to Houzeau (*ibid.* 1868, p. 146), the decomposition does not take place when the solutions are neutral and very dilute].

8. *Potassium permanganate* is decomposed by hydrogen dioxide, in the absence of hydrochloric acid, with separation of manganic hydrate, $Mn^2H^2O^4$, and formation of potassium hydrate:

in presence of hydrochloric acid a manganous salt is formed, as previously shown by Brodie (*Jahresb.* 1861, p. 105):

9. *Potassium ferrocyanide* in neutral solution is converted into ferricyanide, with formation of potassium hydrate:

in presence of hydrochloric acid, not in excess, the reaction is

with excess of hydrochloric acid, hydroferrocyanic acid is separated and further decomposed. On the other hand, ferricyanide is reduced by hydrogen dioxide to ferrocyanide:

on which reaction depends the bluing of a mixture of potassium ferricyanide and ferric chloride by hydrogen dioxide (ferric salts not being reduced thereby).—10. The *peroxides of potassium, sodium, and barium* are resolved by water into hydrates of the alkali-metal and hydrogen dioxide, which, however, is immediately decomposed by the alkali, and can therefore be detected in the solution only in small quantity. On the other hand, it may be supposed that the alkaline hydrates are converted by hydrogen dioxide into hydrated peroxides, which are again resolved, with evolution of oxygen, into alkali-hydrate, oxygen, and water; thus:

and

The rapid decomposition of hydrogen dioxide in all reactions in which alkalis are set free takes place in this manner, and is not due to catalytic action (Weltzien).

When a solution of *ferrous oxide* is mixed with *phenol* and then with hydrogen dioxide, the liquid becomes green, and if sufficiently concentrated yields a dark green precipitate of unknown composition; at the boiling heat, however, it deposits ferric hydrate.

A solution of *potassium dichromate* similarly treated gradually yields a dark brown precipitate; an ammoniacal cupric solution deposits cuprous oxide. In these reactions the reduction takes place only when the hydrogen dioxide is added *after* the phenol (J. Parnell, *Chem. Soc. J.* [2] vi. 356).

Hydrogen dioxide is decomposed by all *ferments*, especially by yeast, these bodies acting as deoxidisers; they lose this power however when heated with water to the boiling point (Schönbein, *J. pr. Chem.* cvi. 257; *Zeitschr. f. Chem.* [2] v. 533).

A solution of *guajacum* mixed with blood-corpuscles, or with infusion of malt, turns blue on addition of hydrogen dioxide, and affords a test for that compound exceeding in delicacy any yet proposed, and producing distinct indications in water containing not more than 1 pt. of it in ten million. By means of this reaction it may be shown that alcohol, ether, wood-spirit, acetone, and other organic liquids contain perceptible quantities of hydrogen dioxide, after being agitated for a few minutes with air in sunshine, and that this compound is instantly formed when zinc or other metals are oxidised in contact with water (Schönbein, *J. pr. Chem.* cv. 219; *Jahresb.* 1868, p. 145).

For the quantitative estimation of hydrogen dioxide, Houzeau (*Zeitschr. f. Chem.* [2] iv. 223) adds to the neutral solution, first dilute titrated sulphuric acid (containing 0.006125 grm. H^2SO^4 in 5 c.c.), then a slight excess of potassium iodide solution (containing 3 grm. of the salt in 100 grm. water); warms the liquid gently to facilitate the reaction; then boils it till all the iodine is expelled; and estimates the quantity of free acid still present with a standard soda-solution. Every cub. cent. of acid neutralised by the alkali from the potassium iodide corresponds to 0.431 milligrm. of hydrogen dioxide.

HYDROGEN PHOSPHIDES. According to Commaille (*J. Pharm.* [4] viii. 221), phosphoretted hydrogen gas is evolved by the action of phosphorus on *potash-ley* even at ordinary temperatures. Hence in determining carbon dioxide and

oxygen in a gaseous mixture, by absorbing the former with potash-ley and then introducing a stick of phosphorus to absorb the oxygen, an error may arise in consequence of the phosphorus becoming wetted by the potash-solution, and then evolving phosphoretted hydrogen.

R. Mahn (*Zeitschr. f. Chem.* [2] v. 730) has examined the action of phosphoretted hydrogen gas, or phosphine PH_3 , on the chlorides of phosphorus, antimony, and tin. With *phosphorus pentachloride* it reacts according to the equation, $\text{PH}_3 + 3\text{PCl}_5 = 4\text{PCl}_3 + 3\text{HCl}$, as previously shown by H. Rose. When passed into heated *phosphorus trichloride*, it slowly forms a red precipitate of phosphorus, as also shown by Rose. When passed into cooled *antimonious chloride*, it forms antimonious chloride, phosphoric chloride, and hydrochloric acid:

Passed into fused *antimonious chloride*, it forms a black precipitate consisting chiefly of antimony and phosphorus. With *stannic chloride* it forms a yellowish-red compound, $\text{Sn}^4\text{Cl}^2\text{P}^2$.

HYDROGEN SULPHIDE, H_2S , *Hydrosulphuric* or *Sulphydric acid*, is formed abundantly when hydrogen gas is passed through boiling sulphur (Morz a. Weith, *Zeitschr. f. Chem.* [2] v. 603); also when a succession of induction-sparks is passed through a mixture of hydrogen gas and sulphur vapour (Chevrior, *ibid.* 608).

According to J. Myers (*Zeitschr. anal. Chem.* 1869, 409), it is formed when aqueous vapour is passed over boiling sulphur, an acid liquid then distilling over which is a solution of sulphydric and pentathionic acids, the latter obviously resulting from the sulphydric acid and sulphurous anhydride simultaneously produced.

HYDROMECONIC ACID. See MECONIC ACID.

HYDROMELLITIC ACID. See MELLITIC ACID.

HYDROPARACOUMARIC ACID. See HYDROCOUMARIC ACID.

HYDROPHLORONE. See PHLORONE.

HYDROPTHALIC ACID. See PHTHALIC ACID.

HYDROPIPERIC ACID. See PIPERIC ACID.

HYDROQUINONE. See QUINONE.

HYDROSALICYLAMIDE, $\text{C}^{21}\text{H}^{16}\text{N}^2\text{O}^3$, is converted by gentle heating with hydrochloric and hydrocyanic acids into yellow hydrocyanosalide, $\text{C}^{22}\text{H}^{16}\text{N}^2\text{O}^3$, and sal-ammoniac:

By washing the solidified product with alcohol, and crystallising it from a large quantity of the latter, hydrocyanosalide is obtained in interlaced orange-yellow needles. It is indifferent, very stable, insoluble in water, very slightly soluble in alcohol, and decomposed by potash, with evolution of ammonia and formation of resinous products. By boiling for several days with alcohol, it is gradually converted into brown needles of an isomorphous compound distinguished from the yellow modification by greater solubility and a different crystalline form.

Hydrocyanosalide is also formed, together with ammonium cyanide and its products of decomposition, when hydrosalicylamide is acted upon by hydrocyanic acid alone (Reinecke a. Beilstein, *Ann. Ch. Pharm.* cxxxvi. 169).

HYDROSOL. The name applied by Graham to the soluble hydrate of a colloidal substance (v. 1088).

HYDROTEPHEROITE. Hydrated manganous silicate from New Jersey, massive, light red, translucent on the edges, contains 28.46 p. c. SiO_2 , 11.89 MgO , 53.44 MnO , 0.49 Mn_2O_3 , and 5.85 H_2O (Igelström, *Jahresb.* 1867, p. 996).

HYDROTEREPHTHALIC ACID. See TEREPHTHALIC ACID.

HYDROXYAMYLENE-AMMONIUM. $\text{C}^8\text{H}^{11}\text{NO} = \text{C}^8\text{H}^{10} \cdot \text{OH} \left\{ \begin{smallmatrix} \text{N} \\ \text{H} \end{smallmatrix} \right\}$ (Wurtz, *Ann. Ch. Pharm. Suppl.* vii. 89).—When the hydrochloride of amylic glycol is heated with excess of ammonia, the chloride of this base, $\text{C}^8\text{H}^{11}\text{NO} \cdot \text{Cl}$ or $\text{C}^8\text{H}^{11}\text{NO} \cdot \text{HCl}$, is formed, together with that of the corresponding valeryl-base, $\text{C}^6\text{H}^9\text{NCl}$ or $\text{C}^6\text{H}^9\text{N} \cdot \text{HCl}$, derived from it by abstraction of water. On evaporating the resulting liquid to a syrup, dissolving it in absolute alcohol to remove sal-ammoniac, mixing the alcoholic solution with platonic chloride, and leaving the filtered liquid to evaporate, crystalline crusts of the platinochloride

$(C^2H^2N)^2.PtCl^4$ (isomeric with that of vinyl-trimethyl-ammonium) separate out, and by recrystallisation this salt may be obtained in rather large dark orange-coloured crystals soluble in water and alcohol. The mother-liquor of the preceding salt finally yields by spontaneous evaporation the platinochloride of hydroxamylene-ammonium, $(C^2H^4NOCl)^2PtCl^4$, isomeric with that of choline (p. 448), which by repeated crystallisation may be obtained in orange-red crystals, very soluble in water and in alcohol.

On mixing the syrupy liquid containing these two platinum salts with excess of very strong potash-solution, a thick oily liquid separates; and on subjecting the whole to distillation, there passes over with the aqueous vapour a base which separates from the alkaline liquid on saturation with potassium hydrate. The decanted oily liquid distils without decomposition, the greater part passing over between 160° and 170° , as a thickish strongly alkaline liquid soluble in water, and smelling of ammonia. The residue of the distillation solidifies on cooling to a crystalline mass. The two bodies thus obtained are doubtless the hydrates corresponding to the platinum salts above described.

HYDROXYETHYLENE - TRIETHYLAMMONIUM. $C^2H^{20}NO = \begin{matrix} C^2H^4.OH \\ (C^2H^3)^3 \end{matrix} N$ (Wurtz, *Ann. Ch. Pharm. Suppl.* vii. 88).—The chloride, $C^2H^{20}NOCl$, is obtained by heating hydroxychloride of ethylene with triethylamine:

It is easily soluble in water and in alcohol, crystallises in beautiful striated prisms, and forms with platinic chloride the salt $(C^2H^{20}NOCl)^2.PtCl^4$, which also crystallises well. The *aurochloride* $C^2H^{20}NOCl.AuCl^3$ is less soluble than the platinochloride, and separates from boiling water in splendid golden-yellow laminae. The *hydrate* $C^2H^{21}NO^2 = C^2H^{20}NO.OH$ is a homologue of choline, $C^2H^{13}NO^2$.

HYDROXYBENZYLURIC ACID. $C^{16}H^{21}NO^3$ (Otto, *Ann. Ch. Pharm.* cxxxiv. 303; *Jahresb.* 1865, p. 354).—An acid produced by oxidation of hydrobenzyluric acid (p. 704) when an alkaline solution of the latter is exposed to the air. It is crystalline; has an offensive odour when moist; melts between 60° and 70° ; is insoluble in cold water, but dissolves easily in alcohol, ether, and alkalis; and is precipitated white by lead, silver, and mercury salts; brown by ferric chloride. Its solution in strong sulphuric acid has a cherry-red colour. The calcium salt $C^{16}H^{19}CaNO^3 + 3H^2O$ is soluble in water, and crystallises with difficulty in needles. In a vacuum hydroxybenzyluric acid is gradually converted (perhaps with formation of an intermediate product, $C^{16}H^{19}N^2O^3$) into the less hydrated acid $C^{16}H^{19}NO^4$, which in contact with water reproduces the original acid. The calcium salt of the less hydrated acid, $C^{16}H^{17}CaNO^4 + 6H^2O$, is less soluble than that of normal hydroxybenzyluric acid. A barium salt, $C^{16}H^{17}BaNO^4$, has also been obtained.

HYDROXYBIBENZOIC ACID. $C^{14}H^{13}O^3$ (Otto, *loc. cit.*).—Produced, together with glyocine and benzyl alcohol, by boiling hydroxybenzyluric acid with alkalis:

Both in the free state and in its salts it changes, as readily as hydrobenzoic acid, into benzoic acid. Its calcium salt dried at 100° has the composition $C^{14}H^{11}CaO^3$. The *ethylic ether*, $C^{14}H^{13}O^3 = C^{14}H^{14}(C^2H^3)^2O^3$, is a limpid liquid, boiling at $205^\circ-207^\circ$, and having an offensive odour, recalling that of ethyl benzoate and of elder-flowers.

HYDROXYLAMINE. $NH^2O = N \begin{matrix} H^2 \\ OH \end{matrix}$ (Lossen, *Zeitschr. f. Chem.* [2] i. 551; iii. 129; iv. 399).—A base intermediate between ammonia and ammonium hydrate, produced by the action of tin and hydrochloric acid on ethyl nitrate:

A mixture of 50 pts. ethyl nitrate, 120 pts. tin, and 50 pts. aqueous hydrochloric acid of sp. gr. 1.12 becomes hot after a short time, without perceptible evolution of hydrogen; and if the mixture be heated for a few minutes, the tin precipitated by hydrogen sulphide, and the filtrate evaporated, sal-ammoniac separates out first, and then the very soluble hydrochloride of hydroxylamine, which may be freed from admixed sal-ammoniac by solution in absolute alcohol and addition of alcoholic solution of platinic chloride: the concentrated alcoholic filtrate yields the pure hydroxylamine hydrochloride in long spicular crystals.

Hydroxylamine is also produced when nitric acid is treated in like manner with tin and hydrochloric acid; but it cannot be conveniently prepared in this way, for part

of the nitric acid remains undecomposed, and in the subsequent concentration of the liquid, this portion, together with the hydrochloric acid present, forms nitrohydrochloric acid, which decomposes the hydroxylamine. This decomposition may indeed be prevented by precipitating the tin with sodium carbonate instead of hydrogen sulphide, the free acids being thereby neutralised, and the hydroxylamine salt remaining unaltered on evaporation; but the salt thus obtained is the nitrate of hydroxylamine, which is very difficult to crystallise and to separate from the ammonium nitrate likewise present.

Hydroxylamine may be formed by direct union of nitrogen dioxide and hydrogen, namely, by passing a stream of nitrogen dioxide through a series of flasks in which hydrogen is evolved by boiling tin with hydrochloric acid, or a series of glass cylinders containing tin and hydrochloric acid, together with a little solution of platinic chloride, whereby hydrogen is evolved at ordinary temperatures. The decanted solution freed from tin by hydrogen sulphide, and evaporated, yields a saline mass, consisting of hydroxylamine hydrochloride, sal-ammoniac, and a little ferrous chloride. This mass is washed with a little absolute alcohol to remove the ferrous chloride, then boiled with absolute alcohol, which dissolves the hydrochloride of hydroxylamine, with only a little sal-ammoniac; the latter is precipitated by alcoholic platinic chloride; and from the filtrate the hydroxylamine salt is precipitated by ether in small crystals which are purified by recrystallisation from absolute alcohol (Ludwig v. Hein, *Zeitschr. f. Chem.* [2] vi. 211). On the preparation of hydroxylamine, see also Maumené (*Compt. rend.* lxx. 147; *Zeitschr. f. Chem.* [2] vi. 187).

Hydroxylamine is a very volatile and easily decomposable base, and can be obtained only in solution. Its salts are decomposed by potash, with evolution of nitrogen and formation of ammonia, quickly in concentrated, gradually in dilute solutions. Solutions of hydroxylamine may however be obtained by decomposing the salts in other ways, an alcoholic solution, for example, by decomposing the nitrate dissolved in alcohol with alcoholic potash. Alkaline carbonates also separate hydroxylamine, with evolution of carbon dioxide. The solutions have an alkaline reaction, and precipitate many metallic salts; with the salts of lead, iron, nickel, and zinc, and with chrome-alum and common alum, they form precipitates insoluble in excess of hydroxylamine. With aqueous cupric sulphate, hydroxylamine forms a grass-green precipitate, which when boiled with water, is reduced, with evolution of gas, to cuprous oxide; an ammoniacal cupric solution is decolorised by it. Mercuric chloride is reduced to mercurous chloride, and if the hydroxylamine is in excess, to metallic mercury. Silver solutions yield a black precipitate, which is quickly reduced, with evolution of gas, to metallic silver. It also reduces acid potassium chromate. In many of these reactions the hydroxylamine appears to be completely decomposed, with formation of nitrogen or its monoxide.

The salts of hydroxylamine decompose when heated, with copious and sudden evolution of gas; most of them easily form supersaturated solutions; none of those yet examined contain water of crystallisation. The *hydrochloride*, $\text{NH}^+\text{O} \cdot \text{HCl}$, crystallises from alcohol in long spicular crystals resembling urea; from water in large irregular six-sided tables, monoclinic according to v. Lang; it melts at 100° , and then decomposes, with violent evolution of gas, into nitrogen, hydrochloric acid, water, and sal-ammoniac. The *nitrate*, $\text{NH}^+\text{O} \cdot \text{HNO}_3$, solidifies slowly by spontaneous evaporation to a radio-crystalline, very deliquescent mass, easily soluble in absolute alcohol, decomposing at 100° . The *sulphate*, $2\text{NH}^+\text{O} \cdot \text{H}_2\text{SO}_4$, remains on evaporating a solution of the hydrochloride with an equivalent quantity of sulphuric acid. It is very soluble in water, is precipitated by alcohol in needles, and crystallises by slow evaporation in well-defined monoclinic crystals, mostly with numerous faces. The *phosphate*, $(\text{NH}^+\text{O})_2\text{H}^+\text{PO}_4$, is sparingly soluble in cold water, and separates in small cubic crystals on mixing dilute solutions of sodium phosphate and an easily soluble salt of hydroxylamine. The *acetate*, $\text{NH}^+\text{O} \cdot \text{C}^2\text{H}^+\text{O}_2$, crystallises from warm absolute alcohol in prisms very slightly soluble in water, melting at $87^\circ\text{--}88^\circ$. The *oxalate*, $(\text{NH}^+\text{O})_2\text{C}^2\text{H}^+\text{O}_4$, crystallises from water in shining triclinic prisms. The *picrate*, $\text{NH}^+\text{O} \cdot \text{C}^6\text{H}^+(\text{NO}_2)_3\text{O}$, dissolves easily in water and alcohol, forming red solutions; less easily in ether and benzol, crystallising therefrom in lemon-yellow prisms melting at 100° .

Hydroxylamine unites directly with *hydrocyanic acid*, forming a compound isomeric with urea.

With *ethyl oxalate*, hydroxylamine forms two acids consisting of $\text{C}^2\text{H}^+\text{N}^+\text{O}^4$, or a multiple thereof:

One of these acids, called oxalo-hydroxamic acid, separates as hydroxylamine salt, $\text{NH}^+\text{O} \cdot \text{C}^2\text{H}^4\text{N}^2\text{O}^4$, in thin laminae, when an alcoholic solution of 1 mol. ethyl oxalate and somewhat more than 3 mol. hydroxylamine is boiled for a few minutes and then left to cool. The acid $\text{C}^2\text{H}^4\text{N}^2\text{O}^4$, separated from this salt by decomposition with hydrochloric acid, forms microscopic prisms sparingly soluble in cold water, and detonating at 105° . Its salts are sparingly soluble or insoluble in water, and detonate loudly at 130° – 180° , or when moistened with strong sulphuric acid. The *hydroxylamine salt* decomposes slowly at 100° , detonates at 105° , and produces on paper or on the skin a reddish colour which is removed by the stronger acids. The *potassium salt* $\text{C}^2\text{H}^4\text{K}^2\text{N}^2\text{O}^4$ crystallises from boiling water in nodular groups of crystals; the *sodium salt* $\text{C}^2\text{H}^4\text{Na}^2\text{N}^2\text{O}^4$ in small tables. The *calcium salt* $\text{C}^2\text{H}^4\text{CaN}^2\text{O}^4$, and the *zinc salt* $\text{C}^2\text{H}^4\text{ZnN}^2\text{O}^4$, are flocculent precipitates, gradually becoming granulo-crystalline, and quite insoluble in water. The *barium salt*, perhaps, $\text{C}^2\text{H}^4\text{Ba}^2\text{N}^2\text{O}^4$ (43 p. c. Ba), is nearly insoluble in water, forms microscopic lenticular crystals, and is decomposed by nitric acid, with formation of oxalic acid and carbonic acid (Lossen).

Diethyl Hydroxylamine. $\text{C}^4\text{H}^{11}\text{NO} = \text{N} \left\{ \begin{array}{l} (\text{C}^2\text{H}^5)^2 \\ \text{OH} \end{array} \right\}$ or $\text{N} \left\{ \begin{array}{l} \text{OC}^2\text{H}^5 \\ \text{C}^2\text{H}^5 \\ \text{H} \end{array} \right\}$ (Lossen, *loc. cit.*).

cit.)—This ethylated base is formed, together with others, in the reduction of ethyl nitrate by tin and hydrochloric acid, the hydrochlorides of these bases being contained in the last mother-liquors after the sal-ammoniac and hydroxylamine hydrochloride have been removed as completely as possible. By converting these hydrochlorides, first into sulphates, then into oxalates, three kinds of oxalate crystals are obtained, the most abundant of which consist of the *acid oxalate of diethyl-hydroxylamine*, $\text{C}^4\text{H}^{11}\text{NO} \cdot \text{C}^2\text{H}^2\text{O}^4$. This salt crystallises from water in stellate groups of shining prisms; from strong boiling alcohol in microscopic needles; when heated it decomposes, with evolution of ammoniacal vapours. The *neutral oxalate*, $(\text{C}^4\text{H}^{11}\text{NO})^2 \cdot \text{C}^2\text{H}^2\text{O}^4$, obtained from the acid salt by precipitating half the acid with milk of lime, is insoluble in absolute alcohol, and crystallises from water in prisms apparently monoclinic. By decomposition with zinc sulphate, it yields the *sulphate* $(\text{C}^4\text{H}^{11}\text{NO})^2 \cdot \text{H}^2\text{SO}^4$, which is precipitated by ether from solution in absolute alcohol, in very delicate microscopic crystalline laminae. The *hydrochloride* is uncrystallisable, soluble in absolute alcohol, and precipitated therefrom by ether as a syrup. The *platinochloride*, $(\text{C}^4\text{H}^{11}\text{NO} \cdot \text{HCl})_2\text{PtCl}_4$, is soluble in water and in boiling absolute alcohol, and separates from the latter in large orange-red crystals. A *phosphate*, $(\text{C}^4\text{H}^{11}\text{NO})_2\text{H}^2\text{P}^3\text{O}^4$, obtained by neutralisation, crystallises from water in prisms, from strong boiling alcohol in capillary needles.

The *base* $\text{C}^4\text{H}^{11}\text{NO}$, separated by mixing any of its salts with potash-ley, agitating with ether, and evaporating the ethereal solution, forms a strongly alkaline, mild-tasting syrup, easily soluble in water, and not easily volatilising with aqueous vapour. Its aqueous solution forms with ferric chloride, chrome-alum, cobalt nitrate, and lead acetate, precipitates insoluble in excess; with cupric sulphate, a bluish-white precipitate soluble in excess with violet-brown colour; it reduces silver nitrate on adding potash and heating; with mercuric chloride in the cold it forms a cloud, which dissolves very easily in excess, the solution yielding a copious precipitate on boiling.

The formation of diethyl-hydroxylamine is probably preceded by that of ethyl-hydroxylamine, as shown by the equations:

and

Dibenzhydroxylamide. $\text{N}(\text{C}^6\text{H}^5\text{O})^2\text{OH}$ (K. A. Heintz, *Zeitschr. f. Chem.* [2] v. 733).—Produced by heating dry hydroxylamine hydrochloride with twice its weight of benzoyl chloride to 110° for twelve hours in a vessel from which the air is excluded. On treating the brownish product with boiling water, as long as benzoic acid is thereby dissolved, there remains a heavy oil which solidifies on cooling, and dissolves for the most part in cold aqueous sodium carbonate, forming a solution from which hydrochloric acid throws down dibenzhydroxylamide as a white flocculent very bulky precipitate, to be purified by repeated crystallisation from alcohol.

Dibenzhydroxylamide is insoluble in cold, nearly insoluble in boiling water, but easily soluble in alcohol, ether, carbon bisulphide, chloroform, and benzol. From its

solutions, which have an acid reaction, it may be obtained in shining white needles, sometimes 2 or 3 centimetres long. It melts with decomposition at 156° – 158° , giving off colourless vapours which strongly attack the mucous membranes. It dissolves very easily in alkalis, but the resulting compounds have not been obtained in definite form.

Tribenzhydroxylamide, $N(C^6H^5O)^2(OC^6H^5O)$, is obtained, though not quite pure, by crystallising from alcohol the portion of the product of the action of benzoyl chloride on hydroxylamine hydrochloride which is insoluble in cold aqueous sodium carbonate. It crystallises in small, white, extremely light needles, which melt at 143° – 145° , and may be heated to 210° without decomposition.

Both di- and tri-benzhydroxylamide are decomposed by boiling with caustic or carbonated alkalis, the resulting solutions yielding with hydrochloric acid a precipitate of benzoic acid (K. H. Heintz, *loc. cit.*).

HYDROXYL-BIURET. See the next article.

HYDROXYL-UREA. $CH^3N^2O^2 = CH^3(HO)N^2O$ (Dressler a. Stein, *Zeitschr. f. Chem.* [2] v. 202).—Produced by transformation of hydroxylamine cyanate, which is formed by double decomposition of potassium cyanate with a salt of hydroxylamine, best with the nitrate. A quantity of hydroxylamine sulphate equivalent to that of the potassium cyanate to be used, is decomposed with barium nitrate; the filtered solution of hydroxylamine nitrate is evaporated to a syrup at a very gentle heat; this syrup is dissolved in 2 or 3 vol. of perfectly absolute alcohol; the liquid cooled to between -10° and -15° ; and the potassium cyanate, dissolved in the smallest possible quantity of cold water, is added by successive portions, the additions being discontinued as soon as the temperature of the mixture has risen to between $+5^{\circ}$ and $+10^{\circ}$, till it has again been cooled to -10° . By proceeding in this manner the solutions may be mixed without perceptible evolution of gas or formation of ammonia. A sample of the solution filtered from the separated salt-petre is then to be mixed with absolute ether, and if a watery layer then separates, more absolute alcohol must be added to the liquid till ether no longer separates a watery liquid, but only a crystalline precipitate (chiefly salt-petre). The alcoholic solution is then to be mixed with about $\frac{1}{2}$ time its volume of ether, the liquid again filtered as rapidly as possible, carefully evaporated over the water-bath to a small volume, and the hydroxyl-urea which separates on cooling, purified by recrystallisation from absolute alcohol.

Hydroxyl-urea is very soluble in water; crystallises on cooling from boiling alcoholic solutions in needles or rosette-shaped aggregations; dissolves less easily in cold absolute alcohol; and is precipitated from the latter by ether in microscopic rhombic laminae, having their acute angles partially truncated. Its solutions are neutral to litmus-paper. It melts at 128° – 130° , and is decomposed by prolonged fusion, giving off gas, yielding a sublimate of ammonium carbonate, and leaving a residue chiefly consisting of ordinary urea, which at higher temperatures yields its usual products of decomposition. Hydroxyl-urea is decomposed by boiling *potash-ley*, with evolution of ammonia; by fuming nitric acid, with abundant evolution of gas. A solution of hydroxyl-urea mixed with *silver nitrate* becomes turbid after a while, from separation of silver, and yields a silver speculum when heated; addition of ammonia causes immediate reduction. Heated solutions of hydroxyl-urea reduce *mercuric oxide* to metal, *chromic acid* to chromic oxide, *cupric oxide* on addition of potash to cuprous oxide. *Ferric chloride* colours the solution of hydroxyl-urea deep blue-violet; in aqueous solution the colour disappears quickly on standing, still more quickly on boiling; in alcoholic solution it is permanent, and with excess of ferric chloride nearly black, or in dilute solution dark green; all these colours are destroyed by addition of hydrochloric or nitric acid.

Salts of hydroxyl-urea have not yet been obtained, its solution in nitric or hydrochloric acid decomposing even by spontaneous evaporation over sulphuric acid.

Hydroxyl-biuret (?). $C^2H^3N^3O^3$ (Dressler a. Stein, *loc. cit.*).—When moderately concentrated aqueous solutions of hydroxylamine sulphate and potassium cyanate are mixed together, the potassium sulphate precipitated by absolute alcohol, the alcoholic solution carefully concentrated over the water-bath, then mixed with ether, and the decanted ethereal solution partially distilled and then left to evaporate over sulphuric acid, gases and ammonia are evolved, indicating decomposition, and ultimately a crystalline mass remains, which after recrystallisation from hot alcohol of 80 p. c. has the composition $C^2H^3N^3O^3$.

This body contains the elements of 2 mol. cyanic acid and 1 mol. hydroxylamine, and may be formed either by direct combination: $2CHNO + NH^3O = C^2H^3N^3O^3$, or by separation of 1 mol. hydroxylamine from 2 mol. hydroxyl-urea: $2CH^3N^2O^2 - NH^3O = C^2H^3N^3O^3$. Empirically it has the composition of hydroxyl-biuret,

$C^2H^4(HO)N^3O^3$. It dissolves in water and in aqueous alcohol, especially when warmed, but only slightly in absolute alcohol, even at the boiling heat. From the alcoholic solution, it is separated by ether in microscopic four-sided prisms, apparently obliquely rhombic. Its solutions are neutral to litmus-paper. It melts at 134° , and then decomposes suddenly, with phenomena similar to those which accompany the decomposition of hydroxyl-urea. Potash and fuming nitric acid act upon it as upon hydroxyl-urea. With *silver nitrate* it forms, on standing or warming, a white flocculent precipitate which dissolves in ammonia, the solution being gradually reduced in the cold, quickly on heating, with formation of a silver speculum. When a solution of hydroxyl-biuret is heated with *cupric oxide* not in excess, the two unite, forming light green microscopic capillary needles. *Alkaline cupric solutions* and *mercuric oxide* are reduced by it on heating. With ferric chloride it does not yield any characteristic reaction.

A solution of hydroxyl-biuret in dilute hydrochloric acid evaporated over sulphuric acid, leaves a mixture of hydroxyl-urea and ammonium chloride; the hydrochloric acid has therefore eliminated 1 mol. cyanic acid from 1 mol. hydroxyl-biuret:

HYOSCYAMINE. On the preparation and properties of this alkaloïd see Rennard (*N. Report. Pharm.* xvii. 91; *Jahresh.* 1867, p. 529).

According to Höhn a. Reichardt (*Ann. Ch. Pharm.* clvii. 98), hyoscyamine has the composition $C^{15}H^{22}NO^3$, and is resolved by boiling for several hours with saturated baryta-water into an acid (hyoscinic acid) isomeric with phloretic acid, and a base (hyoscine):

Hyoscinic acid crystallises in long glistening needles, melts at 104° – 105° , and smells somewhat like benzoic acid. It is monobasic, its barium salt containing $(C^9H^9O^3)^2Ba + 2H^2O$.

Hyoscine was obtained as an oily liquid having a strong alkaline reaction, and crystallising over sulphuric acid. Its platinochloride contains $2(C^6H^{12}N.HCl).PtCl^4$.

HYPERSTHENE from Farsund yields by analysis 47.81 p. c. SiO^2 , 10.47 Al^2O^3 , 3.94 Fe^2O^3 , 10.04 FeO , slight traces of manganous oxide, 25.31 MgO , and 2.12 CaO (= 99.69): hence the formula $6M^3SiO^4.AlFeO^3$ (A. Remelé, *Zeitschr. f. Chem.* [2] iv. 412).

HYPOGÆIC ACID. $C^{16}H^{30}O^2 = \begin{matrix} C^{16}H^{28}O \\ H \end{matrix} \bigg\} O = C^{15}H^{29}.COOH$.—The derivatives of this acid have been examined by H. Schröder (*Ann. Ch. Pharm.* exliii. 22). To prepare the acid itself, and separate it from the arachidic and oleic acids by which it is accompanied in earthnut oil, the mobile straw-yellow oil extracted by carbon bisulphide from the seeds of *Arachis hypogæa* is saponified by boiling for several hours with dilute soda-ley; the white inodorous soap is decomposed by hydrochloric acid; the mixture of fatty acids thereby separated is dissolved in the exact quantity required of hot alcohol; and the solution is evaporated, this treatment being repeated till the alcoholic solution no longer deposits crystals on cooling. On finally evaporating it in a current of hydrogen, pure hypogæic acid remains in small white crystals melting at 33° .

Hypogæic Dibromide, $C^{16}H^{28}Br^2O^2$, is formed by direct combination of hypogæic acid with 1 mol. bromine. To prepare it, bromine is dropped slowly, and with constant stirring, into hypogæic acid cooled with ice, till the colour of the bromine becomes permanent; and the crude product, which has become syrupy, is left for some time in a cool place to allow any excess of bromine to evaporate. It is then saponified in the cold with the exact quantity of potash-ley required; the gelatinous soap is dissolved in alcohol; and the solution, diluted with water and filtered, is decomposed by hydrochloric acid. The buttery compound thereby separated is washed with water till the acid reaction disappears, and then dried in a vacuum. Hypogæic dibromide is solid, uncrystallisable, yellow or brownish, melts at 29° , and is easily dissolved by alcohol and ether, but is insoluble in water. It is very unstable, and decomposes even during saponification if this process is performed with concentrated potash-ley or an excess of it, or if it is aided by heat. Its salts are uncrystallisable and difficult to prepare.

Bromohypogæic acid, $C^{16}H^{28}BrO^2$, is produced by heating the dibromide in alcoholic solution with 2 mol. potassium hydrate:

To complete the transformation, the acid thus obtained must be heated for several days, and finally to the boiling point, with a considerable excess of strong potash-ley, which process however is unavoidably attended with further decomposition. The brominated acid is separated from the alkaline liquid by hydrochloric acid, as a viscid oil which gradually solidifies, but for the reason just mentioned is not quite pure. It melts between 19° and 23° , has a fruity odour, and is easily soluble in alcohol and ether. It unites directly with bromine, forming, when that substance is slowly added to it, and the temperature is kept low, bromohypogaeic dibromide, $C^{12}H^{22}Br^2O^2$ (isomeric or identical with tribromopalmitic acid), which when freed from excess of bromine by exposure to the air and dissolved in ether, remains, on leaving the ether to evaporate (finally in a vacuum), as a solid, yellowish-white, non-crystalline substance soluble in alcohol and ether, melting at 39° .

At higher temperatures, hypogaeic dibromide is decomposed by alcoholic potash, with elimination of 2 mol. HBr , and formation of palmitic acid, $C^{16}H^{32}O^2$, which also unites directly with bromine, forming *palmitic dibromide*, $C^{16}H^{32}Br^2O^2$, and with excess of bromine in sunshine, the *tetrabromide* $C^{16}H^{32}Br^4O^2$, which crystallises from alcohol in laminae. The dibromide heated with alcoholic potash is converted into *bromopalmitic acid*, $C^{16}H^{30}BrO^2$. (See PALMITIC ACID.)

Oxyhypogaeic acid, $C^{12}H^{22}O^3$, is formed by triturating hypogaeic dibromide with excess of recently precipitated silver oxide and a small quantity of water. On adding more water, boiling as long as silver bromide continues to form, and heating the mass for some time with hydrochloric acid, oxyhypogaeic acid is separated as an oily layer, which solidifies in the cold, and after washing with water, solution in alcohol, and evaporation of the solution, remains as a white mass, melting at 34° , but always containing small quantities of dioxyalmitic acid, $C^{12}H^{22}O^4$ ($= C^{12}H^{20}O^3 + H^2O$), into which indeed it is converted by prolonged boiling with potash-ley or with water and silver oxide. Dioxyalmitic acid crystallises by slow evaporation of its hot alcoholic solution in white crystalline laminae melting at 115° . (See PALMITIC ACID.)

Gaidic acid, which is related to hypogaeic acid in the same manner as elaidic to oleic acid, is most advantageously prepared by cautiously heating hypogaeic acid with nitric acid of ordinary strength till vapours of nitrogen tetroxide begin to escape, then immediately cooling, remelting the solidified mass several times in hot water, and purifying it from a simultaneously formed oil by repeated crystallisation from alcohol. It melts at 39° . Gaidic acid likewise takes up a molecule of bromine, forming a crystallisable dibromide, which is decomposed by alcoholic potash, like the isomeric dibromide of hypogaeic acid, though only at a higher temperature, yielding palmitic acid. *Sodium gaidate* crystallises, by slow evaporation of a solution in very dilute alcohol, in white anhydrous laminae (Schröder, *loc. cit.*).

HYPOGALLIC ACID. $C^7H^{10}O^4$.—On the preparation of this acid from hemipinic acid, see Liechti (*Ann. Ch. Pharm. Suppl.* vii. 129; *Zeitschr. f. Chem.* 196).

I

ILEX. Paraguay tea (*Ilex paraguayensis*) contains, according to Strauch (*Jahresh.* 1867, p. 770), in 100 pts.:

Caffeine	0.450	Cellulose	22.148
Essential oil	trace	Apothema	8.640
Caffetannic acid	20.880	Salts	3.896
Gum	2.830	Sand	1.342
Resin *	5.902	Water	8.100
Starch	1.200	Extractive matters	15.251
Protein-substances	9.361		

The ash (after deduction of sand) was found to contain:

K ² O	Na ² O	CaO	MgO	Fe ² O ³	Mn ² O ³	SiO ²	SO ²	P ² O ⁵	HCl
26.84	7.67	23.52	14.82	1.06	4.53	7.85	9.49	4.31	trace = 99.99.

* With chlorophyll and wax.

ILMENIUM. For Hermann's investigations of the compounds of this element, which he supposes to exist, together with tantalum and niobium, in tantalites, &c., and for the criticisms of Marignac thereon, who regards Hermann's analytical methods as defective, and the separate existence of ilmenium as by no means proved, see *J. pr. Chem.* xcv. 65; xcix. 30, 279, 287, 290; ci. 459; cii. 399; cxi. 373; *Zeitschr. f. Chem.* [2] iii. 124, 125, 398; iv. 91; v. 311; *Jahresb.* 1865, p. 209; 1866, p. 207; 1867, p. 209; 1868, p. 216).

INDIGO. When indigo-blue is heated with tin and hydrochloric acid, a compound of indigo-white with stannous oxide is first formed, as a green powder which, on further heating, is converted into the yellow tin-compound of a further reduced indigo. This last compound, on account of its extreme oxidability, has not yet been isolated; in contact with the air it is immediately converted into a red body, soluble in alcohol, and resembling the condensation-products allied to indin. It is remarkable that this more completely reduced indigo cannot be reconverted into indigo-blue, although the first reduction-product, viz. indigo-white, immediately passes into indigo-blue in contact with the air. When the yellow tin-compound is triturated to a paste with water and zinc-dust, a green pulverulent mass is formed, the tin-compound being apparently converted into a zinc-compound, and this green substance when heated yields a considerable quantity of indol, C^8H^7N . The loss of colouring matter in the indigo-vat is perhaps due to the formation of the more highly reduced compound above mentioned (Baeyer, *Deut. Chem. Ges. Ber.* 1868, p. 17; *Zeitschr. f. Chem.* [2] iv. 200).

On the reduction of indigo-blue by stannous chloride and cuprous chloride, see C. D. Braun (*Zeitschr. anal. Chem.* vi. 74; *Jahresb.* 1867, p. 729); by cobaltous nitrate and ammonia, with simultaneous formation of roseo-cobaltic chloride: COBALT BASKS, AMMONIACAL (p. 477).

Indigo-blue heated with 80 times its weight of saturated aqueous hydriodic acid is completely decomposed, yielding, as normal product, octane, C^8H^{18} , together with larger quantities of methane and heptane (Berthelot, *Jahresb.* 1867, p. 348).

For the valuation of commercial indigo-blue, Leuchs (*Zeitschr. f. Chem.* [2] v. 159) converts it into indigo-white by digestion with ferrous sulphate and milk of lime, mixes the clear solution, acidulated with sulphuric acid, with a solution of ammonio-ferrous sulphate, and determines the quantity of ferrous salt thereby produced by means of a $\frac{1}{10}$ normal solution of potassium chromate. The conversion of indigo-white into indigo-blue by ferric salts takes place as shown by the equation:

1.31 grm. of the sample of indigo is mixed, in a tall cylindrical well-closed vessel, with a quantity of lime and solution of ferrous sulphate occupying 300 cub. cent.; 100 c. c. of the clear solution are then added to 66 $\frac{2}{3}$ c. c. of a solution of ammoniacal iron-alum acidulated with sulphuric acid; the liquid is filtered, and 100 c. c. of it titrated with the $\frac{1}{10}$ th chrome-solution. If the latter be added from a measuring tube divided into $\frac{1}{2}$ c. c., each division will correspond to 1 p. c. indigo-blue in the sample under examination.

Yellow Colouring Matter from Indigo.—Bengal indigo, either crude or purified, yields by sublimation a small quantity of a golden-yellow colouring matter, apparently free from nitrogen. It forms long needles which volatilise at about 130°; is nearly insoluble in water, very slightly soluble in alcohol, more easily in soda-ley, strong sulphuric acid, and nitric acid. The greenish-yellow alcoholic solution is decolourised by soda-ley (but not by ammonia); the solution in nitric acid is yellow (Bolley and Crinszo, *Zeitschr. f. Chem.* [2] ii. 573).

INDIRETIN. $C^8H^{10}N^2O^4$.—A resinous substance produced, together with dioxindol, by the action of alcoholic potash upon isatane (p. 734); also by boiling isatin with tin and hydrochloric acid. By removing the tin with hydrogen sulphide, neutralising the filtrate with sodium carbonate, adding caustic soda till it turns yellow, agitating with ether, dissolving the evaporated residue of the ethereal extract in alcohol, and decolorising with animal charcoal, indiretin is obtained in the form of a resin, which gradually solidifies to a mass of prismatic needles, easily soluble in alcohol, ether, and potash, and precipitated from the latter by acids. The solutions smell like benzoic ether, and oxidise on exposure to the air. The silver-compound $C^8H^{14}Ag^2N^2O^4$ separates in yellow scales on mixing the alcoholic solution with ammoniacal silver nitrate (Knop, *J. pr. Chem.* xcvii. 65).

The name indiretin is also applied by Schunck to a resinous body, $C^8H^{17}NO^4$, produced, together with others, by the action of sulphuric acid on indican (iii. 268).

INDIUM. Atomic Weight, 75.63. Symbol, In. Bivalent, belonging to the magnesium group.

This metal, discovered in 1863 by Reich a. Richter (iii. 268), has since been further examined by the same chemists (*J. pr. Chem.* xcii. 480; *Chem. News*, x. 219; *Jahresb.* 1864, p. 240); also by C. Winkler (*J. pr. Chem.* xciv. 1; *Chem. News*, xi. 289; *Jahresb.* 1865, p. 231; *J. pr. Chem.* cii. 273; *Bull. Soc. Chim.* [3] ix. 207; *Jahresb.* 1867, p. 260); by Böttger (*J. pr. Chem.* xcvi. 26; cvii. 39; *Bull. Soc. Chim.* [2] vi. 452; *Jahresb.* 1866, p. 222; 1868, p. 240); and by R. E. Meyer (*Ann. Ch. Pharm.* cl. 137; *Bull. Soc. Chim.* [2] x. 18, 360; *Jahresb.* 1868, p. 241).

Indium is an extremely rare metal, occurring always in very small quantity, associated with zinc and other metals, from which it is separated with difficulty. It was originally discovered in the zinc-blende of Freiberg, and has since been found by Böttger in the fluo-dust of the zinc-furnaces of the Julius works at Goslar in the Hartz (to the amount of about 0.1 p. c.); by Winkler in the black blende (christophite) of Breitenbrunn in Saxony (0.0062 p. c.); by Hoppe-Seyler (*Ann. Ch. Pharm.* ext. 217) in small quantity, together with zinc, in the wolfram of Zinnwald, and in another specimen of wolfram of unknown origin; and by Köchler (*Jahresb.* 1865, p. 231) in the blende which occurs in the steatite (matrix of tin-stone) of Schönfeld, near Schlagenwald.

Extraction.—Indium is more easily prepared from crude metallic zinc than from the original ore, as it passes over in the distillate obtained in the metallurgic distillation of the ore, but, not being very volatile, accumulates in the distilled metal more abundantly than in the zinc-dust, which is the first product of the distillation. Winkler prepares it by the following methods, depending upon its precipitation in the metallic state by zinc, as oxide or carbonate by barium carbonate, and as basic sulphate from solutions containing sulphuric acid by boiling with sodium acetate.

a. Granulated Freiberg zinc, which contains 0.0448 p. c. indium, together with small quantities of lead, arsenic, cadmium, and iron, is digested with dilute sulphuric or hydrochloric acid till it is nearly (but not completely) dissolved; the liquid is heated as long as it continues to give off gas; the residual metallic sponge, consisting chiefly of lead, but containing also the whole of the indium, together with arsenic, cadmium, and iron, is dissolved in nitric acid; the greater part of the lead is precipitated by sulphuric acid; and the filtered liquid, after being freed from all the metals precipitable by hydrogen sulphide from acid solution, is heated with potassium chlorate to convert the ferrous into ferric salt, and then precipitated with excess of ammonia. The washed precipitate of indium oxide containing iron and zinc is dissolved on the filter in warm dilute acetic acid, and the indium (together with a little iron and zinc) is precipitated from the filtrate as sulphide by sulphydric acid. To purify it, the precipitate is dissolved in dilute hydrochloric acid; the sulphydric acid is expelled by warming; the cooled liquid is agitated several times in a closed vessel with barium carbonate, whereby the indium oxide is completely precipitated in a few minutes; the washed precipitate is treated with hot dilute sulphuric acid; and the pure indium hydrate is precipitated from the filtrate by ammonia.—**β.** The metallic sponge remaining after treating the impure zinc with dilute sulphuric acid may also be triturated to a paste with an equal weight of strong sulphuric acid; the mixture left to itself till it becomes a dry friable mass; this mass heated to dull redness to expel the excess of sulphuric acid, then pulverised and thrown into cold water; the water gradually heated to the boiling point; the solution filtered from the lead sulphate, and precipitated by excess of ammonia; and the precipitate of ferruginous indium-oxide treated as above, or in the following manner: The solution of the crude oxide in hydrochloric acid is mixed with an equivalent quantity of sodium chloride and evaporated to dryness; the residue is dissolved in a large quantity of cold water; the solution saturated with hydrogen sulphide, whereby the greater part of the indium is separated nearly free from iron; and the acid filtrate is evaporated to dryness and treated in like manner; after the third precipitation the solution retains only traces of indium, together with ferrous oxide. (See also Böttger, *Jahresb.* 1868, p. 240.)

To detect indium in zinc-blende, and prepare it therefrom, Winkler precipitates the hydrochloric acid solution of the roasted ore with metallic zinc at the boiling heat; dissolves the precipitate in nitromuriatic acid; removes the arsenic, cadmium, &c., by hydrogen sulphide; and precipitates the indium as oxide by barium carbonate. Any iron that this precipitate may contain is removed by redissolution, heating with sodium sulphite, and digestion with barium carbonate in a closed vessel. The indium may also be precipitated from the original solutions either directly by barium carbonate, or from a solution containing sulphuric acid, by neutralisation with sodium carbonate till a precipitate begins to form, and addition of sodium acetate; it is then precipitated as a basic sulphate containing zinc.

Böttger prepares indium from the flue-dust of the Julius zinc-furnaces at Goslar (containing 0.1 p. c. of the metal) as follows. Six or eight pounds of the dust, also containing copper, iron, zinc, cadmium, arsenic, and thallium, together with charcoal and foreign substances derived from the chimneys, is boiled for half an hour with hydrochloric acid; the solution is strained through linen; and after it has been clarified by standing for some time, plates of zinc are immersed in it for about six hours, the liquid being continually stirred. The metallic precipitate thereby formed, containing copper, arsenic, cadmium, thallium, and indium (and perhaps also lead), is collected on a double filter, freed from the adhering ferruginous liquid by careful washing, then boiled for half an hour with a concentrated solution of oxalic acid; and the hot mixture is diluted with a large quantity of hot water, and filtered. The solution containing the oxalates of cadmium, thallium, and indium is supersaturated with ammonia; the gelatinous precipitate of indium hydrate is repeatedly boiled with ammonia to separate the cadmium and thallium still remaining, and washed till it no longer exhibits the spectrum of thallium. The indium oxide thus obtained is mostly pure; any iron that it may contain may be removed by Winkler's method.

According to Meyer, the separation of the last traces of lead and iron from indium oxide by Winkler's method is not complete. Meyer prefers the following method, based upon the reaction of indium salts with potassium cyanide. The solution of indium sulphate, previously freed from the greater part of the iron, is mixed with potassium cyanide till the bulky precipitate at first formed is redissolved, then diluted with water to ten times its volume, and heated to the boiling point, whereby the whole of the indium is separated as pure hydrate in the form of a heavy, amorphous, easily washed precipitate, whilst the iron remains dissolved as potassium ferrocyanide. A trace of lead which adheres to the precipitate can only be removed by dissolving it in sulphuric acid, expelling the excess of that acid by evaporation, and treating the residual sulphate with alcohol and a few drops of sulphuric acid, whereby the indium sulphate is dissolved, while the lead sulphate remains behind.

Metallic indium may be obtained in small quantities by reducing the oxide with hydrogen; its reduction by charcoal or carbonaceous fluxes requires a very high temperature and entails loss by volatilisation. For the preparation of larger quantities, sodium is the best reducing agent. The finely pulverised oxide is mixed in a porcelain crucible with an equal weight of sodium cut into thin slices; the mixture is covered with previously fused sodium chloride; and the porcelain crucible, placed within a covered earthen crucible, is heated in an air-furnace, moderately at first till the reaction is ended, and then to redness. On breaking up the mass when cold, a regulus of indium containing sodium is found, from which the greater part of the sodium may be separated by immersing it in cold water, pressing it together after the violent evolution of hydrogen is over, washing it with water, then with alcohol and ether, heating it in a porcelain crucible, and fusing it with potassium cyanide. The regulus thus obtained is brittle, of the colour of nickel arsenide, and still contains sodium. For further purification, a lump of the metal weighing 1 or 2 grams, and previously warmed, is dropped into a layer of fused sodium carbonate, about 2 millimetres deep, in a porcelain crucible. It then quickly liquefies, gives off vapours of sodium, and becomes covered with a film of indium oxide. If the flame be then removed, and the crucible left to cool, a pure and perfectly malleable regulus of indium is obtained. The reduction of indium chloride with sodium does not yield good results (Winkler). Böttger precipitates the indium by zinc, presses the spongy metal in hot water, then between filtering paper in a screw-press, and finally melts it with potassium cyanide.

Properties.—Indium is a silver-white metal, soft, ductile, compact, and destitute of crystalline structure. Its specific gravity is 7.421 at 16.8°, and is not altered by hammering or rolling. It melts at 176° without oxidising in contact with the air, but at a higher temperature it becomes covered with a grey film of suboxide, which subsequently exhibits iridescent colours and is finally converted into the yellow monoxide. At a bright red heat the metal burns with a violet flame and brown smoke, forming the same yellow oxide. It is much less volatile than cadmium or zinc, and cannot be distilled in a glass tube in a stream of hydrogen; moreover, the hydrogen which has passed over it does not burn with a blue flame. Its electrical relation to cadmium and zinc is represented by the series

hence it is precipitated from its solutions by cadmium as well as by zinc, and is less easily oxidised than either of these metals in air containing carbonic acid. It is slowly dissolved by dilute sulphuric and hydrochloric acid, with evolution of hydrogen, quickly by strong hydrochloric acid; oxidised by nitric acid with evolution of

nitrogen dioxide; and converted by strong sulphuric acid into a pulverulent anhydrous sulphate.

The spectrum of the indium flame exhibits, besides the violet line α and the blue line β (iii. 268), two fainter blue lines, if the burner be fed with hydrogen gas under pressure, instead of coal gas (Winkler). The wave-length of the α line is 0.000455 mm. (J. Müller, *Phil. Mag.* [4] xxx. 76).

Reactions.—Hydrogen sulphide precipitates indium completely from a solution of its acetate, and from neutral solutions of indium salts in general; from solutions slightly acidulated with a mineral acid partially, and from strongly acid solutions not at all; but an acid solution of an indium salt saturated with hydrogen sulphide becomes turbid on dilution and deposits indium sulphide. The lemon-yellow to fiery-yellow precipitate heated with ammonium persulphide turns white, sometimes dissolves partially, and separates on cooling as a white bulky precipitate. A solution of indium oxide in ammonium carbonate is also precipitated by hydrogen sulphide. (See further, p. 733.)

Ammonia, neutral sodium carbonate, and acid sodium carbonate produce white precipitates (in the last case with evolution of carbon dioxide) insoluble in excess of the precipitant; the presence of tartaric acid prevents the precipitation by ammonia. Caustic potash and soda produce a white precipitate of indium hydrate, soluble in excess, but the solution gradually becomes turbid at ordinary temperatures, and immediately on boiling or on addition of sal-ammoniac. Ammonium carbonate also produces a white precipitate soluble in excess, and reprecipitated on boiling. Barium carbonate precipitates indium completely. Sodium phosphate forms a white precipitate, soluble in caustic potash, but separating again immediately from the solution. Potassium monochromate forms a yellow precipitate. Oxalic acid forms a crystalline precipitate in concentrated neutral indium solutions, but the precipitation is never complete. Potassium cyanide forms a white precipitate of indium cyanide, soluble in excess, and forming a solution from which all the indium is precipitated on boiling in the form of hydrate. Potassium ferrocyanide forms a white precipitate; the ferricyanide, potassium dichromate, and tincture of galls do not precipitate indium salts.

Quantitative Estimation.—Indium is most conveniently estimated by precipitating it as hydrate with ammonia, dissolving the washed precipitate in hot dilute nitric acid, evaporating, igniting, and weighing the oxide thus obtained. The ignited oxide is not hygroscopic, and does not increase perceptibly in weight, even after prolonged exposure to moist air. For exact determinations it is not advisable to ignite the precipitated oxide, on account of the loss attending the burning of the filter. Precipitation by hydrogen sulphide does not give exact results, on account of the solubility of the indium sulphide.

For the exact quantitative separation of indium from iron, the following process must be adopted. The ignited oxides are weighed together, and converted into sulphates (which, if much iron is present, is best effected by fusion with acid potassium sulphate); the solution, at the boiling heat, is nearly neutralised with sodium carbonate; the free carbonic acid expelled by boiling; and the solution, when quite cold, is mixed with a quantity of potassium cyanide sufficient to produce a strong alkaline reaction. The solution, coloured red by formation of potassium ferricyanide, is diluted to ten times its volume, and heated to boiling (whereupon the ferricyanide is reduced by the excess of cyanide to ferrocyanide), and the precipitated indium oxide is further treated as above. In the liquid filtered therefrom, and evaporated, if a non-ferruginous potassium cyanide has been used, the iron may be estimated with concentrated sulphuric acid (Meyer).

Atomic Weight.—By converting the pure metal into anhydrous oxide, In_2O_3 , the atomic weight was found, in three experiments, to vary between 75.67 and 75.76. By decomposing sodio-auric chloride with pure indium, and determining the quantity of gold thereby precipitated, the atomic weight of indium was found to be 75.46 and 75.60. Mean of all the experiments: $\text{In} = 75.63$ (Winkler).

Compounds of Indium.

Bromide. InBr_2 .—Formed by heating metallic indium with rather more than an equivalent quantity of bromine in an atmosphere of dry carbon dioxide, and distilling off the excess of bromine. It is white, crystalline, and easily volatile (Meyer).

Chloride. InCl_2 .—Indium immersed in chlorine gas becomes covered at ordinary temperatures with a white film; when heated in chlorine it melts to a brown mass.

Indium at a higher temperature burns with a yellow-green light, forming indium chloride. This compound sublimes without fusion at an incipient white heat in soft white laminae; in contact with the air it sublimes with partial decomposition, and formation of non-volatile oxychloride. The same decomposition takes place in the aqueous solution when evaporated at a temperature above 100° (Reich a. Richter; Winkler).

Indium chloride forms double salts with the chlorides of the alkali-metals. The *ammonium salt*, $4\text{NH}_4\text{Cl} \cdot 3\text{InCl}_2 + 2\text{H}_2\text{O}$, separates on evaporating a solution of equivalent quantities of indium oxide and sal-ammoniac, in small shining easily soluble crystals, permanent in the air. The *potassium salt*, $2\text{KCl} \cdot \text{InCl}_2 + \text{H}_2\text{O}$, crystallises, together with potassium chloride, from a solution of equivalent quantities of its component salts, in thin plates which gradually change into six-sided prisms belonging to the quadratic system, and exhibiting the combination $\infty\text{P} : \infty\text{P}\infty : \text{oP}$, with P subordinate. Ratio of secondary to principal axis = $1 : 0.8196$. Angle $\text{P} : \text{oP} = 130^{\circ} 47'$; $\text{P} : \infty\text{P} = 139^{\circ} 25'$. The *lithium salt* obtained in like manner crystallises in tufts of very deliquescent needles (Meyer).

Iodide. InI_2 .—Prepared like the bromide. Yellow hygroscopic substance, easily melting to a dark brown-red liquid, distilling with difficulty, and solidifying to a crystalline mass (Meyer).

Oxides. Indium forms several oxides. The monoxide InO , obtained by igniting the nitrate or the precipitated hydrate, is of a pale yellow colour (dark yellow if it contains iron), becoming darker when heated. On igniting roasted indium sulphide with nitre and sodium carbonate, and removing the soluble salts by boiling with water, the monoxide remains in the form of a finely divided white powder. It is not volatile even at a white heat; dissolves in acids, with rise of temperature. By precipitating a cold solution of an indium salt with ammonia, the hydrate is obtained as a white gelatinous precipitate, which dries up in the air to horny lumps, and when ignited leaves the oxide in compact lumps of a light yellow to white colour. The hydrate precipitated at the boiling heat is compact and heavy, and yields an earthy oxide when ignited. The air-dried hydrate consists of $5\text{InO} \cdot 6\text{H}_2\text{O}$ or $5\text{InH}_2\text{O}_2 \cdot \text{H}_2\text{O}$, and is converted at 100° into the normal hydrate, $\text{InO} \cdot \text{H}_2\text{O}$ or InH_2O_2 .

The monoxide heated in a stream of hydrogen becomes green or blue-green at 180° – 190° , grey at 220° – 230° , deep black at 300° , and is reduced to the metallic state at a low red heat. The black oxide formed at 300° is *di-indic oxide*, In_2O . It is a light loose powder which, if exposed to the air while still warm, is converted quickly, but without incandescence, into the monoxide. It does not yield any metallic indium to mercury; is rapidly attacked by strong nitric acid, with evolution of nitrogen dioxide; and is dissolved by dilute acids with evolution of hydrogen. The green oxide appears to consist of $\text{In}^{\text{O}} = 5\text{InO} \cdot \text{In}_2\text{O}$; the grey oxide of $\text{In}^{\text{O}} = 4\text{InO} \cdot \text{In}_2\text{O}$; it has not, however, been proved that these two reduction-products are definite compounds. The green colour may perhaps be due to a trace of iron; in one instance of the incomplete reduction of very pure indium oxide, a light blue product was obtained (Winkler).

Oxygen-salts. The *nitrate*, $(\text{NO}^3)_2\text{In} + 3\text{H}_2\text{O}$, crystallises from an acid solution (with difficulty from a neutral) in long prisms or needles, which give off 2 mol. water at 100° , and when more strongly heated are converted into a basic salt previous to complete decomposition (Winkler). The *sulphate*, $\text{SO}^4\text{In} + 3\text{H}_2\text{O}$, remains on evaporating its aqueous solution at 100° as a gummy mass, and is converted, between 250° and 300° , into the spongy, tumefied anhydrous salt, which when heated to redness leaves first a sparingly soluble basic salt, and finally the anhydrous oxide (Winkler). The neutral *chromate* is an insoluble precipitate; the acid chromate remains as an uncrystallisable syrup when its solution is evaporated (Meyer). The *carbonate* is a white gelatinous precipitate, soluble in ammonium carbonate, precipitated therefrom by boiling, insoluble in the carbonates of the fixed alkalis; the white precipitate formed by the acid carbonates of potassium and sodium is likewise insoluble in excess of the reagent (Winkler). The *oxalate*, $\text{C}^2\text{O}_4\text{In} + 2\text{H}_2\text{O}$, is precipitated from neutral solutions by oxalic acid or alkaline oxalates, as a white crystalline powder sparingly soluble in cold, more soluble in boiling water, and separating therefrom in small transparent crystals. When ignited in a close vessel, it leaves the velvet-black suboxide In_2O ; by ignition in hydrogen it is reduced to metallic indium (Winkler). The *acetate* is obtained, by dissolving the cold-precipitated hydrate in glacial acetic acid, and evaporating to the crystallising point, as a mass of white, interlaced, microscopic needles, but so easily decomposable that it cannot be obtained of constant composition. The *formate* is obtained, by evaporating a solution of the hydrate in

formic acid, in small, very soluble crystals. The *tartrate* is obtained by dissolving the hydrate in boiling aqueous tartaric acid till a copious precipitate forms, and filtering the cooled solution. This solution evaporated in a vacuum leaves the salt as an uncrystallisable jelly; it is not precipitated by ammonia, but remains clear in presence of that alkali, even at the boiling heat (Meyer).

Sulphide. Indium unites with sulphur at a red heat, forming a brown sulphide infusible and non-volatile; the same compound is formed when indium oxide is fused with sulphur. By fusing a mixture of indium oxide, sulphur, and sodium carbonate at a red heat, a mass is obtained which, when lixiviated, leaves indium sulphide crystallised in shining scales resembling mosaic gold (Winkler). The sulphide obtained by precipitating neutral or acetic acid solutions of indium with hydrogen sulphide has a deep yellow colour when recently prepared, but becomes brown when dry, and yields an orange-coloured powder; it is infusible and is decomposed by hydrochloric and sulphuric acids (Reich a. Richter). Ammonium sulphide forms with indium solutions a white precipitate (probably a sulphydrate), which when heated with acids, gives off hydrogen sulphide and is converted into yellow indium sulphide; in drying also it continually gives off this gas, and ultimately leaves the yellow sulphide. This precipitate dissolves in yellow ammonium sulphide (persulphide), not only at the boiling heat, but in small quantity at ordinary temperatures; in colourless ammonium sulphide also it is not quite insoluble. From slightly acid indium solutions, potassium sulphide throws down yellow indium sulphide, soluble in excess of the precipitant, forming a colourless solution, which remains clear at the boiling heat, and on exposure to the air gradually deposits indium sulphide. Acetic acid does not alter this solution; hydrochloric acid throws down yellow indium sulphide, easily soluble in excess of the acid; sulphurous acid precipitates white indium sulphydrate mixed with sulphur. Potassium sulphydrate added to indium solutions throws down indium sulphydrate insoluble in excess of the precipitant (Meyer).

INDOL. C^8H^7N (Bayer, *Ann. Ch. Pharm.* cxl. 295; *Suppl.* vii. 56. Bayer a. Emmerling, *Drut. Chem. Ges. Ber.* ii. 679; *Zeitschr. f. Chem.* [2] vi. 213; *Chem. Centr.* 1870, 42).—This substance, which may be regarded as the nucleus of the indigo-group, is produced: 1. By passing the vapour of oxindol (p. 736) over heated zinc-dust. The product may be freed from admixed aniline by washing with dilute hydrochloric acid and solution in boiling water, the liquid on cooling depositing the indol in large colourless shining laminae.—2. Also, though less advantageously, by heating the yellow product of the action of tin and hydrochloric acid upon indigo with zinc-dust, or by subjecting this yellow product to the further action of tin and hydrochloric acid.—3. By fusing nitrocinnamic acid, $C^8H^7(NO^2)O^2$ (from which indol differs by CO^2 and O^2), with potassium hydrate, to remove the CO^2 and iron-filings to remove the two oxygen-atoms belonging to the group NO^2 . This mode of formation indicates the constitution of indol; thus:

showing that the nitrogen in indol is directly combined with only one atom of hydrogen, a mode of arrangement which is in accordance with the relation of nitrous acid to the derivatives of isatin.

The quantity of indol obtained by the last process is not very large—probably because indol and all the bodies of the indigo-group belong to the meta-series of benzene derivatives, as may be inferred from the formation of anthranilic acid and nitrosalicylic acid from indigo, whereas nitrocinnamic acid (which yields paranitrobenzoic acid by oxidation) belongs to the para-series (Bayer a. Emmerling).

Indol melts at 52° and solidifies in the crystalline form on cooling; it volatilises readily, but cannot be distilled without decomposition. It is moderately soluble in hot water, and separates for the most part on cooling; volatilises with vapour of water at the boiling heat; and may be easily distilled with superheated steam. It dissolves very easily in alcohol, ether, and hydrocarbons; the smallest traces of ether-vapour are sufficient to make it deliquesce. It has a peculiar odour, like that of naphthylamine, but not very persistent. It is a very weak base, forming with concentrated hydrochloric acid a sparingly soluble compound, which is decomposed by water and by alkalis, reproducing indol.

Indol is especially distinguished by the faculty with which it forms red compounds. On mixing its aqueous solution with fuming nitric acid somewhat considerably diluted, a red bulky precipitate separates, formed of small needles and probably consisting of indol nitrite, since it yields indol when boiled with water or alkalis. This red compound dissolves in alcohol, but is apparently decomposed thereby. The alcoholic solution of indol treated with nitrous acid yields large needles of another red body. The alcoholic solution mixed with hydrochloric acid colours fir-wood cherry-red, changing after a while to dirty brown-red.

Hydroxyl-derivatives of Indol (C. A. Knop, *J. pr. Chem.* xcvi. 65; *Jahresb.* 1865, p. 582. Baeyer a. Knop, *Ann. Ch. Pharm.* cxl. 1; *Jahresb.* 1866, p. 638).—Isatic acid, $C^8H^7NO^3$, has the composition of trioxindol, $C^8H^4(HO)^3N$, and this acid, or isatin, which is its anhydride, yields by reduction, dioxindol or hydrindic acid, $C^8H^7NO^2 = C^8H^5(HO)^2N$, and oxindol, C^8H^7NO or $C^8H^6(HO)N$, these three bodies being related to one another in the same manner as pyrogalllic acid, oxyphenic acid, and phenol:

Isatin in acid solution is easily reduced to isatyde (iii. 411); and the latter is converted by sodium-amalgam into dioxindol, which again may be reconverted by oxidation into isatyde and isatin, so that isatyde is intermediate in composition between di- and tri-oxindol:

Baeyer a. Emmerling (*loc. cit.*) represent these compounds by the following constitutional formulae, derived from their formula of indol (p. 733):

According to this view, isatin is a quinone, and in its potassium salt, $C^8H^4KNO^2$, the metal is in direct union with the nitrogen, as in the salts of maloxyl-urea and other derivatives of uric acid. Isatic acid is formed from it by resolution of the quinone-group, with simultaneous oxidation of the group NH; dioxindol is a hydroquinone, and oxindol a kind of phenol.

Kekulé (*Zeitschr. f. Chem.* [2] vi. 254) takes a somewhat different view of the constitution of indol and its derivatives. He considers it improbable that isatic acid can have the constitution of trioxindol, inasmuch as the successive reduction of this acid to indol requires the employment of three different reducing agents, which seems to imply that the three oxygen-atoms in this acid are united to the other elements in different ways. For Kekulé's views of the constitution of these compounds, see *Deut. Chem. Ges. Ber.* ii. 748; *Zeitschr. f. Chem.* [2] vi. 253.

DIOXINDOL or HYDRINDIC ACID, $C^8H^7NO^2$, is produced by the action of nascent hydrogen, generated by sodium-amalgam and water, on isatin, $C^8H^5NO^2$, or isatyde, $C^8H^{12}N^2O^4$; also by heating isatyde with alcoholic potash:

and as a potassium salt, together with indiretin, by heating isatane with alcoholic potash to 130°:

It is prepared by gradually adding sodium-amalgam to cold water in which isatin is suspended; the isatin then dissolves, and the action is complete when a sample of the liquid mixed with hydrochloric acid no longer yields a precipitate of isatin. The sodium salt, which separates after some days from the concentrated solution in warty crusts, is dissolved in water, neutralised with hydrochloric acid, and mixed with a saturated solution of barium chloride; and the barium salt which crystallises out is

digested with a slight excess of sulphuric acid. The filtrate freed from sulphuric acid by addition of a little baryta-water, and evaporated as quickly as possible under the air-pump, yields dioxindol in groups of yellowish needle-shaped crystals. From a moderately concentrated solution it crystallises when left at rest in nearly transparent yellowish prisms, which, according to Rammelsberg, are monoclinic, exhibiting the combination $\infty P. (\infty P \infty). oP. + P. + nP \infty$, and having the clinodiagonal to the orthodiagonal as 1.012 : 1. Angle $\infty P : \infty P = 78^\circ 40'$ and $101^\circ 20'$; $(\infty P \infty) : \infty P = 129^\circ 20'$; $oP : \infty P = 117^\circ$, approximately. From hot alcohol it crystallises in dazzling white transparent crystals permanent in the air. It dissolves in 12 pts. cold and 10 pts. boiling absolute alcohol, also in a mixture of alcohol and ether. It decomposes when heated above 130° ; melts at 180° to a violet liquid; and is converted at 195° , with evolution of a small quantity of aniline, into a rose-coloured amorphous mass. The light yellow aqueous solution becomes dark rose-red on exposure to the air, deeper red when heated, and then leaves a mixture of isatin and indin.

A solution of dioxindol in *hydrochloric acid* deposits dioxindol hydrochloride, $C^8H^7NO^2.HCl$, in large nodular crusts; from a solution in strong sulphuric acid, water throws down dioxindol sulphate, $C^8H^7NO^2.H^2SO^4 + H^2O$, in flocks which turn violet on exposure to the air, and appear crystalline when dry. Ammonia colours the solution violet, and on boiling throws down a violet colouring matter soluble in hydrochloric acid. The fixed alkalis and baryta produce a dark violet coloration, changing to red and finally to light yellow, just as with isatin or isatyde.

The metallic derivatives of dioxindol, or *hydrindates*, excepting the sodium salt, are sparingly soluble in water; they crystallise slowly and are precipitated in the crystalline state by a mixture of alcohol and ether; they are permanent in the air in the dry state, but oxidise quickly in solution. The following have been analysed:

Sodium salt, $C^8H^6NO^2Na + 2H^2O$, silvery scales.
 Silver salt, $C^8H^6NO^2Ag$, yellowish-white precipitate.
 Barium salt, $(C^8H^6NO^2)^2Ba + 4H^2O$, white cubic crystals.
 Lead salt, $(C^8H^6NO^2)^2Pb + 2H^2O$, white crystalline precipitate.

When the moist silver compound is heated to 60° , drops of benzoic aldehyde separate, and the silver is reduced. Silver nitrate is also reduced by dioxindol, with formation of isatin. Dioxindol is attacked by *nitric acid*, more easily than isatin, with formation of decomposition-products.

A solution of dioxindol boiled for some time with *glycerin* deposits a violet-red amorphous powder, insoluble in boiling water, and isomeric with indin, $C^8H^6N^2O^2$ (iii. 264) (Knop).

When *chlorine* is passed into a cold-saturated alcoholic solution of dioxindol, chlorodioxindol, $C^8H^6ClNO^2$, first separates in yellowish needles, and afterwards dichlorodioxindol, $C^8H^4Cl^2NO^2$, in opaque scales. Aqueous dioxindol agitated with *bromine* deposits red laminae of dibromodioxindol, $C^8H^4Br^2NO^2$, and the supernatant liquor yields on evaporation, light red crystalline groups of monobromodioxindol, $C^8H^5BrNO^2$ (Knop).

Nitrosodioxindol, $C^8H^6(NO)NO^2$, is produced by passing nitrous acid vapour into an alcoholic solution of dioxindol, but is converted by the prolonged action of the nitrous acid into ethyl benzoate. To prepare it, 10 pts. of absolute alcohol are saturated with nitrous acid, a concentrated alcoholic solution of 1 pt. dioxindol is added, and the whole is shaken up with 5 pts. of pulverised potassium carbonate till the mass becomes red and slightly warm. The powder when cold is washed with absolute alcohol and dissolved in water, and the product, precipitated with hydrochloric acid, is purified by repeated solution in potash, treatment with animal charcoal, and reprecipitation with hydrochloric acid.

Nitrosodioxindol forms a yellowish crystalline powder or interlaced needles, sparingly soluble in water, and crystallising therefrom in yellow brittle moss-like needles. It melts at 300° – 310° , solidifies again in the crystalline form, and sublimes at 340° in white needles. When boiled with alcoholic ammonia it does not give the violet-red reaction characteristic of dioxindol. *Ammonium nitrosodioxindol*, $C^8H^6(NO)NO^2(NH^4) + 1\frac{1}{2}H^2O$, separates in white silky laminae on evaporating the solution of nitrosodioxindol in very dilute ammonia. The *barium compound* $C^8H^6(NO)NO^2Ba$ is a white precipitate; the *silver compound* $C^8H^6(NO)NO^2Ag$ a yellowish-white precipitate.

Bromonitrosodioxindol, $C^8H^5Br(NO)NO^2 + 3H^2O$, is precipitated on mixing the aqueous solution of nitrosodioxindol with bromine-water, and crystallises from alcohol in tufts of needles. It dissolves without alteration in fuming nitric and sulphuric acids and in potash-ley, is not coloured violet by boiling with alcoholic ammonia, gives off its water at 140° , melts at 275° , and sublimes in white laminae.

Azodioxindol, $C^8H^6N^2O$, is produced by boiling nitrosodioxindol with 6 pts. ferrous sulphate, excess of potash-ley, and a large quantity of water, and is precipitated from the filtered liquid by hydrochloric acid in white needles slightly soluble in water, easily in boiling alcohol, insoluble in hydrochloric acid. Bromine-water added to the aqueous solution throws down white flocks of a bromine-compound. It melts at 300° , but sublimates at 260° in colourless square plates. Its aqueous solution mixed with silver nitrate and ammonia yields a white crystalline precipitate of the compound $C^8H^6Ag^2N^2O^2$.

Oxindol, C^8H^7NO .—Dioxindol cannot be further reduced in alkaline solution; but in acid solution it is reduced to oxindol by tin and hydrochloric acid, or better by sodium-amalgam. To prepare oxindol, isatin is first converted as above into dioxindol; the solution is diluted with water in the proportion of 100 pts. water to 1 pt. isatin, then acidulated with dilute sulphuric or hydrochloric acid, and heated in the water-bath; and sodium-amalgam is gradually added, keeping the acid always in excess. If after six hours the liquid remains light yellow, even when it has become alkaline, and an ethereal extract immediately yields needles on evaporation, it is neutralised with sodium carbonate and evaporated, till drops of oil make their appearance on the surface of the liquid. The oxindol which separates after 24 hours is purified by recrystallisation from hot water. It forms long colourless needles or feathery groups, melts at 120° , solidifies again at 110° , and at higher temperatures distils in small quantities without decomposition, as a colourless or reddish oil which immediately solidifies in the crystalline form. In hot water the crystals melt and dissolve abundantly, the liquid yielding crystals on cooling. On evaporating the concentrated solution, oily drops of fused oxindol separate on the surface; on exposure to the air, it is partly converted by oxidation into dioxindol. It dissolves in alcohol and ether, and crystallises therefrom in needles; forms a crystalline compound with potash, precipitates with salts of barium, copper, and calcium, and with basic lead acetate, and a specular deposit of silver when boiled with ammoniacal silver nitrate. *Silver oxindol*, C^8H^6AgNO , is formed on mixing a cold-saturated solution of oxindol with silver nitrate, and then with a little ammonia, as a precipitate which becomes granular on standing, and does not yield benzoic aldehyde when heated to 70° – 80° . *Oxindol hydrochloride*, $C^8H^7NO.HCl$, is deliquescent, and forms groups of spicular crystals.

Bromoxindol, C^8H^6BrNO , separates on mixing the cold-saturated solution of oxindol with bromine-water, in white feathery crystals. It is insoluble in water, slightly soluble in alcohol, melts at 176° , and is precipitated by acids from the alkaline solution without alteration. *Tribromoxindol*, $C^8H^3Br^3NO + 2H^2O$, produced by adding bromine to the aqueous solution of oxindol, and removing the excess of bromine by heat, is insoluble in water, dissolves without alteration in potash, crystallises in feathery tufts, and decomposes without fusion at 270° .

Nitrosoxindol, $C^8H^6(NO)NO$, is formed on passing nitrous acid into a 1 percent. aqueous solution of oxindol, till a sample of the liquid rubbed with a glass rod deposits crystals after a while. The liquid then solidifies immediately, or after 24 hours, to a pulp of very slender golden-yellow needles, which dissolve sparingly in water, more easily in alcohol, and with dark brown-red colour in potash. The compound decomposes when heated, yielding oily drops which smell like nitrobenzene. The *silver salt*, $C^8H^6(NO)NOAg$, is an orange-coloured gummy precipitate which detonates when heated.

Bromonitrosoxindol, $C^8H^5Br(NO)NO$, separates on mixing the cold solution of nitrosoxindol with bromine-water, in light yellow needles, slightly soluble in water, more easily in alcohol, and decomposing at 240° without fusion or sublimation. *Tribromonitrosoxindol*, $C^8H^2Br^3(NO)NO$, formed by treating the preceding compound with excess of bromine, is insoluble in water, easily soluble in hot alcohol, crystallises in needles of a dingy violet colour, melts at 162° , and sublimates at 190° .

Amidoxindol, $C^8H^6(NH^2)NO$, is formed by reducing nitrosoxindol with tin and strong hydrochloric acid. The acid solution, freed from tin by hydrogen sulphide and evaporated, yields colourless nodules of amidoxindol hydrochloride, $C^8H^6(NH^2)NO.HCl$. This salt is decomposed by water, with separation of a red resinous substance soluble in alcohol, gives off hydrochloric acid at 80° , and is completely decomposed at 170° , without previous fusion. Nitrosoxindol reduced with ferrous sulphate and potash yields a metallic-green colouring matter not yet examined.

Azoxindol, $C^8H^6N^2O$.—The sodium-derivative of this compound is formed by treating nitrosodioxindol with sodium-amalgam and a small quantity of water, as an amorphous mass, which, when decomposed by hydrochloric acid, yields azoxindol as an amorphous precipitate containing $2C^8H^6N^2O.H^2O$. It is slightly soluble in water, more easily in alcohol, from which it crystallises in cubes; it sublimates without fusion

at 220°, in white crystalline laminae. Its hot aqueous solution forms with barium chloride and a little ammonia, a bulky precipitate of barium azoxindol, $C^{10}H^{10}N^2O^2Ba$.

INOSITE. This saccharine substance has been found by Gintl in the leaves of the common ash (*J. pr. Chem.* [2] iv. 731).

INSOLINIC ACID, $C^8H^8O^4$, is produced, according to Hirzel a. Boilestein (*Zeitschr. f. Chem.* [2] 23; *Jahresb.* 1866, p. 362), by oxidising xylic acid, $C^8H^{10}O^4$, with chromic acid, and by the action of dilute nitric acid on cumone, $C^{10}H^{12}$. According to H. Müller and others, the acid thus produced is identical with terephthalic acid, $C^8H^4O^4$ (q. v.).

INULIN. $C^{12}H^{20}O^{10}$ (Ferrouillat a. Savigny, *Zeitschr. f. Chem.* [2] v. 509).—They find that inulin from different sources is not identical, and especially that inulin from the dahlia (*Georgina purpurea*) and that from elecampane (*Inula Helenium*) exhibit different reactions when treated under similar circumstances with acetic oxide. For the preparation of inulin, the plants were boiled for an hour with water, and the filtered solution was precipitated with neutral lead-acetate, whereby a gummy substance was removed. The filtrate was freed from lead by hydrogen sulphide, then concentrated and left at rest, and the precipitate of inulin was collected on a filter, washed with water and then with alcohol, and dried at a low temperature. Dahlia inulin turns the plane of polarisation 26° to the left, whereas inulin from elecampane turns it 32·8° to the left. Of each of these varieties of inulin, 1 part was mixed with 1 part of acetic oxide and 2 parts of glacial acetic acid, and heated to boiling for a quarter of an hour, whereupon the inulin first became gummy and then dissolved. The solution was not precipitated by water, but other threw down a pasty, semi-fluid, light yellow, amorphous precipitate, which, after thorough washing with ether and drying at 100°, formed a solid, amorphous, light-yellow mass, very soluble in water and in alcohol, but insoluble in ether. This acetyl derivative yielded by saponification from 29 to 30 per cent. acetyl, corresponding to 1½ acetyl-atoms for the formula $C^8H^{10}O^3$. The usual formula of inulin must therefore be doubled, and this first acetyl-derivative is $C^{12}H^{17}(C^2H^3O)^4O^4O^{10}$. The rotatory power of the compound obtained from dahlia inulin is -20°, of that from elecampane inulin -32°. In a second experiment, 1 part of inulin was heated to boiling for a quarter of an hour with 2 parts of acetic oxide. The resulting solution was not precipitated either by water or by ether. When mixed with a little water and evaporated till the acetic acid was expelled, it left a strongly coloured residue insoluble in pure water, but soluble in alcohol and in water containing acetic acid. The alcoholic solution, when decolorised with animal charcoal and evaporated, left an amorphous yellowish mass. The compound from elecampane inulin had the composition $C^{12}H^{18}(C^2H^3O)^4O^4O^{10}$, and the rotatory power -25°, whereas that from dahlia inulin was $C^{12}H^{18}(C^2H^3O)^4O^4O^{10}$, and its rotatory power was -14°. In a third experiment, one part of inulin was heated to boiling for half an hour with 3 parts of acetic oxide. The solution treated as in the second experiment yielded dextrogyrate products, insoluble in water, soluble in alcohol. The compound from elecampane inulin corresponded with the formula $C^{12}H^{18}(C^2H^3O)^4O^4O^{10}$; that from dahlia inulin with the formula $C^{12}H^{18}(C^2H^3O)^4O^4O^{10}$.

Schützenberger a. Naudin (*ibid.* 265) have also obtained by similar means an acetyl-derivative of inulin containing $C^8H^7(C^2H^3O)^4O^4O^3$ or $C^{12}H^{14}(C^2H^3O)^4O^4O^{10}$, which is soluble in water, has a bitter taste, melts to a syrup at 100°, and solidifies on cooling to a colourless, transparent, vitreous mass. It is easily saponified by alkalis, producing a white substance insoluble in water: and melting at 100°.

IODINE. For the preparation of absolutely pure iodine, Stas finds that only two methods are available, viz.: 1. Precipitation from its solution in potassium iodide by water.—2. Decomposition of nitrogen iodide suspended in water by heating it first to 60°-65°, and finally to 100°, and washing out the soluble salts with water. The product is somewhat less than that which corresponds to the equation $4NH_3 = NH_4I + N^2 + I^2$ (*Jahresb.* 1867, p. 159).

On the solubility of iodine in water and in aqueous potassium iodide, see Dossion a. Werth (*Zeitschr. f. Chem.* [2] v. 379).

On the action of hydrogen sulphide on iodine, see Naumann (*Zeitschr. f. Chem.* [2] v. 435).

For the simultaneous detection of iodine and bromine, Phipson (*Compt. rend.* lxx. 176) mixes the solution, much diluted and acidulated with hydrochloric acid, in a tube two feet long, with a small quantity of carbon bisulphide, and shakes it up with small quantities of a concentrated solution of chloride of lime. If iodine is present, the carbon bisulphide first assumes a purple-violet colour, and becomes colourless on

further addition of the chlorine solution, from formation of iodine chloride. If bromine is also present, the carbon bisulphide, immediately after decoloration, assumes an orange-yellow tint.

On the detection and estimation of iodine in presence of bromine and chlorine, see also p. 368.

The detection of iodine is often hindered by the presence of organic substances. According to Hlasiwetz (*Zeitschr. anal. Chem.* vi. 447), the aqueous solutions of resorcin, orcin, and phloroglucin take up iodine without coloration, or perceptible formation of hydriodic acid, in considerable but definite quantity, and withdraw it from its solution in carbon bisulphide. In these solutions the iodine can neither be detected by the ordinary reagents, nor volatilised by boiling. Nevertheless, the loose combination into which the iodine has entered is broken up when the solution is evaporated in a vacuum, the organic substance crystallising out in its original state, and the iodine subliming.

For the estimation of iodine in iodates and periodates, Rammelsberg (*Pogg. Ann.* cxxxv. 493) decomposes these salts with potassium iodide and dilute sulphuric acid, and titrates the separated iodine with sodium hyposulphite:

On the estimation of iodine, see also Bobierro (*Zeitschr. f. Chem.* [2] v. 192); Struve (*ibid.* 383); Siewert (*ibid.* 307).

Hydriodic Acid. On the preparation of aqueous hydriodic acid by means of iodine and phosphorus, see Michl. Pettenkofer (*Ann. Ch. Pharm.* cxxxviii. 67; *Jahresh.* 1866, p. 138). According to Vigier (*Zeitschr. f. Chem.* [2] v. 412), the most suitable proportions for the preparation are represented by the equation

Winkler (*J. pr. Chem.* cii. 33) passes hydrogen sulphide into an unsaturated solution of iodine in recently distilled carbon bisulphide, covered with a layer of water, and contained in a cylindrical vessel immersed in cold water. The passage of the gas must be continued till the liquid is decolorised, and the quantity of carbon bisulphide present must be sufficient to hold in solution all the separated sulphur. The hydriodic acid formed dissolves in the water, and may be obtained of any required degree of concentration by diminishing the quantity of the latter. After being freed from hydrogen sulphide by heating it for a short time in a retort, it is perfectly pure. A. Naumann (*Zeitschr. f. Chem.* [2] v. 436) modifies this process by leaving out the carbon bisulphide, and operating at first on a small scale, till the reaction becomes considerably accelerated by the solubility of the iodine in the hydriodic acid produced. The liquid is then cooled, and iodine and water are added from time to time as the action slackens. In this manner, even a very rapid stream of hydrogen sulphide is completely absorbed, and in a short time large quantities of hydriodic acid are obtained of sp. gr. 1.56. Of this acid only a small portion distils below 127°, the greater part remaining and exhibiting a sp. gr. of 1.67.

Reactions.—The decomposition of hydriodic acid by heat, and its action on various substances, have been examined by Hautefeuille (*Bull. Soc. Chim.* [2] vii. 198, 200, 203; *Jahresh.* 1867, p. 171). When the pure gaseous acid is gradually heated, it exhibits, at about 180°, a faint violet colour, indicating a commencement of decomposition, which increases slowly up to 440°, and rapidly between 440° and 700°, its amount being influenced by the extent of heated surface, and at a given temperature also by the pressure. Thus, when the gas was passed under ordinary pressure through a tube filled with fragments of glass, the decomposed portion amounted at 440° to 2.6, and at 700° to 34 p. c. On passing it through a glass tube filled with platinum-sponge, the results were:

At about	700°	440°	250°	195°	175°
Decomposed portion	22.2	19.5	18.7	17.5	10.5 p. c.

In a closed glass tube at the boiling point of sulphur:

Under a pressure of	0.760	1.497	1.717	1.910	1.950 met.
Decomposed portion	2.6	3.1	3.7	6.1	6.4 p. c.

Under constant pressure, therefore, the decomposition is considerably facilitated by the presence of platinum-sponge (below 180° iodine condenses on the surface of the platinum, and interferes with its action). When, on the other hand, a mixture of equal volumes of iodine-vapour and hydrogen is passed over heated platinum-sponge, the two elements partly combine, the uncombined portion being equal to that which is separated from pure hydrogen iodide by platinum-sponge at the same temperature.

Glass vessels are attacked by hydrogen iodide even below a red heat, with formation of water, an iodide of alkali-metal, hydrogen sulphide (from sulphur in the glass), and separation of iodine; the decomposition of the gas in glass vessels began at a lower temperature than in porcelain vessels. On the other hand, heated glass induces the formation of hydriodic acid from a mixture of iodine-vapour and hydrogen, to a small amount at 440° under ordinary pressure, more abundantly in closed tubes at the same temperature, the quantity of hydriodic acid formed increasing with the proportion of iodine present. Out of 100 c. c. hydrogen, there remained after heating with:

Iodine in milligr.	461	510	613	709	751	761	840	987	1351	4141
Uncombined H in c. c.	62	54	45	45	37	35	36	26	14.8	5.7

In this case, therefore, as when platinum-sponge is used, a state of equilibrium is obtained, varying with the proportions of the reacting substances.

Sulphur decomposes gaseous hydriodic acid gas, or a cold-saturated aqueous solution, at ordinary temperatures, with formation of hydrogen sulphide and separation of iodine; dilute aqueous solutions only with aid of heat. These conditions are the reverse of those on which the preparation of aqueous hydriodic acid, by passing hydrogen sulphide into water containing iodine, depends. If the moderately concentrated aqueous acid be enclosed with sulphur in a glass tube, application of heat gives rise to the formation of hydrogen sulphide and separation of iodine, whereas on cooling, hydriodic acid is produced and sulphur separated, which after repeated alternations of temperature (between not very wide limits) crystallises in transparent octahedrons. When gaseous hydriodic acid is passed into sulphur chloride, hydrochloric acid is at first evolved, and iodine (or sulphur iodide) separated; afterwards hydrogen sulphide is formed in large quantity. Selenium acts on hydriodic acid in the same manner as sulphur, and the reaction may be made available for the preparation of hydrogen selenide, and of beautifully crystallised selenium. Phosphorous chloride and arsenious chloride exposed to a stream of the gas at ordinary temperatures are converted, with spontaneous rise of temperature and evolution of hydrochloric acid, into the corresponding iodine-compounds, which dissolve in the excess of chloride and finally crystallise out. Titanium chloride is decomposed at its boiling point; ammonium chloride at the temperature at which it volatilises; silicon chloride not below 440°.

These results show that a number of chlorides are decomposed by hydriodic acid at ordinary or at higher temperatures. On the other hand, metallic iodides (and bromides) are decomposed when strongly heated in excess of hydrochloric acid gas, silver iodide, for example, at about 700°. For the continuance of the decomposition, however, it is necessary that the hydriodic acid be removed as fast as it is formed: hence it appears that hydriodic acid can also decompose silver chloride at high temperatures. Lead iodide is decomposed by hydrochloric acid gas, even below its melting point; mercuric iodide and ammonium iodide are but slightly acted upon (Hautefeuille); compare Lieben (p. 437).

Nitrogen dioxide is slowly decomposed by concentrated aqueous hydriodic acid, with formation of ammonia and separation of iodine (Chapman & Smith, *Chem. Soc. J.* [2] v. 166).

The reducing action of hydriodic acid on organic compounds has been elaborately investigated by Berthelot (*Bull. Soc. Chim.* [2] ix. 8, 91, 178, 205; *Jahresb.* 1867, p. 342), who has shown that all such compounds, except the paraffins, C^mH^{2m+2} , are decomposed by the concentrated aqueous acid, at sufficiently high temperatures, with formation of hydrocarbons. The products of the reaction vary with the proportion of hydriodic acid used; when it is pushed to its utmost limits, the only products (besides water, carbon dioxide, carbon monoxide, and ammonia) are paraffins, either containing the same number of carbon-atoms as the original substance, or formed from this substance by division. To ensure this complete reduction, however, the organic substance must be heated in a sealed tube for 10 to 24 hours to 270°-280°, with a saturated solution of hydriodic acid (sp. gr. = 2.0); alcohols and acids of the fatty series with 20 to 30 times, aromatic bodies with 80 to 100 times their weight of this concentrated acid; in general, the excess of acid required above the theoretical quantity is greater, as the proportion of hydrogen in the organic substance is less. With smaller quantities of hydriodic acid, intermediate products are obtained. The following are the principal results:

A. *Fatty Bodies*.—1. The *olefines* C^mH^{2m} are converted at ordinary temperatures, and more quickly at 100°, first into alcoholic iodides, then into paraffins; ethylene, for example, into ethyl iodide and ethane: $C^2H^4 + HI = C^2H^5I$; and $C^2H^4 + HI = I^2 + C^2H^6$.

2. The *hydrocarbons* C^2H^{2n-2} , homologous with acetylene, react in a similar manner: *e.g.*,

and

3. The *chlorine, bromine, and iodine derivatives* of the hydrocarbons likewise exhibit similar transformations; *e.g.*,

4. The *paraffins*, as already observed, remain unaltered under the influence of hydriodic acid, and constitute the ultimate products resulting from its action, unless they are decomposed by the heat.

5. *Alcohols* are converted, first into iodides and then into paraffins; *aldehydes* yield the same products, being first converted into alcohols. They however yield, together with the normal paraffin, small quantities of its lower homologues; thus acetic aldehyde yields ethane with a little methane; *acetone* yields chiefly propane, together with ethane and methane.

6. All the *acids, monobasic or polybasic*, of this group, are reduced under the above-named conditions—if they do not split up by themselves—to paraffins containing the same number of carbon-atoms; thus acetic acid yields ethane:

and butyric acid yields butane, C^4H^{10} . Formic acid yields only water and carbon monoxide, the latter not being attacked by hydriodic acid. Oxalic acid is resolved in like manner into carbon dioxide, carbon monoxide, and water. Succinic acid yields butane:

Tartronic acid, $C^4H^5O^5$, forms ethane and carbon dioxide, being first converted into malonic acid, $C^3H^4O^4$, which is then resolved into acetic acid and carbon dioxide. *Bibasic acids*, treated with a quantity of hydriodic acid not sufficient for complete reduction, are converted in great part into the corresponding monobasic acids, succinic acid, for example, into butyric:

7. *Compound ethers* behave like their components, into which they are in the first instance resolved by assumption of water; ethyl formate, for example, yields carbon monoxide, water, and methane.

B. *Aromatic Compounds*.—Benzene heated for 24 hours to 280° with 80 parts of the aqueous acid is almost wholly converted into hexane; but at the same time a small quantity of propane is formed by splitting up of the benzene:

and

With 15 to 20 pts. of the acid, benzene is resolved into carbon and propane:

with 30 to 40 pts. it appears to yield hexane, and in the first instance hexylene, which is afterwards resolved into difficultly volatile condensation-products. The chlorinated derivatives of benzene are first reduced to benzene, which then reacts with the excess of acid as above.

Phenol treated with insufficient quantities of acid is partly reduced to benzene, partly converted, with separation of carbon, into propane; with excess of acid it yields the same products as benzene.

Benzoic acid treated with 80 pts. hydriodic acid, yields heptane as normal product, and hexane in consequence of the resolution of the benzoic acid into carbon dioxide and benzene. With 20 pts. acid toluene is produced:

and in smaller quantities, benzene and carbon dioxide. *Benzoic aldehyde* with

20 pts. acid yields, as normal product, toluene, together with smaller quantities of benzene, xylene, and perhaps higher homologues.

Toluene heated with 80 pts. of this acid is completely converted into heptane, C^7H^{16} , with simultaneous abundant decomposition of hydriodic acid; heated with 20 pts. acid it yields charcoal and propane:

Cumene, C^9H^{12} , is converted by 80 pts. acid into nonane, C^9H^{20} , with abundant decomposition of the hydriodic acid. With 23 pts. acid it yields charcoal and propane:

Cymene, $C^{10}H^{14}$, is converted by excess of the acid into decane, $C^{10}H^{22}$; *xylene*, C^8H^{10} , apparently into octane, C^8H^{18} .

According to Baeyer (*Zeitschr. f. Chem.* [2] iv. 445), hydriodic acid combined with phosphine, $(PH^3.HI)$, does not act upon benzene even at 350° , but converts toluene into $C^7H^8.H^2$, xylene into $C^8H^{10}.H^4$, naphthalene at 170° into $C^{10}H^{18}.H^4$.

C. The more complex hydrocarbons allied to the aromatic group are partly resolved, by saturation with hydrogen, into several groups. *Diphenyl*, $C^{12}H^{10}$, treated with 80 pts. acid is almost wholly converted into hexane, C^6H^{14} ; with 20 pts. of the acid, partly (to $\frac{2}{3}$) into benzene, partly (to $\frac{1}{3}$) into propane and charcoal:

Cinnamene, C^9H^8 , treated with 80 pts. of the acid yields, as chief product, an octano boiling at 115° to 120° , with small quantities of ethane and hexane:

With 20 pts. of the acid, it is for the most part converted into cinnamene hydride, C^9H^{10} (? ethyl-phenyl), with benzene, ethane, and a difficultly volatile resinous hydrocarbon as secondary products:

Ethyl-phenyl, C^8H^{10} , and *bromethyl-phenyl*, C^8H^9Br , yield with 80 pts. of the acid, octane and small quantities of ethane and hexane.

Naphthalene, $C^{10}H^8$, may yield the hydrides $C^{10}H^{10}$, $C^{10}H^{12}$, $C^{10}H^{14}$, $C^{10}H^{16}$; also ethyl-phenyl and ethane; octane and ethane; benzene and ethane; hexane and ethane.

Anthracene, $C^{14}H^{10}$, treated with 80 pts. of the acid, yields as chief product, tetradecane, $C^{14}H^{26}$, together with heptane, hexane, ethane, and a paraffin boiling at 360° , perhaps $C^{24}H^{50}$. With 20 pts. acid it yields chiefly toluene, with small quantities of benzene, ethane, and a liquid hydrocarbon boiling at 260° , perhaps $C^{14}H^{24}$.

D. Bodies allied to the preceding hydrocarbons. *Alizarin* is converted by 20 pts. of the acid into a carbonaceous mass; by 100 pts. it is gradually but completely converted into paraffins, among which have been distinguished C^8H^{18} (boiling at 270° – 280°), one boiling above 360° , and in smaller quantity, hexane and ethane. *Phthalic acid*, $C^8H^6O^4$, with 10 pts. hydriodic acid yields heptane and octane:

and

The isomeric compound *terephthalic acid* similarly treated yields only heptane.

E. Polymeric hydrocarbons treated with excess of hydriodic acid are partly converted into paraffins containing the same number of carbon-atoms, and are partly split up into simpler compounds, with addition of hydrogen; thus *polyethylene* (oil of wine), C^2H^2 , boiling at about 280° , yields the paraffins $C^{10}H^{22}$, $C^{12}H^{26}$, C^8H^{18} , and C^6H^{14} . Similar results are obtained with the *polypropylenes* and *polyamylenes*. *Oil of turpentine*, $C^{10}H^{16}$, gives $C^{10}H^{22}$ and C^8H^{18} . With 20 pts. of the acid, decane, $C^{10}H^{22}$, is at first produced, and finally lower hydrocarbons of the same series, together with xylene.

F. Substances richer in carbon. *Bitumene* (p. 349) heated with 100 pts. of the acid is for the most part converted into hexane and an oily paraffin, $C^{14}H^{30}$ or $C^{24}H^{50}$. *Ulm*, *wood*, and *wood-charcoal* are converted more or less completely into paraffins, the principal of which are $C^{12}H^{26}$, C^8H^{18} , and an oily body volatilising only at a red heat ($C^{24}H^{50}$?). *Coal* is attacked by 106 pts. of the acid, to the amount of about 60 p. c., and converted into similar hydrocarbons; the residue has the constitution of a resin. Graphite and charcoal ignited in a stream of chlorine are not attacked by hydriodic acid. But charcoal heated to whiteness in chlorine (after which treatment it may

be regarded as pure carbon) dissolves slowly in strong nitric acid at 80°, forming a brown extractive substance which is acted upon by hydriodic acid like wood.

G. *Nitrogenous substances* heated with excess of hydriodic acid yield, as essential products, ammonia and saturated hydrocarbons. *Methylamine* yields ammonia and methane; *ethylamine*, ammonia and ethane; *aniline*, with 20 pts. of the acid, yields ammonia and benzene; *toluidine*, with 80 pts. acid, yields ammonia and heptane:

a large portion of the hydriodic acid being at the same time decomposed. *Methylaniline*, isomeric with toluidine, yields, under similar circumstances, methane and hexane; *ethylaniline*, ethane and hexane; *amylaniline*, quintane and hexane. *Amides* and *nitriles* are first converted, by assumption of water, into the corresponding ammonia-salts, after which the acid further decomposes. Respecting the reaction of hydriodic acid with *cyanogen* and *cyanides*, see pp. 521, 538; with *indigo*, p. 728.

Iodine Chlorides. The trichloride ICl_3 acts at ordinary temperatures on carbon bisulphide, forming a brown-red liquid containing sulphur chloride, carbon tetrachloride, and a crystallisable compound. The same products are formed when a solution of iodine in carbon bisulphide is saturated with chlorine gas. As the liquid cools, the compound separates in large well-defined prismatic crystals, having the colour of potassium dichromate, and so deliquescent that they can only be dried in a stream of dry chlorine gas and preserved in a sealed tube. When gently heated in a closed vessel they melt, giving off a small quantity of iodine chloride, and forming a liquid which solidifies in the crystalline form on cooling; they are decomposed by water and by hydrogen sulphide. These crystals have the composition $\text{ICl}_3 \cdot \text{SCl}_2$ (Weber, *Pogg. Ann.* cxxviii. 459; *Jahresb.* 1866, p. 138). Jaillard (*Jahresb.* 1860, p. 95), by passing chlorine over a mixture of iodine and sulphur, obtained a compound to which he assigned the formula $2\text{ICl}_3 \cdot \text{SCl}_2$; according to Weber, however, it is identical with that just described.

Iodine monochloride, ICl , added in aqueous solution to the acidulated hydrochlorides of various organic bases, forms crystalline compounds which separate as yellow precipitates, and in some cases may be recrystallised without decomposition from dilute hydrochloric acid. The *tetretethylammonium compound* $(\text{C}^2\text{H}^5)_4\text{NCl} \cdot \text{ICl}$ forms fern-like groups of needles, which are decomposed by water. The *triethylamine compound* crystallises in needles. The *caffeine compound* $\text{C}^8\text{H}^{10}\text{N}^4\text{O}^2 \cdot \text{HCl} \cdot \text{ICl}$ is easily obtained pure, and forms crystals which appear to be oblique rhombic prisms. *Quinine hydrochloride* forms a yellow precipitate which assumes a dark colour when recrystallised from dilute hydrochloric acid (Tilden, *Chem. Soc. J.* [2] iv. 145).

Oxygen-acids of Iodine.

Iodic Acid. According to Stas (*Jahresb.* 1867, p. 162), the iodic acid prepared by decomposing barium iodate with dilute sulphuric acid always retains in solution a small quantity of barium sulphate, from which it cannot be freed. Perfectly pure iodic acid may be obtained by oxidising pure iodine with fuming nitric acid in a retort of glass not attacked by the acid,* evaporating to dryness, redissolving in water, again evaporating, and heating the white solid acid for some time to 200°, till it is converted into anhydride, and all the nitric acid is driven off with the water. The quantity of iodic acid thus obtained does not exceed $\frac{1}{4}$ pt. of the iodine used. If the oxidation is performed in a vessel of common glass, the iodic acid is contaminated with traces of soda and lime.

The following table of the specific gravity of aqueous iodic acid of different strengths is given by H. Kämmerer (*Pogg. Ann.* cxxxviii. 390; *Zeitschr. f. Chem.* [2] 277):

Percent. of I^2O^5	Sp. gr. at 14°	Percent. of I^2O^5	Sp. gr. at 14°
1	1.0053	40	1.5371
5	1.0263	45	1.6315
10	1.0525	50	1.7356
15	1.1223	55	1.8689
20	1.2093	60	1.9954
25	1.2773	65	2.1269
30	1.3484	100.5	4.7887 (at 9°)
35	1.4428		

* Stas finds that an easily fusible glass not attacked by acids may be made by replacing half the potash in ordinary potash-lime glass with soda, such glass containing 77.0 p. c. SiO_2 , 7.7 K_2O , 6.0 Na_2O , and 15.3 CaO (*Jahresb.* 1867, p. 920).

From a comparison of these densities with those of aqueous chloric acid, Kämmerer infers that the corresponding hydrates of the two acids occupy equal atomic volumes:

Formula of the Hydrate	Percent. of Anhydride	Molecular Weight	Sp. gr.	Atomic Volume
$\text{HClO}_3 \cdot 7\text{H}_2\text{O}$	35.73	210.5	1.262	166.7
$\text{HIO}_3 \cdot 7\text{H}_2\text{O}$	55.3	304	1.8256	165.4
$\text{HClO}_3 \cdot 15\text{H}_2\text{O}$	21.29	354.5	1.161	305.2
$\text{HIO}_3 \cdot 15\text{H}_2\text{O}$	37.44	446	1.489	299.5
$\text{HClO}_3 \cdot 20\text{H}_2\text{O}$	16.98	444.5	1.128	394.2
$\text{HIO}_3 \cdot 20\text{H}_2\text{O}$	31.16	536	1.389	391.6

Periodic Acid (Lautsch, *J. pr. Chem.* c. 65. Fernlund, *ibid.* c. 99. Rammelsberg, *ibid.* ciii. 278; civ. 434; *Pogg. Ann.* cxxxiv. 134, 368, 499. *Jahresb.* 1867, pp. 162, 166; 1868, p. 162. Kämmerer, *loc. cit.*).—Kämmerer prepares this acid by decomposing the silver salt with chlorine, or better with bromine. The solution evaporated in a vacuum leaves the pure acid HIO_3 or $\text{I}_2\text{O}_7 \cdot 5\text{H}_2\text{O}$. Lautsch confirms the observation of Langlois (iii. 308) that periodic acid $\text{I}_2\text{O}_7 \cdot 5\text{H}_2\text{O}$ or HIO_3 melts at 130° , and is converted into iodic anhydride, I_2O_5 , by loss of water and oxygen, between 200° and 210° . He finds, however, that the pure acid effloresces rather quickly in the air at ordinary temperatures. According to Rammelsberg, on the other hand, the crystals of periodic acid remain quite unaltered when left over sulphuric acid or when heated to 100° ; they melt between 130° and 136° , and are completely resolved, even at that temperature, into iodic anhydride, oxygen, and water. Neither periodic anhydride, I_2O_7 , nor the normal monohydrate HIO_3 has yet been obtained.

The basicity of periodic acid is still a matter of discussion. Rammelsberg regards it as monobasic, and classifies the metallic periodates as follows:

1. Normal Periodates.

MIO^4	$\text{M}'\text{T}'\text{O}^4$
KIO^4 $(\text{NH}_4)\text{IO}^4$	NaIO^4 LiIO^4 AgIO^4
$\text{SrI}_2\text{O}^8 + 6\text{H}_2\text{O}$ $\text{MgI}_2\text{O}^8 + 10\text{H}_2\text{O}$ CdI_2O^8	

2. Three-fifths Periodates.

$$\text{M}^3\text{I}^6\text{O}^{24} = \begin{cases} \text{M}'\text{T}'\text{O}^8 \\ 2\text{M}^2\text{T}'\text{O}^8 \end{cases}$$

3. Four-sevenths Periodates.

$$\text{M}^4\text{I}^8\text{O}^{32} = \begin{cases} \text{M}'\text{T}'\text{O}^8 \\ 3\text{M}^2\text{T}'\text{O}^8 \end{cases}$$

4. Hemi-periodates

$\text{M}^2\text{I}^6\text{O}^8$	$\text{M}^2\text{T}'\text{O}^8$
KI^6O^8 $\text{K}^4\text{I}^6\text{O}^8 + 9\text{H}_2\text{O}$ $(\text{NH}_4)_4\text{I}^6\text{O}^8 + 3\text{H}_2\text{O}$ $\text{NaI}^6\text{O}^8 + 3\text{H}_2\text{O}$ $\text{LiI}^6\text{O}^8 + 3\text{H}_2\text{O}$ $\text{AgI}^6\text{O}^8 + 3\text{H}_2\text{O}$ $\text{Ag}^4\text{I}^6\text{O}^8 + \text{H}_2\text{O}$	$\text{Ba}^2\text{I}^6\text{O}^8$ $\text{Ba}^2\text{I}^6\text{O}^8 + 6\text{H}_2\text{O}$ $\text{Ba}^2\text{I}^6\text{O}^8 + 7\text{H}_2\text{O}$ $\text{SrI}^6\text{O}^8 + \text{H}_2\text{O}$ $\text{SrI}^6\text{O}^8 + 4\text{H}_2\text{O}$ $\text{CaI}^6\text{O}^8 + 9\text{H}_2\text{O}$ $\text{MgI}^6\text{O}^8 + 15\text{H}_2\text{O}$ $\text{ZnI}^6\text{O}^8 + 6\text{H}_2\text{O}$ $\text{CuI}^6\text{O}^8 + 6\text{H}_2\text{O}$ $\text{CdI}^6\text{O}^8 + 9\text{H}_2\text{O}$

6. Two-fifths Periodates.

$$\text{M}^5\text{I}^{10}\text{O}^{10} = \begin{cases} 3\text{M}^2\text{T}'\text{O}^8 \\ \text{M}'\text{T}'\text{O}^{11} \end{cases}$$

6. Three-eighths Periodates.

$$\text{M}^6\text{I}^{12}\text{O}^{20} = \begin{cases} 2\text{M}^2\text{T}'\text{O}^8 \\ \text{M}'\text{T}'\text{O}^{11} \end{cases}$$

7. Trilo-periodates.

8. Tetarto-periodates.

9. One-fifth Periodates.

$\text{M}^{10}\text{I}^2\text{O}^8$	$\text{M}^4\text{T}'\text{O}^{13}$
$\text{H}^{10}\text{I}^2\text{O}^8$ NaI^2O^8 LiI^2O^8 AgI^2O^8	$\text{Ba}^4\text{I}^2\text{O}^{13}$ $\text{SrI}^2\text{O}^{13}$ $\text{CaI}^2\text{O}^{13}$ $\text{HgI}^2\text{O}^{13}$ $\text{CuI}^2\text{O}^{13} + 5\text{H}_2\text{O}$

10. One-sixth Periodates.

The normal periodates of the univalent metals are decomposed by heat into metallic iodide and oxygen; many other periodates give off oxygen and iodine, leaving either a pure oxide (magnesia, nickel-oxide), or a mixture of oxide and iodide (lead, copper, cadmium, &c.). The mercury salts give off metallic mercury, iodide, and oxygen; the ammonium salts are resolved, with violent detonation, into iodine, nitrogen, oxygen, and water. Among the hemiperiodates, the silver salt is the only one that leaves a residue free from oxygen (metallic silver and iodide). The potassium and sodium salts of this division give off at most $\frac{1}{2}$ of their oxygen, leaving a residue of the composition $M'I^2O$; the sodium salt at a lower temperature gives off only $\frac{1}{3}$ of its oxygen, leaving $Na'I^2O^3$. From the behaviour of this residue with silver and barium salts (with which it forms an iodide and a one-fifth periodate), it might be regarded as a mixture of sodium iodide and one-fifth sodium periodate, $Na'I^2O^3$; but it more probably consists of a mixture of sodium iodide and a peroxide Na_2O^2 , not known in the separate state: $Na'I^2O^3 = 2NaI + Na_2O^2$; $NaI + 2Na_2O^2 = Na'I^2O^3$. The same view may be extended to the residues left on ignition by the hemiperiodates of lithium, barium, strontium, and calcium, as well as to the identical residues left by the iodates of barium, strontium, and calcium; thus:

(Rammelsberg, *loc. cit.*; further, *Zeitschr. f. Chem.* [2] v. 373).

Periodates are decomposed by *hydrochloric acid*, with evolution of chlorine; by *sulphurous acid*, with separation of iodine; by *hydrogen sulphide*, with separation of sulphur. With *potassium iodide* they turn yellow, and on addition of an acid deposit iodine, amounting, in the case of the normal potassium salt, KIO^4 , and of the sodium salt, $NaIO^4 \cdot 3H^2O$, to about $\frac{1}{2}$ of the total quantity of iodine in the salt (Rammelsberg). A characteristic reaction for periodates is afforded by their behaviour with mercurous nitrate (Lautsch, p. 747).

The normal periodates in solution are not acted upon by *chlorine* or *iodine* at ordinary temperatures. But when the solutions of these salts are heated with iodine to 160° , the iodine is oxidised to iodic acid, and the periodate is reduced to iodate. In general, the solutions of periodates act as oxidising agents, manganese and bismuth compounds, for example, being brought by them to a higher state of oxidation. When chlorine is passed into a boiling solution of sodium hemiperiodate, $Na'I^2O^3$, a solution is formed, containing normal periodate, chloride, and chlorate: hence in preparing the hemiperiodate by passing chlorine into aqueous sodium carbonate containing iodine (iii. 310), it is necessary to avoid an excess of iodine. Chlorine acts in a similar manner on potassium hemiperiodate, forming a precipitate of the less soluble normal salt:

On boiling a solution of sodium hemiperiodate containing iodine, a clear solution is formed, containing only iodate and iodide of sodium:

Potassium hemiperiodate is decomposed in a similar manner (J. Philipp, *Zeitschr. f. Chem.* [2] v. 374).

* The normal periodates separate from solutions containing excess of acid, the various basic salts from neutral or nearly neutral solutions; or they are obtained by precipitating the solutions of the respective bases in periodic acid with ammonia, or by double decomposition.

An *ammonium periodate*, containing $(NH^4)'I^2O^3 + 3H^2O$, is obtained by evaporating a solution of periodic acid supersaturated with ammonia, in monoclinic or rhombohedral crystals, which give off their water at 100° , ammonia at a higher temperature, and detonate violently at 200° (Rammelsberg).

Potassium Salts.—Rammelsberg has obtained the *normal salt* KIO^4 in well-defined crystals isomorphous with the perchlorate. It requires 300 pts. of water to dissolve it, forms an acid solution, and when evaporated with potash, yields transparent monoclinic crystals of the *tetrapotassic salt* $K_4I^2O^3 + 9H^2O$, which dissolves in 10 pts. water at ordinary temperatures, gives off its crystallisation-water, both over sulphuric acid and at 100° , and is decomposed at a stronger heat, leaving a mixture of potassium iodide and hydrate (Rammelsberg).

Sodium Salts.—The *hydrated normal salt* $NaIO^4 + 3H^2O$ is produced by evaporating a solution of the tetrasodic salt $Na_4I^2O^3$ (iii. 310) in nitric acid. It crystallises in homimorphous combinations of a rhombohedron, having an angle of

94° 28' in the terminal edge, with an obtuser and an acuter rhombohedron, a prism, and the basal end-face. The crystals dissolve in 12 pts. water at mean temperature, and effloresce over sulphuric acid, ultimately giving off all their water, as also at 100°; at 275° the anhydrous salt is converted into iodate (Rammelsberg).

Lithium Salts.—The *tetralithic salt* $\text{Li}^4\text{I}^2\text{O}^6 + 3\text{H}^2\text{O}$ separates from a nearly saturated solution of lithium carbonate in periodic acid, in the pulverulent form when evaporated by heat, in white crystalline crusts by evaporation over sulphuric acid. It is very slightly soluble, gives off all its water at 200°, begins to decompose at 275°, and is decomposed at a higher temperature, giving off iodine and oxygen, and leaving a yellowish-white residue of the pentalithic salt:

A solution of the tetralithic salt in periodic acid deposits the *normal salt*, LiIO^4 , in quadratic octohedrons P. $\frac{1}{2}$ P, having the secondary to the principal axis as 0.6548 : 1, isomorphous, therefore, with the normal ammonium, sodium, and silver salts. It also dissolves sparingly in water, forming an acid solution (Rammelsberg).

Silver Salts.—The *pentargentie salt* $\text{Ag}^5\text{I}^2\text{O}^6$, corresponding to the crystallised acid, H^5IO^6 , is obtained as a nearly black precipitate, when the solution of a periodate, either neutral or slightly acidulated with nitric acid, is mixed with silver nitrate. It does not alter at 200°, but when raised to a higher temperature leaves 87.4 p. c. of a mixture of silver iodide and metallic silver ($\text{AgI} + 2\text{Ag}^0$). By solution in nitric acid and careful evaporation, it is converted, like the tetragentic salt $\text{Ag}^4\text{I}^2\text{O}^6$, into the orange-yellow normal salt AgIO^4 , which when evaporated by heat crystallises in quadratic octohedrons (99° in the terminal and 133° in the lateral edges), and is decomposed by water in the manner represented by the equation:

The orange-red normal salt, AgIO^4 , is completely converted at 175° into the white iodate, AgIO^3 , the decomposition beginning however at a much lower temperature (Rammelsberg).

Lausch describes a *decargentie salt*, $\text{Ag}^{10}\text{I}^2\text{O}^{10}$, obtained by pouring silver nitrate on the tetrasodic salt:

as a brown pulverulent precipitate becoming nearly black when heated; also an *octargentie salt*, $\text{Ag}^8\text{I}^2\text{O}^{11}$, obtained as a black-brown or black powder by digesting the yellow tetragentic salt with ammonia, or as a reddish-brown precipitate by mixing the nitric acid solution of the yellow tetragentic salt (or its mother-liquor) with ammonia, according to the equation:

Fernlund, by cooling the nitric acid solution of the tetragentic salt, obtained straw-yellow rhombohedral crystals, which he regards as $\text{Ag}^2\text{HIO}^3 + \text{H}^2\text{O}$; the same solution evaporated by heat yielded orange-coloured six-sided prisms to which Fernlund assigns the formula AgH^2IO^3 . The straw-yellow salt was converted by prolonged boiling with water into the black-brown anhydrous triargentie salt Ag^3IO^3 , which, according to Fernlund, is also produced when the aqueous solution of the tetrasodic salt is mixed with silver nitrate. According to Rammelsberg, however (*Zeitschr. f. Chem.* [2] v. 373), the product formed by treating the tetragentic salt with nitric acid is the anhydrous normal salt AgIO^4 , which is decomposed by heat in the manner above described.

Barium Salts.—The *dibarie salt* $\text{Ba}^2\text{I}^2\text{O}^6 + 7\text{H}^2\text{O}$ is produced by mixing the concentrated solutions of an alkaline periodate and a barium salt, the former being in excess, as a crystalline precipitate very sparingly soluble in water, easily soluble in nitric acid. It gives off 4 mol. water below 200°, the rest at 300°, and when more strongly heated in a closed vessel, leaves a yellowish residue of the salt $\text{Ba}^2\text{I}^2\text{O}^{12}$. Heated to redness in a covered platinum crucible, it leaves a fused residue consisting of iodide, oxide, $\frac{1}{2}$ -periodate ($\text{Ba}^2\text{I}^2\text{O}^{12}$), and carbonate of barium. A solution of periodic acid mixed with a quantity of baryta-water not sufficient to saturate it yields a precipitate of the hydrated *dibarie salt*, $\text{Ba}^2\text{I}^2\text{O}^6 + 5\text{H}^2\text{O}$. The normal salt, BaI^2O^6 , has not been obtained. This solution of the dibarie salt in nitric acid gives with ammonia a bulky amorphous precipitate of a basic salt, while periodic acid passes into solution. Similar precipitates are thrown down by alkaline periodates from mixtures of barium salts and ammonia, or by ammonia from acid mixtures of periodic acid and barium salts. From their somewhat variable composition, Rammelsberg infers that

dibasic periodate may be converted by ammonia, with separation of periodic acid, into the $\frac{2}{3}$ -periodate $\text{Ba}^2\text{I}^{\text{O}}_{10}$, or the $\frac{3}{2}$ -periodate $\text{Ba}^3\text{I}^{\text{O}}_{10}$; thus:

and

The yellowish pentabasic salt which remains on treating with water the residue obtained by igniting the dibasic salt in a platinum crucible, dissolves easily in nitric acid, and this solution likewise yields with ammonia a precipitate of the $\frac{2}{3}$ -periodate; thus:

Kämmerer, by mixing a hot aqueous solution of normal potassium periodate with a hot solution of barium nitrate, and adding potassium or sodium acetate after cooling, obtains an amorphous precipitate to which he assigns the composition $\text{Ba}^2\text{H}^{\text{I}}\text{O}^{\text{O}} \cdot \text{KNO}_3 \cdot \text{HNO}_3$. From a solution of this salt the barium is not precipitated by alkaline carbonates or sulphates; this reaction (with ammonium carbonate) affords a means of distinguishing periodic from iodic acid (*Zeitschr. f. Chem.* [2] v. 276).

Strontium Salts.—The normal salt, $\text{SrI}^{\text{O}}_9 + 6\text{H}^2\text{O}$, crystallises from acid solution over sulphuric acid in transparent or milk-white, six-sided, often tabular prisms acuminated with three faces, and probably belonging to the triclinic system. The *distronitic salt* $\text{Sr}^2\text{I}^{\text{O}}_9 + 4\text{H}^2\text{O}$ crystallises from a solution nearly neutralised with strontium carbonate, in crystalline crusts, mixed with the normal salt, which may be dissolved out by water. It gives off one-third of its water at 200° (Rammelsberg).

Calcium Salts.—The normal salt, CaI^{O}_9 , separates from a highly concentrated acid solution together with crystals of the acid. The *dicalcic salt*, $\text{Ca}^2\text{I}^{\text{O}}_9 + 9\text{H}^2\text{O}$, is obtained by imperfectly saturating periodic acid with calcium carbonate, and evaporating over sulphuric acid, in soluble crystals which when heated above 100° give off their water, with partial decomposition. From the aqueous solution ammonia throws down a gelatinous precipitate of the salt $\text{Ca}^3\text{I}^{\text{O}}_{10}$ (Rammelsberg).

Magnesium Salts.—A solution of magnesium carbonate in excess of periodic acid deposits first the *dimagnesian salt*, $\text{Mg}^2\text{I}^{\text{O}}_9$, then the *normal salt*, $\text{MgI}^{\text{O}}_9 + 10\text{H}^2\text{O}$, which dissolves in water with acid reaction. The dimagnesian salt is also produced by mixing the solutions of a magnesium salt and normal sodium periodate, and crystallises in small tabular rhombic prisms of 116° . When magnesium carbonate is digested with water and a slight excess of periodic acid, the *tetramagnesian salt*, $\text{Mg}^4\text{I}^{\text{O}}_{11}$, separates as a crystalline powder; the same salt is obtained as an amorphous precipitate on saturating the mother-liquor of the preceding salt with sodium carbonate. It contains between 6 and 9 mol. water, effloresces over sulphuric acid, and partially also on exposure to the air. *Potassio-magnesian periodates* are obtained on adding magnesium sulphate to a solution of the potassium salt, $\text{K}^2\text{I}^{\text{O}}_9 + 9\text{H}^2\text{O}$. The liquid then becomes acid, and a crystalline precipitate is formed, varying in composition according to the proportions and concentration of the solution, but apparently always consisting of the normal potassium salt and the tetramagnesian salt $\text{Mg}^4\text{I}^{\text{O}}_{11}$. The reaction takes place in the manner shown by the equations:

Rammelsberg observed the salts

When the magnesium sulphate is added in excess, the precipitate may also contain the salt $\text{Mg}^2\text{I}^{\text{O}}_9$. *Ammonio-magnesian periodate*, $(\text{NH}^4)\text{MgIO}^4 + 3\text{H}^2\text{O}$, is precipitated by ammonia from a solution of the salt $\text{Mg}^2\text{I}^{\text{O}}_9$ in nitric acid, as a finely crystalline precipitate which may be washed with cold water. The salt may be regarded either as $(\text{NH}^4)^2\text{IO}^6 \cdot \text{Mg}^2\text{I}^{\text{O}}_{11} + 12\text{H}^2\text{O}$, or as $(\text{NH}^4)^2\text{IO}^6 \cdot \text{Mg}^2\text{I}^{\text{O}}_9 + 6\text{H}^2\text{O}$.

Zinc Salts.—The salt $\text{Zn}^2\text{I}^{\text{O}}_9 + 6\text{H}^2\text{O}$ separates as a white powder on partially saturating a dilute solution of periodic acid with zinc oxide. The salt $\text{Zn}^3\text{I}^{\text{O}}_{10} + 14\text{H}^2\text{O}$ is thrown down on adding normal sodium periodate to a solution of zinc-sulphate, as a pulverulent precipitate, in small quantity in the cold, more abundantly when the liquid is heated. The filtrate mixed with ammonia, not to saturation, yields an amorphous precipitate having the composition $\text{Zn}^3\text{I}^{\text{O}}_{10} + 12\text{H}^2\text{O}$. *Zinco-potassic*

periodate, $2\text{KIO}^4 \cdot \text{Zn}^2\text{I}^2\text{O}^{11} + 4\text{H}^2\text{O}$, is precipitated by tetrapotassic periodate from a solution of zinc sulphate; the acid filtrate contains zinc as well as periodic acid, and gradually deposits crystals of normal potassium periodate (Rammelsberg).

Nickel Salts.—Recently precipitated nickel carbonate dissolves in periodic acid, with green colour, and formation of peroxide, iodate, and insoluble basic periodate of nickel. The acid green solution evaporated at a very gentle heat, or over oil of vitriol, yields light green crystals (rectangular four-sided prisms with oblique end-faces) of the salt $\text{NiI}^2\text{O}^{13}$ or $\text{NiI}^2\text{O}^8 \cdot 3\text{NiI}^2\text{O}^8$, with variable amount of water (49 to 63 mol.). It is insoluble in water, but blackens when heated with water, forming iodate and peroxide of nickel. The same compound is precipitated from the acid mother-liquor by incomplete saturation with ammonia (Rammelsberg).

Cobalt Salts.—Lautsch by treating dry tetrasodic periodate with excess of cobalt sulphate, or by evaporating a solution of the two salts to dryness, obtained a dark yellow-greenish powder, to which he assigns the composition $\text{CoI}^2\text{O}^{21} + 16\text{H}^2\text{O}$ or $7\text{CoO} \cdot 2\text{I}^2\text{O}^7 + 16\text{H}^2\text{O}$; he finds, however, that it gives off chlorine when dissolved in hydrochloric acid: hence it should contain a cobaltic compound. According to Rammelsberg, alkaline periodates produce in solutions of cobaltous salts a precipitate consisting of hydrated cobalt peroxide mixed with cobaltous iodate (part of the latter also remaining in solution); the same products are likewise formed when cobaltous carbonate is dissolved in periodic acid. Exactly similar results are obtained with manganous salts. Ferrous salts yield with alkaline periodates a brownish-yellow precipitate of ferrous iodate.

Ferric Periodate, $(\text{Fe}^3)^{21}\text{I}^2\text{O}^{13} + 21\text{H}^2\text{O}$ or $2\text{Fe}^2\text{O}^3 \cdot \text{I}^2\text{O}^7 + 21\text{H}^2\text{O}$, is formed on adding tetrapotassic periodate to solutions of ferric salts, as a light brownish-yellow precipitate, which dries up to dark brown lumps having a shining fracture.

Cadmium Salts.—The normal salt, CdI^2O^8 , is formed as a heavy white powder mixed with a small quantity of the following salt, on treating cadmium carbonate with a hot solution of periodic acid. If an insufficient quantity of the acid is used, the tetracadmic salt $\text{Cd}^4\text{I}^2\text{O}^{11} + 3\text{H}^2\text{O}$ is produced. The acid mother-liquor of these two salts yields by spontaneous evaporation, the salt $\text{Cd}^2\text{I}^2\text{O}^9 + 9\text{H}^2\text{O}$ in rectangular four-sided tables belonging to the rhombic system. It is insoluble in water, and is converted by boiling therewith into a yellowish powder. A fourth salt, $\text{CdI}^{10}\text{I}^2\text{O}^{21} + 15\text{H}^2\text{O}$, or perhaps $\text{Cd}^2\text{I}^2\text{O}^8 \cdot 2\text{Cd}^4\text{I}^2\text{O}^{11} + 15\text{H}^2\text{O}$, is obtained as an insoluble white precipitate, on pouring cadmium sulphate into normal sodium periodate.

Copper Salts.—The *pentacupric salt*, $\text{Cu}^5\text{I}^2\text{O}^{12} + 5\text{H}^2\text{O}$, separates as a green powder on adding cupric carbonate to aqueous periodic acid: it gives off half its water at 200° . When a solution of cupric nitrate is mixed with normal potassium periodate, a green precipitate is formed at first, and the blue acid filtrate afterwards deposits the tetracupric salt, $\text{Cu}^4\text{I}^2\text{O}^{11} + 7\text{H}^2\text{O}$, in dark green microscopic crystals. A solution of recently precipitated cupric hydrate in periodic acid first deposits the pentacupric salt, and then, by spontaneous evaporation, the dicupric salt $\text{Cu}^2\text{I}^2\text{O}^9 + 6\text{H}^2\text{O}$, in dark green crystalline aggregates. A *potassio-cupric salt* of uncertain composition is formed as a bright green precipitate on mixing the solutions of cupric nitrate and tetrapotassic periodate (Rammelsberg). Lautsch obtained the salt $\text{Cu}^4\text{H}^2\text{I}^2\text{O}^{12}$ or $4\text{CuO} \cdot \text{I}^2\text{O}^7 + \text{H}^2\text{O}$, as a green crystalline mass, by treating the dry sodium salt with aqueous cupric sulphate, or as a siskin-green powder, by mixing the solutions of cupric sulphate and tetrasodic periodate (whereby no precipitate is produced), evaporating to dryness, redissolving, again evaporating, and washing (Rammelsberg).

Lead Salt.—The lead periodate precipitated on mixing the solutions of normal sodium periodate and lead nitrate has the composition $\text{PbI}^2\text{O}^{10} + 2\text{H}^2\text{O}$ established by Langlois. When heated with a solution of periodic acid, it acquires a yellowish-red colour without giving up any of its lead, and is afterwards insoluble in nitric acid (Rammelsberg).

Mercury Salts.—A slightly acidulated solution of mercurous nitrate forms with normal sodium periodate a precipitate of *octomercurous periodate*, $\text{Hg}^8\text{I}^2\text{O}^{11}$ or $4\text{Hg}^2\text{O} \cdot \text{I}^2\text{O}^7$, having a fine yellow colour. It is anhydrous, soluble in nitric acid, and when heated is resolved without residue into yellow and red mercuric iodide, metallic mercury, and oxygen (Rammelsberg). A *decamercurous salt*, $\text{Hg}^{10}\text{I}^2\text{O}^{12}$ or $5\text{Hg}^2\text{O} \cdot \text{I}^2\text{O}^7$, is obtained by precipitating the solution of the tetrasodic salt with mercurous nitrate, or by digesting the same sodium salt in the solid state with the mercurous solution, as a light yellow precipitate, affording a characteristic reaction of periodic acid; it becomes somewhat darker at 100° , dissolves in nitric acid, and likewise in hydrochloric acid, with evolution of iodine chloride. Hydrogen sulphide throws down mercury from these solutions, without previous separation of iodine. Stannous chloride converts the

salt into green mercurous iodide (Lautsch). *Mercuric periodate*, $\text{Hg}^2\text{I}^2\text{O}^{12} = 5\text{Hg}^2\text{O} \cdot \text{I}^2\text{O}^7$, is prepared, similarly to the corresponding mercurous salt, with mercuric nitrate (not with the chloride). It is a red precipitate, easily soluble in hydrochloric acid, sparingly in nitric acid, and is precipitated from the latter solution both by dilution with water and by saturation with ammonia, but is redissolved by excess of ammonia (Lautsch; Rammelsberg).

IRIDIUM. W. v. Schneider (*Ann. Ch. Pharm. Suppl.* v. 261; *Jahresh.* 1867, p. 314) prepares pure iridium from the aqueous solution of impure potassium chloriridate by a process founded on the observation of Bunsen, that iridium is much less easily reduced from the aqueous solution of its tetrachloride by hydrogen than the other platinum metals. The portion of platinum-ore insoluble in nitromuriatic acid is freed from osmium by heating it, mixed with sodium chloride, to low redness in a stream of chlorine; the remaining mixture of chlorides is triturated with the smallest possible quantity of water, and then washed on a filter; the solution thus obtained is treated with chlorine; and after addition of a little hydrochloric acid, agitated to saturation with pulverised potassium chloride. The resulting precipitate, after being washed with water and with a saturated solution of potassium chloride, consists of the nearly pure potassio-chlorides of iridium, ruthenium, and platinum. It is dissolved in a large quantity of boiling water; the solution is placed in a vessel closed with a perforated caoutchouc stopper; and hydrogen gas is passed into it for several days, till the platinum and ruthenium are wholly precipitated in the metallic state, which may be known by testing the remaining olive-green liquid with potash, whereupon it will first become colourless, and after some time blue or turbid. The hydrogen in the apparatus must then be expelled by a stream of carbon-dioxide (otherwise explosions will happen on opening the vessel, resulting from the action of the precipitated metals on the mixture of hydrogen and oxygen); and the solution, which contains the greater part of the iridium as trichloride, is subjected to continued treatment with hydrogen. The iridium is then precipitated on the surface of the liquid in large brittle laminae having a metallic lustre.

Respecting Gibbs's methods of separating iridium from other platinum metals, founded on the reactions of the chlorides with potassium nitrite and with luteo-cobaltic chloride, see PLATINUM METALS.

Iridium Bromides (Birnbäum, *Ann. Ch. Pharm.* cxxxiii. 161).—These compounds are not obtained by boiling iridium with nitric and hydrobromic acids, or by passing bromine over a red-hot mixture of metallic iridium and sodium bromide. But when moist iridic hydrate is treated with hydrobromic acid, a blue solution is obtained, which becomes more stable when mixed with nitric acid, and leaves on evaporation a blue deliquescent crystalline mass, which, however, does not unite directly with other metallic bromides.

Potassium Bromiridate, $2\text{KBr} \cdot \text{IrBr}^4$, is obtained by mixing potassium bromide with iridium tetrachloride, or by treating ammonium chloriridate (or better the sodium salt) with potassium bromide. It forms black-blue octohedrons, and decomposes when its solution is evaporated. With alkalis it yields first the tribromide, then the hydrated sesquioxide; with silver nitrate it forms a precipitate of silver bromiridite, $6\text{AgBr} \cdot \text{Ir}^3\text{Br}^4$.

Ammonium Bromiridate, $2\text{NH} \cdot \text{Br} \cdot \text{IrBr}^4$, prepared from the chloriridate and sodium bromide, resembles the potassium salt. The sodium salt, $2\text{NaBr} \cdot \text{IrBr}^4$, is deliquescent and unstable.

The **tribromide**, $\text{Ir}^3\text{Br}^4 + 8\text{H}^2\text{O}$, is deposited in olive-green crystals on evaporating the aqueous solution of the tetrabromide (obtained by decomposing potassium bromiridate with silicofluoric acid). It forms very stable double salts, which are produced from those of the tetrabromide by heating, or more quickly by the action of sulphurous or sulphydric acid. The potassium salt $6\text{KBr} \cdot \text{Ir}^3\text{Br}^4 + 6\text{H}^2\text{O}$ crystallises in large, olive-green, four-sided needles, which, if an excess of sulphurous acid has been used in their preparation, are mixed with white crystals. The sodium salt $6\text{NaBr} \cdot \text{Ir}^3\text{Br}^4 + 24\text{H}^2\text{O}$ crystallises in rhombohedrons; the ammonium salt $6\text{NH} \cdot \text{Br} \cdot \text{Ir}^3\text{Br}^4 + \text{H}^2\text{O}$, in microscopic olive-green needles; on evaporating the aqueous solution of the tribromide, the compound $6\text{HBr} \cdot \text{Ir}^3\text{Br}^4 + 6\text{H}^2\text{O}$ separates in blue needles, brown-red by transmitted light.

The **sulphides** of iridium obtained by Birnbäum are described under SULPHUROUS ACID (v. 546).

IRON. Pure iron, of silver-white colour and strong lustre, may be obtained by heating nitride of iron moderately (below the melting point of lead) in a stream of hydrogen. Iron thus obtained has a sp. gr. of 6.03, and is soft enough to be cut with a knife. It oxidises in the air more easily than ordinary iron, especially at high temperatures and in contact with moisture (Stahlschmidt, *Jahresh.* 1865, p. 256).

Troost (*Bull. Soc. Chim.* [2] ix. 250) prepares pure iron by fusing pig iron in a lime crucible by the oxyhydrogen flame, assisted towards the end of the process by a stream of oxygen to oxidise the foreign constituents. On removing the slag from the surface, the iron remains pure, and in the form of a fused mass. According to Matthiessen & Szezeparowski (*Chem. News*, xviii. 114), iron cannot be obtained perfectly free from sulphur. The metal obtained by igniting ferric oxide or chloride purified as completely as possible, in a stream of hydrogen, or by electrolytic precipitation, or by igniting purified potassium ferrocyanide, always yielded distinct traces of hydrogen sulphide when dissolved in dilute hydrochloric acid.

On the absorption of gases by iron, and on its permeability by hydrogen at a red heat, see GASES (p. 634).

Iron is attacked by Calvert (*Chem. News*, xxiii. 98), it appears

On the absorption of gases by iron, and on its permeability by hydrogen at a red heat, see GASES (p. 634). Recently, by Calvert (*Chem. News*, xxiii, 98), it appears

Reactions.—1. From experiments by Calvert (*Chem. News*, xxiii. 98), it appears that the rusting of iron is due, not to free oxygen or aqueous vapour of the air, but to carbonic acid. Iron does not rust in perfectly pure water. Caustic alkalis and alkaline carbonates prevent the oxidation. When a plate of iron half immersed in a weak alkaline solution is exposed to the air, not only the immersed, but also the projecting part, remains bright and unaltered for months.

projecting part, remains bright and unaltered for months.

2. Malleable iron (turnings or wire) is attacked by dilute *nitric acid* of sp. gr. 1.03 to 1.06, either with elimination of hydrogen and formation of ferrous salt, or with elimination of nitrogen dioxide and formation of ferric salt, or without any evolution of gas. Sometimes hydrogen is evolved at the beginning of the action, and nitrogen dioxide afterwards, in which case the solution contains both ferrous and ferric salt. Ammonium nitrate may be formed in either of these reactions, but always in small quantity; nitrites do not appear to be formed. The passivity of iron and steel produced by nitric acid of given specific gravity depends upon a particular temperature. With acid of sp. gr. 1.38, it is produced after a short time at 31°; if the initial temperature was 32°, the passive state is not developed. A colourless acid of sp. gr. 1.42, produces passivity at 56°, but not at 56°; in red fuming nitric acid of sp. gr. 1.42, iron remains passive at 82°, but dissolves at 83°. With cast iron the results are not equally definite (Orlway, *Sill. Am. J.* [2] xl. 316).

3. Iron heated to 200° in a sealed tube with aqueous sulphurous acid forms a solution of ferrous sulphite and hyposulphite, together with brass-yellow crusts of iron bisulphide; the latter compound is also formed in distinct microscopic crystals when ferric oxide or pounded basalt is heated in like manner with sulphurous acid (Geitner, *Ann. Ch. Pharm.* cxxix, 350).

4. For the reaction of iron with hydrogen dioxide, see p. 719.

5. Solutions of ferrous salts heated to 130° – 140° in sealed tubes with sodium hyposulphite are completely decomposed, yielding ferrous sulphide, FeS , which does not oxidise in contact with the air is not perceptibly decomposed by strong hydrochloric or dilute sulphuric acid, but is quickly oxidised by nitric acid. Strongly ignited ferric oxide heated to redness with excess of sodium hyposulphite, yields a black sulphide of iron soluble in hydrochloric acid (Gibbs, *Jahresb.* 1864, p. 183).

6. According to Natanson (*ibid.* 1864, p. 714; 1865, p. 716), the smallest trace of iron in the form of ferric salt may be detected by agitating the solution, mixed with recently prepared potassium sulphocyanate, and scarcely coloured thereby, with ether. The ether then dissolves the ferric sulphocyanate and becomes rose-red, or, with somewhat larger quantities of ferric salt, blood-red. According to Erlenmeyer, the purple-red colour of the ethereal solution is completely destroyed by a large quantity of potassium sulphocyanate or by potassium tartrate; in great part also by sodium acetate. The reaction cannot be applied to the detection of potassium sulphocyanate with ferric chloride, as the ether in this case [*i.e.* with excess of ferric chloride] does not become coloured (Natanson).

Volumetric Estimation.—Oudemans (*Zeitschr. anal. Chem.* vi. 129) gives the following method, founded on the observation that sodium hyposulphite gradually added to a ferric solution containing free hydrochloric acid decomposes it, with formation of tetrathionic acid, and without evolution of sulphurous oxide or separation of sulphur, according to the equation,

$$2\text{FeCl}_3 + 2\text{Na}_2\text{S}_2\text{O}_4 + 2\text{H}^+\text{H}^+\text{O}^+ \rightarrow \text{Fe}_2(\text{SO}_4)_3 + 2\text{H}_2\text{O} + 2\text{H}^+\text{H}^+\text{O}^+$$

The acid solution, free from ferrous salts and heated to 40°, is mixed with a few drops of solution of cupric sulphate, then with potassium sulphocyanate till a dark red colour is produced, and the standard solution of sodium hyposulphite is added till the liquid appears transparent and colourless. The cupric salt acts as a contact substance, accelerating the reduction of the ferric oxide.

Mohr (*Zeitschr. anal. Chem.* ii. 243) has modified the method depending upon the use of potassium iodide, starch solution, and sodium hyposulphite described at

p. 385, vol. iii., so far as to heat the ferric solution with potassium iodide in a closed vessel, add the starch-paste only after cooling, and then the standard solution of hyposulphite. This solution is most readily titrated by means of potassium dichromate, 20 c. c. of a solution of this salt (containing 4.919 grms. in a litre) being heated in a closed flask with hydrochloric acid and potassium iodide, and the liberated iodine determined by the hyposulphite solution previously brought to an equal volume.

Winkler (*Jahresb.* 1865, p. 717) estimates iron in a solution of ferric chloride by reduction with cuprous chloride, according to the equation

the end of the reduction being indicated by the disappearance of the red produced in the solution by a few drops of potassium sulphocyanate. According to Hoch a. Clemm (*ibid.* 1866, p. 803), this method does yield accurate results.

On the analysis of cast iron, see Tosh (*Chem. News*, xvi. 67, 94, 168); Mène (*Compt. rend.* lxxiii. 449; *Zeitschr. f. Chem.* [2] v. 515). On the estimation of carbon in cast iron, see Elliot (*Chem. Soc. J.* [2] vii. 182); of sulphur, Eggertz (*Chem. News*, 1868, p. 207).

Compounds of Iron.

Iron belongs to the hexad group of metals, being bivalent in the ferrous, quadrivalent in the ferric salts, and sexvalent in the ferrates, its compounds being analogous to those of chromium:

Chlorides. *Ferrous chloride* is easily obtained well crystallised by heating sublimed ferric chloride in a stream of dry hydrogen (Wöhler, *Ann. Ch. Pharm. Suppl.* iv. 255).

A compound of ferrous chloride with ethylene, C_2H_4 . FeCl_2 , is obtained by heating an ethereal solution of ferric chloride in a sealed tube for some hours to 140° – 150° ; more readily with addition of a small quantity of phosphorus dissolved in carbon bisulphide, in which case the heat of the water-bath is sufficient. It forms brittle, nearly colourless crystals, without lustre, easily soluble in water, moderately hygroscopic; they contain 2 mol. water of crystallisation. If the ether is quite anhydrous, the crystals are not formed. The recently prepared aqueous solution of the crystals exhibits the reactions of ferrous salts, and oxidises as readily as ferrous chloride (Kachler, *Deut. chem. Ges. Ber.* ii. 510; *Zeitschr. f. Chem.* [2] vi. 58).

Ferric Chloride.—The crystallised hexahydrated chloride, $\text{Fe}^3\text{Cl}^3 \cdot 6\text{H}^2\text{O}$, melts, according to Ordway (*Sill. Am. J.* [2] xi. 329), at 31° ; the decahydrate, $\text{Fe}^3\text{Cl}^3 \cdot 12\text{H}^2\text{O}$, at 35.5° . Fresenius has shown (*Zeitschr. anal. Chem.* vi. 92) that ferric chloride is not volatilised from its solution mixed with hydrochloric acid, either by evaporation over the water-bath, or by tumultuous ebullition, or when the acid solution containing chlorides of alkali-metals is evaporated to dryness and heated for some time over the water-bath.

To prepare *basic ferric chloride* for medical purposes, Jeannel (*Compt. rend.* lxxi. 799) triturates 1,000 pts. of recently precipitated ferric hydrate free from sulphuric acid (containing 75 p. c. water), with 85 pts. hydrochloric acid of sp. gr. 1.2 and 500 pts. water, macerates for two days, and then filters. The above proportions correspond to the oxychloride $\text{Fe}^3\text{Cl}^3 \cdot 9\text{Fe}^2\text{O}^3$. The dark garnet-red solution evaporated on plates at 50° leaves black scales which may be heated without alteration to 160° , become insoluble at 170° , and decompose at 220° . They are easily soluble in water, weak spirit, and glycerin. The solutions have an astringent, somewhat acid taste, are permanent, but yield precipitates with small quantities of sulphuric acid, sulphates, citric acid, tartaric acid, and even with a few drops of strong hydrochloric or nitric acid. They coagulate albumin, act as styptics in a higher degree than ferric chloride, and do not, like the latter, excite pain when applied to wounds. On the pharmaceutical preparation of ferric chloride, see also Attfield (*Pharm. J. Trans.* [2] vi. 396).

Fluoride. Ferric fluoride forms double salts with the fluorides of the alkali-metals. Berzelius obtained the potassium salts $2\text{KF} \cdot \text{Fe}^3\text{F}^4$ and $4\text{KF} \cdot \text{Fe}^3\text{F}^4$ (iii. 390).

Nickles (*J. Pharm.* [4] vii. 15; *Jahresb.* 1868, p. 262) has obtained the ammonium salt $4\text{NH}_4\text{F} \cdot \text{Fe}_2\text{F}_6$, and a sodium salt, both by direct combination and by decomposing the alkaline fluoride with a ferric salt. All these double fluorides crystallise readily, are sparingly soluble in water, and their solutions are decomposed by boiling, depositing yellow flocks. These solutions are not reddened by potassium sulphocyanate till the alkali-metal has been precipitated by means of an alcoholic solution of silicium fluoride.

Nitride. N^2Fe^4 or $\begin{array}{c} \text{Fe}=\text{N}=\text{Fe} \\ | \\ \text{Fe}=\text{N}=\text{Fe} \end{array}$.—This compound, analogous in composition to

ammonium, is produced, according to Stahlschmidt (*Pogg. Ann.* cxxv. 37; *Jahresb.* 1865, p. 258), by the action of ammonia on metallic iron or ferric oxide. Sublimed ferrous chloride absorbs a considerable quantity of ammonia gas at ordinary temperatures, forming ferrammonium chloride, which when heated nearly to redness is converted into the nitride:

The nitride thus obtained forms a grey powder or thin laminae, sometimes also a compact very brittle silver-white mass, which may be rubbed to a very fine powder, burning with dazzling light when thrown into a flame. When moderately heated in hydrogen gas, it is reduced to pure iron, with formation of ammonia. Heated alone, or in a stream of nitrogen or ammonia, it gives off all its nitrogen, the last portions however with difficulty: hence the contradictory statements respecting its composition. Ignited in aqueous vapour it forms ammonia and ferroso-ferric oxide. It is slowly and imperfectly decomposed by boiling with water; dissolved by nitric acid with evolution of nitrogen dioxide, by dilute sulphuric or hydrochloric acid with evolution of hydrogen (but not of nitrogen, as stated by Despretz, iii. 391):

Heated with chlorine, bromine, and iodine, in presence of water, it is decomposed, with evolution of hydrogen (and probably also of nitrogen) and formation of ammonia and a ferric salt. Stahlschmidt is of opinion that this compound sometimes exists irregularly diffused in steel, and attributes to its occurrence the contradictory statements respecting the presence of nitrogen in steel.

Oxides. When borax is saturated in the outer blowpipe-flame with ferric oxide till the bead acquires a blackish-green colour and exhibits a dull crystalline surface on cooling, and the bead is then dissolved in hot nitric acid, the ferric oxide remains in three- or six-sided, sometimes rhombic plates, appearing yellowish red or black according to their thickness. Ferroso-ferric oxide may also be obtained in the crystalline form by similar means (Chatelier, *Jahresb.* 1867, p. 10). According to Elsner (*ibid.* 1866, p. 35), ferric oxide is somewhat volatile at the heat of a porcelain furnace. Sidot (*Compt. rend.* lxxvii. 175) has obtained an oxide exhibiting magnetic polarity by heating ferric oxide in an earthen tube placed in the magnetic meridian to a temperature not sufficient to fuse the oxide; also by placing iron-foil rolled up into a tube in a vertical position in a furnace, and heating it till it is completely oxidised.

When a solution of ferric chloride diluted till its colour is scarcely perceptible is heated to 27° and above, it again becomes strongly coloured, exhibiting the characteristic tint of basic ferric chloride. This change is not due to loss of hydrochloric acid, for it takes place even in closed vessels. The solution retains its colour on cooling, but its chemical properties are completely altered; with potassium ferrocyanide it yields only a pale blue precipitate instead of Prussian blue, and with sodium chloride when warmed a gelatinous precipitate of pure ferric hydrate, which if immediately washed dissolves in pure water, but loses its solubility if left for a day or two in contact with the saline solution. When the solution modified by a heat of about 70° is dialysed, hydrochloric acid free from iron passes through, and ferric oxide remains on the dialyser, soluble in water and in dilute hydrochloric acid, insoluble in saline solutions, and identical with Graham's colloidal ferric oxide (iii. 718). When the dilute solution of ferric chloride is heated to 100° , the water being replaced as it evaporates, the soluble hydrate gradually passes into the modification discovered by Péan de St. Gilles (iii. 395), which is insoluble in dilute mineral acids and in most saline solutions, but forms with water a solution clear by transmitted, turbid by reflected light. This modification was obtained by St. Gilles by prolonged heating of ferric acetate, and by Scheurer-Kestner in like manner from the nitrate. All these ferric salts of monobasic acids therefore exhibit the same reaction, splitting up at first into acid and soluble oxide, which remain separate if much water is present, while the soluble oxide is afterwards converted into the meta-oxide of St. Gilles. The salts of

bibasic acids, the sulphate for example, yield when heated only insoluble basic salts. Lastly, if the solution be heated to 250° – 300° , at which temperature neither the colloidal oxide nor the meta-oxide can exist, crystallised anhydrous ferric oxide is precipitated, as observed by Sénarmont. These observations explain the necessity of the precautions to be observed in the quantitative precipitation of iron with sodium acetate. The precipitate formed on heating is the colloidal oxide, which is insoluble in the saline solution, but dissolves for the most part when washed with cold water, and must therefore be washed with solution of ammonium chloride or acetate (Debray, *Zeitschr. f. Chem.* [2] v. 290).

According to F. Muck (*Zeitschr. f. Chem.* [2] iv. 41), the ferric hydrates formed from ferrous hydrate or carbonate by atmospheric oxidation differ in their properties (though not in their amount of water) from those which are precipitated from ferric salts. The latter when recently precipitated are bulky and gelatinous, dry up with considerable diminution of bulk to brittle lumps having a shining fracture, and when heated to redness are converted, with incandescence, into hard, black, vitreous ferric oxide. The ferric hydrates formed from ferrous hydrate, on the other hand, are pulverulent, and dry up, without much diminution of volume, to friable lumps, which have no shining fracture, do not glow when heated, and leave a brown-red lustreless earthy oxide. When ferrous sulphate is precipitated at the boiling heat by sodium carbonate, with addition of hypochlorite (1 mol. NaClO and 2 mol. Na_2CO_3 to 2 mol. FeSO_4), the precipitate dried at 100° has the composition $\text{Fe}^{\text{O}^3} \cdot \text{H}_2\text{O}$ or $\left(\text{Fe}^{\text{O}^2}\right)^{\frac{1}{2}} \text{O}^4$. If

the precipitation takes place in the cold (in which case the complete conversion into ferric oxide takes several hours) the amount of water in the precipitate dried at 100° corresponds to the formula $\text{Fe}^{\text{O}^3} \cdot 2\text{H}_2\text{O}$. At intermediate temperatures hydrates of intermediate composition are obtained. The precipitates thrown down at the boiling heat exhibit peculiar changes of colour when ignited; at a red heat they leave brown ferric oxide, which at a higher temperature becomes light brick-red, and at a white heat, light ochre-yellow and gradually violet-red. In spite of their soft and friable consistency, these oxides do not differ in their specific gravity (5.19 to 5.21) from iron-glance. An oxide of this character cannot be prepared from ferric salts in the wet way, but it may be obtained by adding basic ferric sulphate (precipitated from solutions of ferrous sulphate in contact with the air) to fused potassium hydrate, and lixiviating the fused mass. Such a preparation dried at 100° exhibited approximately the composition $3\text{Fe}^{\text{O}^3} \cdot 5\text{H}_2\text{O}$, and when ignited, was converted, without incandescence, into a light brick-red and ultimately yellow oxide. By continued fusion with potassium hydrate, the precipitate loses water, and then assumes a violet colour when ignited (Muck).

Respecting the reactions of ferroso-ferric hydrate with acids, see Lofort (*Zeitschr. f. Chem.* [2] vi. 607).

Phosphides. These compounds have been examined by Froese (*Pogg. Ann.* cxxxii. 225; *Jahresh.* 1867, p. 282), who finds that of all those which have been hitherto described, only three are really definite compounds, viz. $\text{Fe}^{\text{O}^3}\text{P}^1$, $\text{Fe}^{\text{O}^2}\text{P}^2$, and $\text{Fe}^{\text{O}^1}\text{P}^3$.

The phosphides of iron are non-magnetic and nearly, if not quite, infusible; a small addition of iron carbide, however, renders them more fusible than cast iron. They are not attacked by cold hydrochloric acid; are dissolved and completely oxidised by hot nitric or nitromuriatic acid, also by hot strong sulphuric acid, with evolution of sulphurous oxide, and formation of phosphoric acid and ferrous oxide; very slowly by boiling dilute hydrochloric acid, $\frac{2}{3}$ of the phosphorus passing into the solution as phosphoric acid, while $\frac{1}{3}$ are given off as phosphine: $16\text{P} + 15\text{H}^{\text{O}} = 10\text{PH}^3 + 3\text{P}^2\text{O}^5$; the undissolved portion has the composition of the original substance. They are also slowly attacked by dilute sulphuric acid at the boiling heat, with evolution of phosphine.

1. The compound $\text{Fe}^{\text{O}^3}\text{P}^1$, which Rose obtained by heating iron pyrites in phosphine, may also be prepared:

a. By heating finely divided iron, anhydrous ferrous chloride, or magnetic pyrites in phosphine:

also, mixed with ferric phosphate, by heating ferric oxide in phosphine as long as water continues to form. The pure phosphide, $\text{Fe}^{\text{O}^3}\text{P}^1$, forms a dark bluish-grey powder of sp. gr. 5.04. It is permanent in the air at ordinary temperatures, but burns when heated, giving off a fourth of its phosphorus and forming ferroso-ferric phosphate, $\text{Fe}^{\text{O}^2}\text{P}^2\text{O}^5$. Ignited in hydrogen or carbon monoxide, it gives off part of

its phosphorus, and is apparently converted into Fe^2P^2 ; it is not altered by heating in carbon dioxide.

2. The compound Fe^2P^2 is formed: α . Very slowly, by heating ferrous sulphide in a stream of phosphine:

β . By passing phosphorus vapour, carried forward by a stream of hydrogen, over red-hot ferric oxide, this oxide being first reduced by the hydrogen to metallic iron, which then unites with the phosphorus.— γ . By decomposing anhydrous ferric chloride with phosphine at a red heat:

The product obtained by this last process is a black lamino-crystalline mass; the first two methods yield the compound as a bluish-grey powder of sp. gr. 5.21, very much like the preceding phosphide, but of lighter colour. When heated in the air, it burns brightly, without evolution of phosphorus, and likewise forms ferroso-ferric phosphate. It is not altered by ignition in hydrogen, but gives off part of its phosphorus when heated to redness in carbon monoxide.

3. The compound Fe^2P^2 , which has been frequently obtained by different methods in an impure state and with various properties, may be prepared by mixing $3\frac{1}{2}$ pts. anhydrous ferric phosphate with 1 pt. of lampblack in a Hessian crucible, covering the mixture with a layer of common salt, and heating it to whiteness for several hours. On exhausting the contents of the crucible with dilute hydrochloric acid, the phosphide Fe^2P^2 remains as a light grey, crystalline, non-magnetic powder, of sp. gr. 5.74, and resembling the preceding phosphides in its other physical characters. When ignited in hydrogen, carbon monoxide, or carbon dioxide, it retains its pulverulent form and undergoes no alteration; ignited in contact with the air, it burns brightly and melts to a bluish mass of ferric phosphate. To obtain this compound pure, it is necessary that the iron salt (ferrous or ferric) be in excess, to prevent the formation of carbide of iron, and that the air be excluded. As the phosphide Fe^2P^2 is not altered by ignition in carbon monoxide, whereas the phosphides Fe^3P^2 and Fe^2P^2 give up phosphorus, it is probable that the two latter are converted by prolonged ignition in carbon monoxide into the first. Freese is also of opinion that this compound is the only phosphide present in pig-iron.

Silicides. 1. By fusing a mixture of 60 grms. sodium silicofluoride, 20 sodium, 22 cast steel, and 60 zinc, with common salt in a blast-furnace, a brittle crystalline-laminar, perceptibly magnetic regulus is obtained, containing 10.1 p. c. silicon, having a sp. gr. of 7.018 at 17° , and not attacked by strong hydrochloric acid.—2. Sodio-ferrous chloride (obtained by melting 40 grm. iron, 150 sal-ammoniac, and 80 sodium chloride, 5 grm. silicon, and 25 grm. sodium), fused for $2\frac{1}{2}$ hours with 25 grm. fluor-spar, yields a well-fused, white, brittle silicide of iron, Fe^2Si (20.29 p. c. silicon and 79.71 iron), having a sp. gr. of 6.611. On dissolving a considerable quantity of this compound in dilute hydrofluoric acid, there remained a crystalline residue, containing nearly equal parts of silicon and iron.—3. Sodio-ferrous chloride (prepared from 60 grm. iron), 60 grm. sodium silicofluoride, and 45 grm. sodium, heated together to the melting point of nickel, yielded about 9 grm. of a very brittle iron silicide imbedded in the slag; it contained 30.86 p. c. silicon and 69.14 iron, answering to the formula Fe^2Si^2 , and was probably therefore a mixture of FeSi and Fe^2Si . It was but slightly magnetic, non-crystalline, and had a sp. gr. of 6.239 at 19° (Hahn, *Ann. Ch. Pharm.* cxxix. 57).

Sulphides. When dry hydrogen sulphide is passed over precipitated ferroso-ferric oxide heated to whiteness in a tube, the oxide is first converted into magnetic pyrites, Fe^2S^2 , which at a very intense heat is partly reduced by monosulphide, FeS . The latter is found in the cooler part of the tube, in non-magnetic black to lemon-yellow six-sided prisms with double pyramids, belonging to the hexagonal system; the former in the part of the tube which has been strongly heated, as a greyish-yellow, metallicallly lustrous, strongly polar magnetic mass; it is decomposed by hydrochloric acid, with evolution of hydrogen sulphide and separation of sulphur (Sidot, *Compt. rend.* lvi. 1257).

On the double sulphides of iron with potassium, sodium, and silver, see SULPHUR SALTS.

IRON, METALLURGY OF. So far as relates to the chemistry of this branch of industry, little advance has been made since the publication of the article in the Dictionary. In smelting iron ores, the attempt to realise still greater economy of fuel by the use of the hot blast has been continued with some further success, and, with
Sup.

the same object, useful experiments have been made in augmenting the height and capacity of blast furnaces; but the improvement thus attained has not involved any new chemical facts, and it has consisted chiefly in carrying out to a further extent the principles previously understood to obtain.

In the conversion of pig metal into malleable iron or steel, the practice of the method introduced by Bessemer has been largely extended; but otherwise there has been, as in iron smelting, an equal absence of any direct advance of a chemical nature. Apart from the multitude of merely speculative or supposititious inventions, there has been indeed only one suggested improvement in the manufacture of malleable iron and steel which could be regarded as novel and intelligible on chemical principles, while even that claims mention here more as a matter of history than otherwise, since it has not been found available in practice. The method referred to was introduced by Mr. Heaton, who claimed that it was applicable to the production of malleable iron and steel of good quality from the inferior brands of pig iron obtained by smelting ores containing phosphorus. This claim gave a special interest to the Heaton method, in consequence of the necessity of using pig iron practically free from phosphorus in making malleable iron by Bessemer's method, for that necessity had been found a very serious limitation to the applicability of the Bessemer method.

Heaton's method of decarburisation consisted in bringing the melted pig iron in contact with nitrate of soda, mixed with sand and lime in such proportion as to mitigate the mechanical effect of the explosive decomposition of the nitrate on its coming in contact with the melted pig iron. The operation was performed in a cylindrical iron vessel lined with fire-clay, the mixture of nitrate, lime, and sand being retained at the bottom by a perforated plate of cast iron, while the melted metal was run into the converter.

According to the description of the late Professor Miller, the reaction between the nitrate and the melted iron commenced in a very short time after the charge was run in, a moderate quantity of brown nitrous fumes escaped, and then there was a copious discharge of dark vapour, carrying out with it a portion of the liquid slag. After the lapse of five or six minutes there was a violent deflagration, attended with loud roaring noise and a burst of brilliant yellow flame, lasting for about a minute and a half. When that had subsided, the contents of the converter were emptied out on the ground, and the pasty mass of decarburated metal was rendered compact and homogeneous by the usual operations of hammering and rolling.

The oxygen evolved from the nitrate of soda during its decomposition was undoubtedly the agent of decarburisation, and probably the sodium of the nitrate operated at the same time in such a way as to separate sulphur and phosphorus from the iron. The exact nature of the reaction taking place has never been rendered evident, and though the experimental trials of the method left some uncertainty as to the extent to which phosphorus was separable in this way from pig iron, there was reason to believe that the treatment of pig iron in this way would be in any case too costly, by reason of the amount of nitrate required. Another, and at least equally serious objection to this method, as a means of making steel, arose from the condition in which the decarburised metal was left after the operation; for it may now be regarded as an axiom established by experience, that any method of producing steel, to be practically admissible, must ensure the perfect liquefaction of the metal during the decarburisation, so as to give the highest degree of homogeneity, and must also yield the malleable metal in a liquid state, so as to afford the possibility of dealing with large masses of the melted metal, independent of the consumption of fuel hitherto needed for remelting.

It is in regard to this particular point that the chief recent advance has been made in the manufacture of malleable iron and steel. This has been done indirectly by means of the regenerative furnace introduced by Mr. C. W. Siemens, the principle of which is the gradual accumulation of the heat that would be wasted under ordinary conditions by passing off in the gaseous product of combustion. By this accumulation of heat within the furnace, a very much higher temperature may be attained than is possible with ordinary furnaces; it may also be maintained more easily and with a smaller consumption of fuel.

The fuel employed in the regenerative furnace introduced by Mr. Siemens is combustible gas produced by burning coal with a limited supply of air insufficient for perfect combustion. Any description of carbonaceous material may be worked in a suitable gas-producer, so as to furnish gas sufficiently good for the supply even of those furnaces in which the highest degree of heat is required. Coal is the fuel chiefly used for these gas furnaces in England; small coal has been employed in some cases, as in gasworks, where it is to be had at a cheap rate; wood is used in France,

Bohemia, and Spain; sawdust in Sweden, furnishing gas for welding and other high-heat furnaces; lignite in various parts of Germany and Austria; peat in Italy and elsewhere. The gas-producer used for non-caking coal-slack consists of a rectangular fire-brick chamber, one side of which, as shown at *b* in the section, fig. 29, is inclined at an angle of from 45° to 60° , and provided with a fire-grate, *c*, at the lower part. The fuel is filled in at the top of this incline at *a*, so as to form a thick bed upon the grate. Air being admitted at the grate, the fuel is burnt immediately in contact

FIG. 29.

with it to carbonic acid, but the gaseous product of combustion passes slowly upwards through the overlying red-hot fuel, while the carbonic acid it contains takes up an additional quantity of carbon, and is converted into carbonic oxide, while at the same time the gas becomes mixed with hydrocarbon gases and vapours distilled off from the raw fuel during its gradual descent along the inclined plane *b* towards the grate. The combustible gas thus produced is led off by a flue, *e*, into the furnace where it is to be burnt. Any ashes or clinkers that accumulate on the grate are removed at intervals of one or two days.

The composition of the gas varies with the nature of the fuel used and the arrangement of the gas-producer. At the Plate Glass Works of St. Gobain the gas obtained from a mixture of caking coal with one-third its weight of non-caking coal consisted of

	Volume	
Carbonic oxide	23.7	34.6
Hydrogen	8	
Carburated hydrogen	2.2	65.4
Carbonic acid	4.1	
Nitrogen	61.5	99.9
Oxygen	0.4	
	99.9	100

The oxygen was no doubt due to some leakage of air into the flue, and allowing for that, the percentage composition of the gas would be as stated in the second column of figures, the combustible constituents amounting to about 35 per cent. by volume. The presence of so large an amount of inert gas as 65 per cent. renders it difficult to maintain a high heat when gas of this description is burned in the ordinary way, but when the gas is burnt in a regenerative furnace that difficulty is overcome.

The principal feature of the regenerative furnace consists of four detached chambers situated beneath the furnace, and filled with fire-bricks stacked loosely together, so as to expose as much surface as possible. The chambers are made to communicate in pairs by means of flues, and these are fitted with valves in such a way that the hot waste gases from the flame may be made to pass from the furnace down through either pair of chambers at will. In this way the gaseous product of combustion, passing over surfaces successively cooler and cooler, gives up its heat to the layers of brick in the chambers, and at length escapes to the chimney nearly cold. The current of hot gas through one pair of chambers is kept up until the brickwork is uniformly heated to a considerable depth from the top, up to a temperature nearly equal to that of the gas entering them. Then by means of the valves the direction of the draught is changed, so that the hot gas passes down through the other pair of chambers, while

at the same time the combustible gas supplied to the furnace, as well as the air required for burning it, are made to pass upwards through the heated pair of chambers, where, by contact with the brickwork, they become heated as they ascend. At some distance from the top the combustible gas and air thus attain a temperature nearly equal to the initial heat of the waste gases, and when they afterwards burn, on coming into contact in the furnace, the temperature produced by combustion is of course greater than if the gas and air had been supplied to the furnace at the ordinary temperature. By the time the temperature of the combustible gas and air begins to decrease the other pair of chambers will have been sufficiently heated, and the draught is to be again reversed, so as to make the combustible gas and air pass through the heated chambers, while the gaseous product of combustion passes through the cooled chambers.

By thus reversing the draught at regular intervals, nearly all the heat is retained in the furnace that would be otherwise carried off by the gaseous product of combustion. If the heat of the furnace be not abstracted continually by charging into it cold materials, the temperature will increase after each reversal of the draught, and by the gradual accumulation of heat in this way it is possible to obtain very high temperatures. But it is probable there must soon be a limit reached beyond which increase of temperature is impossible, for at a high temperature water vapour and probably carbonic acid are decomposed, and by that change a considerable quantity of heat is rendered latent.

With a regenerative furnace of this kind Mr. Siemens has succeeded in producing malleable iron and steel directly from the ore in a single operation. The furnace used for this purpose is shown in section by fig. 30, where FF is the combustion

Fig. 30.

chamber, and RRRR the regenerators; AA are hoppers formed of cast-iron cylinders supporting clay cylinders attached to them at their lower ends and reaching down into the furnace. Round each hopper is a fire space, ss, into which flame ascends from the furnace sufficiently to keep the hopper and its contents red hot. Each hopper has also a wrought-iron pipe, G, dipping down into it and connected with a main above, so that a current of ordinary combustible gas from the gas-producer may be forced in amongst the heated ore.

These hoppers are filled with iron ore, which is charged into them from above, after some charcoal has at first been introduced to form a basis for the ore in starting, and about half a ton of pig iron is placed upon the bed or hearth of the furnace through port-holes at the back or front. By the time the pig iron has melted, the ore in the lower part of the hoppers will have been reduced by the action of the gas, and the

metallic sponge, sinking down into the bath of melted pig iron, is readily dissolved by it, thus making room for the upper portions of ore to sink down, become reduced and, in due course, dissolved in the bath of melted iron, fresh ore being continually supplied from above." This is continued until such time as the amount of carbon in the melted metal has been so far reduced as to correspond with the kind of steel required, and then the charge is run off into an ingot mould.

This kind of furnace has also been used for manufacturing steel from scrap iron and old malleable iron rails, the only difference in this case being that, in place of the vertical hoppers above described, the furnaces have slanting hoppers, through which the bars of iron are introduced, so that their ends rest in the bath of liquid metal, the bars sliding down as the metal is dissolved.

It is probable that in this operation the atmosphere of the furnace may itself contribute in part to the production of steel by direct carburization of the malleable iron, in consequence of its being free from the surplus oxygen present in an ordinary reverberatory puddling furnace, and being relatively much more highly carburized. But, however this may be, there can be no doubt as to the practical advantage of the non-oxidising nature of the furnace atmosphere. In consequence of this, and of the small consumption of fuel, the charge of metal may be kept for some length of time in a melted state without suffering injury. The progress of the operation may be ascertained by removing from time to time a sample of the metal, and thus the character of the product may be regulated as required.

This method of producing steel, or that kind of steely iron which is now so much in demand for rails, has also a further advantage beyond effecting economy of fuel and admitting of old material being made serviceable again; for, while the ores from which rails are made generally contain too much phosphorus to admit of steel being made from them directly, the malleable iron obtained by puddling pig iron smelted from those ores is comparatively poor in phosphorus, the puddling operation being up to the present time the most effectual means of separating phosphorus and sulphur from iron.

B. H. P.

ISATANE. $C^{12}H^{24}N^4O^4$.—This compound, which Laurent obtained by boiling disulphisatyde with acid ammonium sulphite (iii. 404), is likewise produced by the action of sodium-amalgam on isatin, in a solution kept acid by continual addition of sulphuric acid. It may be extracted by ether from the neutralised solution, and crystallises from ether or hot absolute alcohol in small white cubes insoluble in water. The alcoholic solution forms with ammoniacal silver nitrate a white precipitate of silver isatane, $C^{12}H^{22}Ag^2N^4O^4$. Heated with alcoholic potash to 130° , it forms potassium dioxindol and indiretin:

(Knop, *J. pr. Chem.* xcvi. 65).

ISATIC ACID. Syn. with TRIOXINDOL. (See INDOL, p. 734.)

The following salts of bromisatic acid have been examined by Gericke (*J. pr. Chem.* xcv. 176, 257):

Potassium salt,	$C^8H^5BrNO^3K$, easily soluble, cauliflower-like crystals.
Sodium salt,	$C^8H^5BrNO^3Na$, warty crystals.
Silver salt,	$C^8H^5BrNO^3Ag$, light yellow needles.
Barium salt,	$(C^8H^5BrNO^3)^2Ba$, sparingly soluble yellow crystals.
Copper salt,	$(C^8H^5BrNO^3)^2Cu + 2H^2O$, red granular precipitate.
Lead salt,	$(C^8H^5BrNO^3)^2Pb + 2H^2O$, scarlet crystalline precipitate.
Zinc salt,	$(C^8H^5BrNO^3)^2Zn + 2H^2O$, " " "

The potassium salt also forms yellow or brown precipitates with most other metallic salts.

ISATIN. $C^8H^5NO^3$.—On the preparation of isatin, see Gericke and Knop (*Jahresb.* 1865, p. 480). On the constitutional formula, see INDOL (p. 734).

Isatin suspended in water is converted by sodium-amalgam into dioxindol or hydrindic acid (p. 734). With tin and hydrochloric acid it forms indiretin, $C^{16}H^{16}N^2O^4$ (p. 728), together with another body which separates as a violet-red powder on evaporating the liquid filtered from the tin sulphide. This body heated to 180° is converted into a sublimate of yellow shining spangles, insoluble in alcohol, ether, and benzol, and not attacked even by concentrated acids and alkalis (Knop).

Isatin heated to 100° with hydriodic acid of sp. gr. 1.4 is converted, with separation of iodine, into isatyde, $C^8H^{12}N^2O^4$, and then at 140° into a dark green insoluble mass, which when freed from iodine by washing with sulphurous acid and with water, consists of three bodies. On treating this mass with boiling alcohol, a grey, nearly

black residue, isatochlorin, is left, whilst a white and a red body pass into solution. On mixing the alcoholic solution with water, and treating the resulting precipitate, after drying, with ether, the white substance isatone remains undissolved, while the red substance isatopurpurin dissolves.

Isatochlorin, $C^{12}H^{11}N^1O^3$, is insoluble in alcohol, ether, and acetic acid, burns without melting on platinum foil, and dissolves when heated with tin and caustic soda, to a yellow liquid, from which hydrochloric acid throws down white flocks turning green on exposure to the air.

Isatone, $C^{12}H^{11}N^1O^3$, recrystallised from warm alcohol, forms yellowish-white slender needles, which melt when heated, and then carbonise without subliming.

Isatopurpurin, $C^{12}H^{11}N^1O^3$, obtained by evaporating the ethereal solution above mentioned, freed from a yellow substance by treatment with hot soda-ley, and recrystallised from glacial acetic acid, forms slender needles, dark red in the moist state, violet-red when dry. It is distinguished from indin (iii. 264) by its larger amount of carbon, and by its greater solubility in acetic acid and carbon bisulphide. Treated with tin and soda-ley, it dissolves, and the solution yields with hydrochloric acid a white precipitate which turns red in contact with the air (Schützenberger, *Bull. Soc. Chim.* [2] iv. 170).

An alcoholic solution of bromisatin heated with ammonia and evaporated, deposits bromimasatin, $C^6H^5Br^2N^2O^3$, in brownish-yellow crystalline masses or granules. On boiling bromisatin with strong alcoholic ammonia, and leaving the dark brown-red solution to evaporate, bromimesatin, $C^6H^5Br^2N^2O$, is deposited as a yellow-brown crystalline substance. Bromamasatin, $C^{12}H^{10}Br^2N^2O^2$ (?), is produced by evaporating an aqueous solution of ammonium bromisatate, and remains on treating the pasty residue with water, as an orange-yellow substance, slightly soluble in water, insoluble in alcohol and ether, but dissolving with violet colour in acids. Bromisamic acid, $C^6H^5Br^2N^2O^4$, separates from the potash-solution of bromamasatin, on neutralisation with dilute hydrochloric acid, as a powder of a fine red colour, nearly insoluble in water, but easily soluble in alcohol and ether. Its potassium salt, $C^6H^5Br^2N^2O^4K$, and its barium salt, $(C^6H^5Br^2N^2O^4)^2Ba$, crystallise in sparingly soluble yellow needles; the solution of the potassium salt gives yellow, brown, or bluish-red precipitates with most metallic salts. A hot alcoholic solution of bromisatin treated with hydrogen sulphide deposits a yellowish-white powder consisting of trisulphobromisatyde, $C^6H^5BrNO_3S_3$ (?), and disulphobromisatyde, C^6H^5BrNOS (Gericke, *J. pr. Chem.* xcv. 176, 257; *Jahresb.* 1865, p. 580).

Compounds of Isatin with Sulphites (H. Schiff, *Ann. Ch. Pharm.* cxliv. 45; *Zeitschr. f. Chem.* [2] iv. 13).—Laurent showed that isatin unites at the boiling heat with the acid sulphites of ammonium and potassium, forming compounds which he regarded as salts of a peculiar acid called *isato-sulphurous acid* (iii. 410). According to Schiff, these compounds are easily formed at ordinary temperatures, and are analogous in composition to the compounds of the aldehydes with alkaline bisulphites, so that the assumption of a peculiar isatosulphurous acid is unnecessary. Isatin, like the aldehydes, also combines directly with the acid sulphites of primary monamines.

Aniline salt, $C^6H^5NO^2.C^6H^5N.SH^2O^3$. On mixing the solutions of isatin in aqueous aniline and in aqueous sulphurous acid, the colour of the mixture immediately changes from orange-red to light straw-yellow, the liquid previously saturated with isatin becomes capable of taking up fresh quantities of it, and the solution yields on evaporation crystals of the compound of isatin with acid sulphite of aniline. This compound when separated from aqueous solution is always yellowish; from solution in ether it is obtained in white needles which shrink together considerably when pressed and dried. The corresponding *amylamine-compound* crystallised from ether has the composition $C^6H^5NO^2.C^5H^{11}N.SH^2O^3$, and is likewise easily soluble in water and in alcohol. Similar compounds are obtained with the sulphites of *ethylamine* and *toluidine*.

The preceding compounds are decomposed by acids, with separation of isatin; by alkalis with formation of isatates; hence in an acid or ammoniacal atmosphere they gradually assume a yellowish colour. The aniline-compound heated by itself first gives off sulphurous anhydride, then water, leaving a resinous mass which solidifies on cooling, and when several times recrystallised from ether-alcohol yields brownish crystals of phenylimesatin, $C^{11}H^{10}N^2O$:

This latter compound, which contains the elements of isatin and aniline minus H^2O , was obtained by Engelhardt by the action of aniline on isatin in boiling alcoholic solution (iv. 485).

In like manner, amylimesatin, $C^{11}H^{10}N^2O = C^6H^5NO^2 + C^5H^{11}N - H^2O$, and

ethyl-phenylimesatin, $C^8H^{12}N^2O = C^8H^8NO^2 + 2C^8H^8(C^2H^4)N - H^2O$, are produced by heating isatin with amylamine or ethylaniline. Both are slightly soluble in ether, easily in alcohol, crystallise with difficulty in yellow laminae, and are decomposed by dilute acids or by prolonged treatment with water, with reproduction of isatin and the bases.

ISATOCHLORIN.**ISATONE.****ISATOPURPURIN.**

See ISATIN (p. 758).

ISATROPIC ACID. See ATROPIC ACID (p. 250).**ISO-ALLOXANIC ACID.** See ALLOXAN (p. 90).**ISO-AMYLAMINE.** See AMYLAMINE (p. 116).

ISODIOXYSTEARIC ACID, $C^{18}H^{36}O^4$, is produced by prolonged boiling of a solution of oxyleic acid in dilute potash-ley; in small quantity also, together with the latter, by trituration oleic dibromide, $C^{18}H^{32}Br^2O^2$, with moist silver oxide. It crystallises from alcohol in white laminae consisting of well-defined rhombic tables, melts at 126° , solidifies to a hard, alabaster-like, non-crystalline mass, and carbonises at about 260° . Its salts are mostly crystallisable. The *calcium salt* $(C^{18}H^{34}O^4)^2Ca + H^2O$ crystallises from dilute alcoholic solution in laminae resembling the acid; the *barium salt* $(C^{18}H^{34}O^4)^2Ba$ is a granular precipitate, insoluble in water and in alcohol; the flocculent *silver salt* $C^{18}H^{34}O^4Ag$ is likewise insoluble in alcohol (Overbeck, *Ann. Ch. Pharm.* exl. 39).

ISODULCITE. $C^8H^{10}O^6$.—A crystalline sugar produced by the action of dilute acids on quercitun (v. 1091).

ISODULCITIC ACID. $C^8H^{10}O^6$ (Malin, *Ann. Ch. Pharm.* exlv. 197).—This acid, first observed by Hlasiwetz u. Pfaunder, is produced by the oxidation of isodulcite. It is prepared by boiling isodulcite for an hour with nitric acid of sp. gr. 1.33, evaporating the excess of that acid in the water-bath, slightly supersaturating the diluted solution with milk of lime, and precipitating with lead acetate. By decomposing the well-washed lead salt with hydrogen sulphide, and evaporating the filtrate, isodulcitic acid is obtained as a faintly coloured syrup, which on standing yields granular vitreous crystals, nearly insoluble in alcohol, but easily soluble in water. The acid has a pure and agreeably sour taste, does not reduce alkaline cupric solutions, melts with brown colour at 100° . When dried over sulphuric acid it has the composition above given. The *barium salt* $C^8H^8BaO^6$, and the *calcium salt* $C^8H^8CaO^6$ (dried at 120°), are white, scarcely crystalline precipitates; the *cadmium salt* $C^8H^8CdO^6$ forms indistinct crystalline deposits and crusts; the white precipitate formed by lead acetate has nearly the composition $C^8H^8Pb^2O^6$; the *ammonium salt* forms a hygroscopic crystalline mass; the *silver salt* a white precipitate moderately soluble in water.

ISOFUMARIC ACID. See ISOMALIC ACID.**ISOHYDROMELLITIC ACID.** See MELLITIC ACID.

ISOMALIC ACID. $C^8H^8O^6$ (iii. 796).—Further observations on this acid have been published by Kämmerer (*Ann. Ch. Pharm.* cxxxix. 257; *Jahresh.* 1863, p. 378). It crystallises, according to measurements by Carius, in well-defined anguloidal monoclinic combinations, $\infty P. (\infty Pn). + P. - P.$, having the angle $\infty P : \infty P$ (clinod.) = 104° ; $(\infty Pn) : (\infty Pn)$ (orthod.) = 160° ; $+ P : + P - 155^\circ 10'$; $- P : - P = 154^\circ 15'$. It dissolves easily in water and in alcohol; the aqueous solution is optically inactive. It moist air the crystals become turbid without deliquescing; they melt like diglycolic acid, exactly at 49° , but the acid cannot be recrystallised after fusion. *Isfumaryl chloride*, $C^8H^2O^2Cl^2$, produced by the action of phosphorus pentachloride on potassium isomalate, is partly decomposed by distillation, and may be separated by ether from the mass left after the removal of the phosphorus oxychloride. It is a dark brown liquid, which is converted by water into *isofumaric acid*, $C^8H^8O^6$, formerly called isomaleic acid (iii. 788).

Isomalic acid heated to 160° gives off water, and yields a yellowish oily distillate which after a while reacts on the water in the receiver, in such a manner as to form pyro-isomalic acid, $C^8H^8O^6$. This acid forms large colourless crystals, which appear under the microscope as long, four-sided radially united rhombic prisms, frequently having their oblique longitudinal edges replaced by faces. By prolonged exposure to the air they deliquesce, and cannot be recovered by evaporation, inasmuch as the acid volatilises completely with the aqueous vapour. Its *calcium salt* is crystalline and almost insoluble; the *barium salt* slightly soluble and amorphous;

the *silver salt* is pasty and reducible by heat; the *lead salt* $C^4H^4PbO^3$ is a bulky precipitate, becoming crystallo-granular when heated with water.

ITACONIC ACID. $C^4H^4O^4$ or $CO^2H-CH^2-C-CH^2-CO^2H$ (see ACIDS, ORGANIC, p. 48).—Wilm (*Ann. Ch. Pharm.* cxli. 28) prepares this acid by subjecting citric acid, previously dehydrated over the water-bath, to dry distillation, till the distillate exhibits a light brown colour, and heating this distillate, which is a concentrated solution of citraconic acid, to $120^\circ-130^\circ$ in sealed tubes, whereby it is quickly converted into itaconic acid. The contents of the tube solidify on cooling to a crystalline mass of itaconic acid, which separates from concentrated aqueous solution in rhombic octohedrons, aggregated into a hard crust.

Itaconic acid heated with aqueous hydrobromic, hydrochloric, and hydriodic acids, unites directly therewith, forming itamonobromopyrotartaric acid, $C^4H^4BrO^4$, and the corresponding acids $C^4H^4ClO^4$ and $C^4H^4IO^4$. With excess of hydriodic acid iodine is separated, and pyrotartaric acid, $C^4H^4O^4$, is produced. Itaconic acid treated with chlorine is converted into itadichloropyrotartaric acid, $C^4H^4Cl^2O^4$ (Swarts, *Bull. Soc. Chim.* [2] iv. 374; *Jahresb.* 1865, p. 392; 1866, p. 404). See PYROTARTARIC ACID.

Paraconic Acid. $C^4H^4O^4$.—An acid isomeric with itaconic acid, produced by abstraction of HCl from itamonochloropyrotartaric acid. It is prepared by heating this chlorinated acid with water to 140° for several hours in a sealed tube—or better by boiling it for 48 hours in an open vessel—neutralising with calcium carbonate, precipitating the calcium salt of itamalic acid, formed at the same time, with alcohol, mixing the filtrate with ether, and decomposing the calcium paraconate thereby separated, with oxalic acid. A better mode of preparation is to boil the solution of itachloropyrotartaric acid with silver carbonate. The filtered liquid on cooling deposits hard shining crystals of silver paraconate, from which the acid may be separated by hydrogen sulphide.

Paraconic acid forms a crystalline mass resembling itamalic acid. It is very soluble in water and in alcohol, sparingly in ether; melts at about 70° ; is converted by dry distillation into citraconic anhydride, $C^4H^4O^3$, and by hydrobromic acid into itamonobromopyrotartaric acid.

Paraconic acid is monobasic. The metallic paraconates have a great tendency to change into itamulates, the latter being formed indeed whenever paraconic acid is neutralised with a base. The paraconates are prepared by decomposing silver paraconate (obtained as above) with a metallic chloride, but even then the product is sometimes not a paraconate, but an itamulate. The most stable paraconates are the calcium and silver salts. The *calcium salt* $(C^4H^4O^4)_2Ca + 3H^2O$ is easily soluble, and crystallises in slender shining needles, which give up 1 mol. water on exposure to dry air, the other two at 120° . The *silver salt* $C^4H^4O^4Ag$ crystallises from hot water in stellate groups of needles, and when boiled with silver oxide is converted into itamulate. The *sodium salt* $C^4H^4O^4Na$, crystallises by evaporation in a vacuum in confused deliquescent needles; its solution becomes acid when heated, and then after neutralisation yields the gelatinous sodium salt of itamalic acid (Swarts, *Jahresb.* 1867, p. 474).

ITA-IODOPYROTARTARIC ACIDS. See PYROTARTARIC ACID.

ITAMALIC ACID. $C^3H^3O^3$ (Swarts, *Bull. Acad. Belg.* [2] xxiv. 25; *Bull. Soc. Chim.* [2] ix. 317; *Laboratory*, p. 369).—This acid, homologous with malic acid, is produced by heating itamonochloropyrotartaric acid with bases, the change consisting in the replacement of the chlorine by hydroxyl:

When, however, water alone is used, paraconic acid is formed at the same time, which is difficult to separate. It is better, therefore, to boil the chlorinated acid in dilute solution with an alkaline carbonate till it is neutralised, then evaporate, saturate with hydrochloric acid, expel the excess of the latter by heating over the water-bath; extract the itamalic acid by means of ether free from alcohol; distil off the greater part of the ether; and crystallise the itamalic acid over sulphuric acid. A still better method is to heat a solution of the chlorinated acid with calcium carbonate as long as carbon dioxide continues to escape, then evaporate to a syrup, and add a large quantity of alcohol, which dissolves the calcium chloride, and throws down a gummy mass consisting of a soluble modification of itamalatate. On decanting the alcoholic liquid, and heating this mass with a fresh portion of alcohol, it is transformed into a pulverulent insoluble precipitate, which is easily washed, and may then be suspended in water, and decomposed with a quantity of oxalic acid exactly sufficient to remove the calcium. The filtered solution may then be evaporated and left to crystallise over sulphuric acid.

Itamalic acid crystallises from a syrupy solution in long white interlaced needles. It is extremely soluble in water, and rapidly absorbs moisture from the air; dissolves also in alcohol and in ether; has a pleasant sour taste, but no smell. It melts at 60° – 65° , and volatilises with vapour of water even at 100° . It is resolved by dry distillation into water and itaconic acid, $C^3H^3O^4$, which is partly converted by further dehydration into citraconic anhydride, $C^3H^2O^4$, just as malic acid, $C^3H^4O^5$, is resolved into water and fumaric acid, $C^3H^2O^4$, and converted by further dehydration into maleic anhydride, $C^3H^2O^3$.

The relation of itamalic acid to itaconic and itachloropyrotartaric acid is represented by the following formulæ:

Itamalic acid is therefore triatomic and bibasic, and may be represented by the typical formula $(C^3H^3O^3)^{\frac{1}{2}} O^2$. When heated in a sealed tube with hydrobromic acid, it gives up its alcoholic hydroxyl in exchange for bromine, and is converted into itamonobromo-pyrotartaric acid, $(C^3H^3O^3)^{\frac{1}{2}} O^2$.

Itamalic acid forms both acid and neutral salts. The latter may be formed by double decomposition, when insoluble, or by decomposing itachloro- or itabromo-pyrotartaric acid with metallic hydrates or carbonates. They have a remarkable tendency to assume at first a pitchy or gummy state, but may be rendered pulverulent and crystalline by prolonged boiling with water. A neutralised solution of itamalic acid forms a brownish-red gelatinous precipitate with ferric salts; greenish-blue with cupric salts after some time or on boiling; white with lead nitrate (with the acetate only on addition of ammonia); and with silver nitrate a white gelatinous precipitate, soluble in boiling water, insoluble in a solution of silver nitrate, and deposited after prolonged boiling in the form of a crystalline powder. The acid itamalates may be obtained by the ordinary methods, or by heating the aqueous solution of the paraconates:

Sodium Itamalatate, $C^3H^3Na^2O^4$, is obtained by boiling itachloropyrotartaric acid with sodium carbonate, and mixing the neutral solution with alcohol, as a syrupy liquid,

which by prolonged boiling with water is converted into a crystalline mass. The acid ammonium salt $\text{C}^3\text{H}'(\text{NH}^4)\text{O}^2 \cdot \text{C}^3\text{H}^2\text{O}^3$ remains on evaporating its solution over sulphuric acid, as a fibrous mass, separating from hot alcohol in small hexagonal tables like barium chloride. The calcium salt $\text{C}^3\text{H}^2\text{CaO}^3 + \text{H}^2\text{O}$, prepared as above described, forms a chalky powder more soluble in cold than in hot water, and converted by long contact with cold water into the gummy soluble modification. Nitric acid converts it, not into an acid salt, but into the trihydrated salt $\text{C}^3\text{H}^2\text{CaO}^3 + 3\text{H}^2\text{O}$, which separates in small hard crystals. The lead salt $\text{C}^3\text{H}^2\text{PbO}^3$, obtained by precipitation, forms a curdy mass which melts in hot water (like the malate), but loses this property after long boiling. The silver salt $\text{C}^3\text{H}^2\text{Ag}^2\text{O}^3$ is a gelatinous precipitate, probably containing 1 mol. water; it dissolves in hot water, and separates after prolonged boiling as a crystalline powder. The copper salt $\text{C}^3\text{H}^2\text{CuO}^4$ is precipitated slowly from hot solutions as a greenish-blue crystalline powder; by neutralising the free acid with cupric hydrate, the basic salt $2\text{C}^3\text{H}^2\text{CuO}^4 \cdot \text{CuO}$ is obtained. Ethylic itamaleate is a colourless liquid having an agreeable peppery odour, but not distilling without decomposition.

ITATARTARIC ACID. $\text{C}^3\text{H}^2\text{O}^3$ (Wilm, *Ann. Ch. Pharm.* cxli. 28).—An acid produced by the action of hypochlorous acid upon itaconic acid. When a 1 p.c. solution of hypochlorous acid mixed with the levigated mercuric oxychloride formed in its preparation (p. 438) is gradually added to a solution of sodium itaconate containing not more than 2 p. c. of the salt, cooled by ice and excluded from light, the liquid in five or ten minutes loses the odour of hypochlorous acid and acquires an agreeable odour of chloroform. With more concentrated solutions the action is so violent that complete decomposition takes place, attended with evolution of carbon dioxide. The filtrate freed from mercury by hydrogen sulphide contains the additive product $\text{C}^3\text{H}^2\text{ClO}^3$ (which may be dissolved out by ether, but cannot be separated in the pure state), and on evaporating the solution, this compound is converted into itatartaric acid, as shown by the equation:

To obtain the itatartaric acid, the liquid, freed from hydrochloric acid by repeated evaporation, is precipitated by lead acetate with addition of ammonia; the washed precipitate is decomposed by hydrogen sulphide; the filtrate is carefully concentrated, then freed from the rest of the chlorine by silver carbonate, and from silver by hydrogen sulphide, and left to evaporate in a vacuum. Or the residue, consisting of itatartarate and chloride of sodium, is mixed with the requisite quantity of sulphuric acid, and the acid extracted from the dried mass is purified by conversion into a lead salt.

Pure itatartaric acid is amorphous, vitreous, smells like honey when gently heated, deliquesces in the air, dissolves easily in alcohol, and does not volatilise perceptibly at 100° with aqueous vapour. The itamalates of the alkali-metals do not crystallise; they prevent the precipitation of ferric oxide and cupric oxide by alkalis. Calcium itatartarate, $\text{C}^3\text{H}^2\text{CaO}^3 + \text{H}^2\text{O}$ (?), forms crystalline masses sparingly soluble in water. The barium salt $\text{C}^3\text{H}^2\text{BaO}^3$ (at 100°) is amorphous, easily soluble in water, and precipitable therefrom by alcohol. The copper and zinc salts are amorphous and easily soluble. The lead salt $\text{C}^3\text{H}^2\text{PbO}^3$ is sparingly soluble in water, and crystallises from a mixture of the ammonium salt with lead acetate in highly lustrous monoclinic tabular crystals with truncated summits. The silver salt $\text{C}^3\text{H}^2\text{Ag}^2\text{O}^3$ is a bulky precipitate soluble in water, but not recrystallisable without decomposition.

Itatartaric acid is resolved by dry distillation between 125° and 170° into carbon dioxide, water, and pyro-itaracemic acid, $\text{C}^3\text{H}^2\text{O}^3$, which condenses in oily streaks in the neck of the retort:

between 190° and 230° coloured empyreumatic products are formed. On evaporating the distillate over sulphuric acid in a vacuum, pyro-itaracemic acid remains as a mass having an acid odour, easily soluble in water and in alcohol, volatilising with vapour of water. Its salts do not crystallise. The barium salt $(\text{C}^3\text{H}^2\text{O}^2)^2\text{Ba} + \text{H}^2\text{O}$ (dried at 100°) is amorphous and glossy; the lead salt, which is likewise amorphous, is, after drying, sparingly soluble, but hygroscopic; the silver salt is soluble and very easily decomposable.

J

JADE. On the composition and localities of several varieties of this mineral, see Damour (*Compt. rend.* lvi. 861; lxi. 313, 357; *Jahresb.* 1865, p. 880).

JAROSITE. This mineral, from the Sierra Almagrera in Spain, has, according to Ferber (*Jahresb.* 1864, p. 860), the composition $\text{K}^2\text{SO}^4 \cdot 6\text{FeO}^2 \cdot \text{SO}^4 + 10\text{aq.}$

JASPER. An ochre-yellow jasper of sp. gr. 2.69 from Isle Royale in Lake Superior, has, according to Stieren (*Jahresb.* 1864, p. 848), the composition 67.33 p. c. SiO^2 , 24.87 Al^2O^3 , 1.68 MgO , 3.23 Fe^2O^3 , 1.29 K^2O , and 1.58 water.

JEFFERISITE. This name is given by Brush (*Sill. Am. J.* [2] xli. 248) to the chloritic mineral from the serpentine of Westchester, Pennsylvania, formerly regarded by him as a variety of vermiculite (v. 997), but now recognised as a distinct species, inasmuch as it is optically biaxial. A similar mineral, also laminar and decrepitating, has lately been found in Japan, on the peninsula of Kadzusa, south of Yeddo.

JOLLYTE. A mineral related to hisingerite, from Bodonmais in Bavaria. It is compact, with flat-conchoidal and splintery fracture, of dark brown colour, translucent with green or brown-red colour in thin splinters; powder leek-green to light grayish-green. Lustre faintly unctuous. Hardness = 3. Sp. gr. = 2.61. Melts with difficulty before the blowpipe, with slight intumescence, to a black slightly magnetic or non-magnetic mass. Gives by analysis 35.55 SiO^2 , 27.77 Al^2O^3 , 16.67 FeO , 6.66 MgO , and 13.18 water, corresponding with the formula $3(2\text{FeO} + \text{MgO} \cdot \text{SiO}^2) \cdot 2(2\text{Al}^2\text{O}^3 \cdot \text{SiO}^2) + 12\text{H}^2\text{O}$ (v. Kobell, *J. pr. Chem.* xciv. 495).

JORDANITE. A rhombic sulphur-compound, not yet analysed, but probably a sulpharsenite, occurring, together with dufrénoysite (ii. 347), in the Binnenthal (G. v. Rath, *Pogg. Ann.* cxxii. 371; *Jahresb.* 1864, p. 827).

JUGLANS. The green shell of the walnut (*Juglans regia*) contains a yellow substance (*regianin*) which crystallises in elongated octohedrons or needles, dissolves easily in alcohol and in benzol, and changes in a few hours into an acid (*regianic acid*), $\text{C}^8\text{H}^{12}\text{O}^7$, which is black, amorphous, resinous, forms with alkalis soluble salts having a fine purple colour, and with lead oxide an insoluble brown-violet salt, $\text{PbO} \cdot \text{C}^8\text{H}^{12}\text{O}^7$ (Phipson, *Compt. rend.* lxi. 1372). *Regianin* appears to be identical with Vogel's *Reischauer's nucin* (iv. 143). The epispERM of the nut contains a tannin. (See NUCITANNIN.)

K

KÄMMERERITE. J. B. Pearse (*Sill. Am. J.* [2] xxxvii. 211) has analysed three differently coloured varieties of this mineral from Lancaster County, Pennsylvania, in rhombic crystals of hardness 2.76, resembling many varieties of chlorite: A. pure green; sp. gr. 2.355; B. reddish-green; C. red; sp. gr. 2.383.

	SiO^2	Al^2O^3	Cr^2O^3	FeO	NiO	CaO	MgO	H^2O
A.	28.622	18.375	1.967	3.734	0.370	1.446	32.125	14.025 = 100.664.
B.	31.857	13.746	2.154	2.370	0.215	1.273	34.901	13.982 = 100.498.
C.	31.315	12.840	2.985	2.475	0.450	0.815	35.020	13.200 = 99.100.

From these analyses, Pearse calculates, for the green variety the formula $2\text{Al}^2\text{O}^3 \cdot 9\text{MgO} \cdot 5\text{SiO}^2 + 8\text{H}^2\text{O}$, and for the red and reddish-green varieties, which may be regarded as identical, the formula $2\text{Al}^2\text{O}^3 \cdot 13\text{MgO} \cdot 7\text{SiO}^2 + 10\text{H}^2\text{O}$.

According to J. P. Cooke (*ibid.* xlv. 201), the crystals of kämmererite are optically biaxial, exhibiting faint but distinct positive double refraction; they are also dichroic,

the crystals of the violet variety (violet chrome-chlorite) transmitting light with violet colour in the direction of the optic axis, while in all directions at right angles to this axis the ordinary ray is violet, the extraordinary ray hyacinth-red.

KAINITE (from *kavds*, new). A double salt, consisting mainly of potassium chloride and magnesium sulphate, occurring in the Leopold shaft of the Stassfurt salt-works. It forms a fine-grained mass of yellowish or grey colour; does not become moist in the air, but effloresces over sulphuric acid. According to Rammelsberg (*J. pr. Chem.* xcix. 63; *Jahresb.* 1867, p. 951), it consists of $\text{KCl} \cdot \text{MgSO}_4 + 3\text{H}_2\text{O}$, about $\frac{1}{2}$ of the potassium being replaced by sodium. The purer yellow variety gave by analysis 14.52 p. c. Cl, 13.54 K, 1.30 Na, 32.98 SO_4 , 16.49 MgO , and 21.00 water. Its aqueous solution first deposits the known double salt $\text{K}^2\text{Mg}(\text{SO}_4)_2 + 6\text{H}_2\text{O}$; afterwards magnesium sulphate, $\text{MgSO}_4 + 7\text{H}_2\text{O}$, while the chlorides of magnesium and potassium remain in the mother-liquor. The magnesio-potassic sulphate is likewise precipitated from the solution of kainite by alcohol (Rammelsberg). See also Zinckon and Reichardt (*Jahresb.* 1865, pp. 899, 900). According to Frank (*Jahresb.* 1868, p. 1019), kainite contains 36.34 K^2SO_4 , 25.24 MgSO_4 , 18.95 MgCl_2 , and 19.47 H_2O , agreeing with the formula $\text{K}^2\text{Mg}(\text{SO}_4)_2 \cdot \text{MgCl}_2 + 6\text{H}_2\text{O}$.

KAOLIN, KAOLINITE. S. W. Johnson and J. M. Blake (*Sill. Am. J.* [2] xliii. 351, 405) propose the name *Kaolinite* for the minerals hitherto designated as phalerite, nacrite, lithomarge, and kaolin. They also describe a kaolinite occurring on Summit Hill, Pennsylvania, in small scaly crystals, and containing 45.93 p. c. SiO_2 , 39.81 Al_2O_3 , with traces of ferric oxide, and 14.02 water. For analysis of kaolin-earths from various localities, see L. Knuffl (*Dingl. pol. J.* clxxiv. 292; *Jahresb.* 1864, p. 846).

To distinguish kaolin from common clay, Elsner (*Dingl.* clxxv. 85) agitates it in a test-tube with pure strong sulphuric acid, till a uniform mixture is produced; decants the acid after subsidence; dilutes it carefully with six volumes of water; and supersaturates the cooled solution with ammonia. Kaolin thus treated separates but slowly from the strong acid, and the diluted acid solution gives an immediate white precipitate with ammonia; whereas ordinary clay is but slightly attacked by the acid, separates quickly from it, and the acid after dilution gives but an insignificant precipitate with ammonia.

KEROLITE or CEROLITE (i. 836). An apple-green variety of this mineral from Lake Itkul in the Ural, was found by R. Hermann (*J. pr. Chem.* xcv. 134) to contain 47.06 p. c. SiO_2 , 31.81 MgO , 2.80 NiO , and 18.33 water.

KETONES. *Acetones* (Friedel, *Compt. rend.* xlv. 1013; xlvii. 552; lv. 53; *Ann. Ch. Pharm.* cxii. 236, 376. Fround, *Ann. Ch. Pharm.* cxviii. 1. Frankland & Duppa, *Phil. Trans.* clvi. 37; *Chem. Soc. J.* [2] iv. 395; v. 102; *Jahresb.* 1865, p. 304; 1867, p. 394. Geuther, *Jahresb.* 1863, p. 323; 1865, p. 302. Wanklyn, *Chem. Soc. J.* [2] ii. 371; *Chem. News*, xviii. 121, 181; *Jahresb.* 1864, p. 461; 1868, p. 509).—Organic compounds consisting of carbon monoxide united with two alcohol-radicles; e.g.,

The two alcohol-radicles may be either similar, as in the example just given, or they may be dissimilar; e.g.,

Sometimes the ketones are written as consisting of acid-forming radicle united with alcohol-radicle. This was the case in Gerhardt's *Traité de Chimie organique*. But, inasmuch as it has been shown that methyl-propionyl and acetyl-ethyl are identically the same things (see Popoff, *Jahresb.* 1867, p. 399), we are compelled to regard the distinction between the acid-forming and alcohol-radicle as lost in the production of the ketone. Moreover, ketones are actually generated by union between carbon monoxide and nascent alcohol-radicles; e.g.,

The ketones form a very well-marked natural family, and exhibit the closest resemblance to one another. All the lower members of the family are thin colourless liquids, possessing a peculiar penetrating smell, which deserves to be called the ketone-smell. The lowest ketone, viz. common acetone, is soluble in water in all proportions; and all the ketones are perceptibly soluble in water, and likewise

dissolve a certain quantity of water, which they retain with some degree of obstinacy. Ketones have little or no tendency to take up oxygen from the air, in this respect being different from aldehydes, which have this tendency, and are composed of carbon monoxide with one equivalent of alcohol-radicle and one equivalent of hydrogen; *e.g.*,

Ketones undergo very precise oxidation by treatment with a mixture of bichromate of potash and dilute sulphuric acid of a certain strength (*viz.* a solution containing 8 per cent. of the bichromate, and just enough sulphuric acid to form chrome-alum).

The products of oxidation by means of such a chrome-solution employed at temperatures not exceeding 100° are acids of the acetic series. A very simple law appears to govern the course taken by the oxidation, *viz.* that the carbon monoxide becomes attached to the lower of the two alcohol-radicles. Thus methyl-amyl ketone gives acetic and valerianic acids:

In accordance with this law, methyl-ethyl ketone gives only acetic acid, and not acetic and propionic acids:

In the instance of the simplest possible ketone, *viz.* dimethyl-ketone, which is common acetone, the products are acetic acid and formic acid, the latter, however, from its instability, rapidly passing into carbonic acid and water on prolonged oxidation:

In the instance of ketones containing any other normal alcohol-radicles, and even when the radicles are to some degree iso-compounds, the oxidation of the ketone by means of the above-mentioned chrome-solution is an operation yielding two atoms of acid with almost mathematical precision. When, however, the alcohol-radicles are in a marked degree iso-radicles, the oxidation becomes irregular. Thus, methyl-isopropyl ketone may be expected to give

Ketones can also take up hydrogen, and thereby pass into secondary alcohols; *e.g.*,

This reaction is effected by the employment of sodium-amalgam in presence of water (Friedel).

Those ketones which contain methyl enter into combination with alkaline bisulphites, and form compounds which are often beautifully crystalline, and from which by distillation with a caustic alkali the ketone may be recovered in its original state. Ketones not containing methyl do not form compounds with alkaline bisulphites, or form them only with the utmost difficulty.

The ketones are produced in the following reactions:

1. By the action of carbon monoxide on the compounds of the alkali-metals: $\text{CO} + 2\text{NaC}^2\text{H}^3 = \text{Na}^2 + \text{CO}(\text{C}^2\text{H}^3)^2$ (Wanklyn).

2. By the action of the chloride of an acid-radicle on the zinc-compound of an alcohol radicle: $\text{C}^2\text{H}^3\text{OCl} + \text{Zn}(\text{CH}^3)^2 = \text{C}^2\text{H}^3\text{O} \cdot \text{CH}^3 + \text{ZnClCH}^3$ (Pebal a. Freund).

3. By distillation of the baryta- or lime-salts of the fatty acids, this being the original process by which common acetone was first prepared:

If a mixture of the salts of two different fatty acids be employed, the product is a ketone containing different alcohol-radicles (Williamson):

4. When salts of acetylinated ethyl (p. 591) are boiled with baryta-water, a reaction takes place which is essentially similar to the last.

Thus caproate of acetylinated ethyl gives methyl-amyl ketone:

Here the hydrogen of the barium hydrate, $\text{H}^2 \bigg\{ \text{Ba} \bigg\} \text{O}^2$, takes the place of the two acid-forming radicles, and so produces alcohol; and the two acid-forming radicles, whilst in the act of yielding barium salts, split up into ketone and carbonic oxide, which gives barium carbonate. It is the ancient ketone-preparation, effected at comparatively low temperatures. Examples of this exceedingly interesting reaction were first observed by Geuther, and subsequently by Frankland and Duppa in the course of researches on the successive action of sodium and iodide of ethyl on acetic ether.

Doubtless also salts of valerylated ethyl, &c., might be substituted for salts of acetylinated ethyl in the above reaction, and a different set of ketones would be thereby produced. If it were required to produce a new ketone of specified constitution, this method would appear to be the best to select for the purpose.

5. By oxidation of certain acids of the lactic series (Chapman and Smith, *Chem. Soc. J.* [2] v. 186). Thus diethoxalic acid gives diethyl-ketone:

6. By oxidation of the secondary alcohols.

7. In the preparation of the aniline of commerce, there is production of more or less acetone, doubtless owing to the oxidising of the acetic acid by means of the nitryl of the nitrobenzene. Certain destructive distillations, *e.g.* sugar with caustic alkali, yield ketones.

There has been a good deal of unnecessary confusion in the nomenclature of the ketones. In addition to names founded on the assumed persistence of the distinction into acid- and alcohol-forming radicles, names have been invented, referring to the interior constitution of the alcohol-radicles: thus a certain ketone was called *diethylated acetone*, meaning common acetone wherein one of the methyls had suffered the replacement of two equivalents of its hydrogen by two equivalents of ethyl. It is better to name the ketones according to the two alcohol-radicles which they contain, as in the following examples:

- | | | |
|--------------------------------------|----|--|
| 1. Dimethyl-ketone | CO | $\bigg\{ \begin{array}{l} \text{CH}^{\text{H}} \\ \text{CH}^{\text{H}} \end{array} \bigg\}$ |
| 2. Methyl-ethyl ketone | CO | $\bigg\{ \begin{array}{l} \text{CH}^{\text{H}} \\ \text{CH}^{\text{H}}\text{CH}^{\text{H}} \end{array} \bigg\}$ |

21. Ethyl-isobutyl ketone	CO	$\begin{Bmatrix} \text{C}^2\text{H}^5 \\ \text{CH}^2\text{CH}(\text{CH}^3)^2 \end{Bmatrix}$
22. Ethyl-isobutyl ketone	CO	$\begin{Bmatrix} \text{C}^2\text{H}^5 \\ \text{CH} \begin{Bmatrix} \text{CH}^3 \\ \text{CH}^2\text{CH}^1 \end{Bmatrix} \end{Bmatrix}$
23. Ethyl-isobutyl ketone	CO	$\begin{Bmatrix} \text{C}^2\text{H}^5 \\ \text{C}(\text{CH}^3)^2 \end{Bmatrix}$
24. Ethyl-amyl ketone	CO	$\begin{Bmatrix} \text{C}^2\text{H}^5 \\ \text{CH}^2\text{CH}^2\text{CH}^2\text{CH}^2\text{CH}^1 \end{Bmatrix}$

&c. &c.

The methyl-ketones (1-16) form compounds with alkaline bisulphites, and yield acetic acid by 'limited' oxidation (p. 150). The ethyl-ketones (17-24) do not form compounds with alkaline bisulphites; they yield propionic acid by limited oxidation.

The modes of formation and principal properties of the methyl-ketones are as follows:

1. *Dimethyl Ketone*. $\text{CO}(\text{CH}^3)^2$.—Common acetone. Boils at 55.6° . Sp. gr. 0.7921 at 18° . Prepared: a. By dry distillation of barium or calcium acetate:

b. By the action of zinc-methyl on acetyl chloride (Pebal a. Freund):

c. By limited oxidation of dimethoxalic acid (Chapman a. Smith):

d. By the action of alkalis on acetate of acetylinated ethyl:

e. By oxidation of isopropyl alcohol:

2. *Methyl-ethyl Ketone*, $\text{C}^2\text{H}^5\text{O}^2 = \text{CO} \begin{Bmatrix} \text{CH}^3 \\ \text{CH}^2\text{CH}^1 \end{Bmatrix}$; also *methylated acetone* (i. 31).—Boils at 81° ; sp. gr. = 0.8125 at 13° . Obtained: a. By the action of zinc-ethyl on acetyl chloride:

8. By the action of zinc-methyl on propionyl chloride :

γ. By the action of alkalis on propionate of acetylinated ethyl :

3. *Methyl-propyl Ketone*. $\text{CO}\left\{\begin{smallmatrix} \text{CH}_3 \\ \text{CH}_2\text{CH}_2\text{CH}_3 \end{smallmatrix}\right\}$.—Boils at 101° (barometer 760 mm.).
Sp. gr. at $13^\circ = 0.8132$; sp. gr. at $22^\circ = 0.8046$.

Discovered by Geuther; also described by Frankland a. Duppa as ethylacetone. Obtained by the action of butyrate of acetylinated ethyl on potash or baryta-water :

4. *Methyl-isopropyl Ketone*. $\text{CO}\left\{\begin{smallmatrix} \text{CH}_3 \\ \text{CH}(\text{CH}_3)_2 \end{smallmatrix}\right\}$.—Boils at 93.5° . Sp. gr. at $13^\circ = 0.8099$. Discovered by Geuther (described by Frankland a. Duppa as dimethylated acetone). Prepared by the action of isobutyrate of acetylinated ethyl on baryta-water :

The isobutyrate of acetylinated ethyl is produced by acting on acetate of ethylene-sodium with methyl-iodide.

5. *Methyl-butyl Ketone*. $\text{CO}\left\{\begin{smallmatrix} \text{CH}_3 \\ \text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_3 \end{smallmatrix}\right\}$.—Obtained by the action of chloride of valeryl on zinc-methyl.

6. *Methyl-isobutyl Ketone*. $\text{C}^6\text{H}_{12}\text{O} = \text{CO}\left\{\begin{smallmatrix} \text{CH}_3 \\ \text{CH}_2\text{CH}(\text{CH}_3)_2 \end{smallmatrix}\right\}$.—The *isopropacetone* of Frankland a. Duppa. The ketone obtained by oxidising β hexylic alcohol from mannite appears to have this constitution. It boils at 127° C. Sp. gr. 0.8298 at 0° (Wanklyn a. Erlenmeyer). By oxidation it gives acetic and isobutyric acids. It forms crystalline compounds with alkaline bisulphites. It is also produced by the action of alkalis on isovalerate of acetylinated ethyl :

Isovalerate of acetylinated ethyl was obtained by Frankland a. Duppa by the action of isopropyl iodide on sodium-triacetyl, and designated by them as isopropacetone-carbonate.

7. *Methyl-isobutyl Ketone*. $\text{CO}\left\{\begin{smallmatrix} \text{CH} \\ \text{CH} \end{smallmatrix}\right\}\left\{\begin{smallmatrix} \text{CH}_3 \\ \text{CH}_2\text{CH}_3 \end{smallmatrix}\right\}$.—It appears to be unknown.

Theory, however, indicates that it should be formed similarly to the ketone just described, viz. from the isovalerate of acetylinated ethyl which is obtainable by acting with mixed iodide of methyl and iodide of ethyl on acetate of ethylene-sodium.

8. *Methyl-isobutyl Ketone*. $\text{CO}\left\{\begin{smallmatrix} \text{CH}_3 \\ \text{C}(\text{CH}_3)_3 \end{smallmatrix}\right\}$.—Unknown.

15. *Methyl-isoamyl Ketone*. $\text{CO}\left\{\begin{smallmatrix} \text{CH}_3 \\ \text{CH}(\text{C}^2\text{H}_5)_2 \end{smallmatrix}\right\}$.—Boils at 137.5° to 139° . Sp. gr. at $22^\circ = 0.8171$. Discovered by Frankland a. Duppa, and named by them diethylated acetone. Prepared by the action of caproate of acetylinated ethyl on hydrate of barium :

The caproyl was diethylated acetyl, $\text{CO}.\text{CH}(\text{C}^2\text{H}_5)_2$, and therefore the resulting amyl was diethylated amyl. The caproate of acetylinated ethyl was obtained by the action of iodide of ethyl on acetate of ethylene-sodium. J. A. W.

KRYPTOPHANIC ACID. Syn. with CRYPTOPHANIC ACID.

KUBA WOOD, the best kind of fustic, from *Morus tinctoria*, contains a substance which exhibits the kind of fluorescence observed by Hlasiwetz a. Pfaundler in isomarin.

* The butyryl was normal butyryl, obtained by the action of ethyl iodide on sodium triacetyl.

The alcoholic solution of the aqueous extract of kuba wood is dark garnet-red by transmitted light, and fluorescent, with dark green colour, by reflected light. After being considerably diluted with alcohol, and then mixed with alum or any other aluminium salt, it exhibits a fluorescence similar to that of uranium glass, which disappears on addition of excess of alkali or hydrochloric acid, but reappears on exact neutralisation. The solution of the extract in ether, amylie alcohol, or methylic alcohol exhibits similar properties (Goppelsröder, *Pogg. Ann.* cxxxi. 464).

KUPFFERITE. An emerald-green variety of hornblende, allied to actinolite, occurring imbedded in the coarse-grained calcspar in the country of the Uralian Cossacks; also, imbedded in garnet, in the Ilmen mountains. It forms prismatic crystals ($\infty P : \infty P = 124^{\circ} 15'$), cleaving parallel to ∞P , transparent in thin splinters, with glassy lustre; hardness = 5.5; sp. gr. = 3.08. Crystals from the Ilmen mountains gave by analysis:

SiO ^a	Cr ^a O ^a	NiO	FeO	CaO	MgO	Alkalis	Loss by ignition
57.46	1.21	0.65	6.05	2.93	30.88	trace	0.82 = 100

(R. Hermann, *Jahresb.* 1862, p. 726; Kokscharow, *ibid.* 1866, p. 927).

KUPHANILINE. A name applied by Reimann to the aniline oil obtained from that portion of crude benzol which boils at temperatures not above 100° . It contains 90 p. c. aniline and 5 p. c. toluidine, and distils at 100° – 150° (*Dingl. pol. J.* clxxxv. 49; *Jahresb.* 1867, p. 460).

KYAPHENINE. Syn. with CYAPHENINE (p. 539).

KYNURENIC ACID. According to Voit a. Richter (*Jahresb.* 1865, p. 676), the quantity of this acid in dogs' urine increases when fat or carbohydrates are added to the food. Sodium sulphate, on the other hand, has no influence in this respect, contrary to the statement of Seegen (*ibid.* 1864, p. 650).

Kynurenic acid does not decompose barium carbonate. Its barium salt has a neutral reaction, is not decomposed by carbonic acid, but is precipitated thereby, together with barium carbonate, from the strongly alkaline solution. If after the passage of the carbonic acid gas, the liquid be heated to boiling, the neutral barium salt separates on cooling in stellate groups of needles, and the remaining liquid is found to be free from kynurenic acid (Liebig, *Ann. Ch. Pharm.* cxl. 143).

L

LABURNINE. A poisonous alkaloïd, occurring, together with cytisine, in the unripe seeds of the common laburnum (p. 539).

LACTALBUMIN and **LACTOPROTEIN.** Two albuminous substances, occurring, according to Commaïlle (*J. Pharm.* [4] iv. 108), in milk together, with casein.

LACTAMIDE. According to Wislicenus (*Ann. Ch. Pharm.* cxxxiii. 257), the only products obtained by the action of dry ammonia gas on dilactic acid, $C^3H^4O^3$, are ammonium lactate and lactamide, $C^3H^3NO^2$. Laurent's lactamic acid (iii. 451) has no existence.

LACTIC ACID. $C^3H^4O^3 = \begin{matrix} C^3H^3OH \\ | \\ COOH \end{matrix}$ —The structure of the two modifications

of this acid, known as ordinary or fermentation lactic acid, and paralactic acid, is represented by the following formulæ:

Ordinary lactic acid, which may be supposed to contain the radicle ethylidene, CH^2-CH , is produced: α . By the oxidation of propylene glycol, $\text{CH}^2-\text{CHOH}-\text{C}^2\text{H}^2\text{OH}$ (iii. 454).— β . By the action of water and silver oxide on α -bromopropionic acid, $\text{CH}^2-\text{CHBr}-\text{CO}^2\text{H}$ (Friedel a. Machuca, iii. 454; Buff, *Ann. Ch. Pharm.* cxl. 156).— γ . By the action of hydrochloric acid on a mixture or compound of aldehyde and hydrocyanic acid (Wislicenus, *Ann. Ch. Pharm.* cxxviii. 1; Simpson a. Gautier, *ibid.* cxlvi. 254):

Paralactic acid, which is an ethylene compound, is formed: α . By heating ethylene chlorohydrate (glycolic chlorhydrin) with an alcoholic solution of potassium cyanide, and boiling the resulting ethylene cyanohydrate with potash (Wislicenus, *loc. cit.*):

β . By the action of nitrous acid upon alanine (amidopropionic acid) (Buff, *Ann. Ch. Pharm.* cxl. 156):

γ . By combining ethylene with carbonyl chloride, whereby paralactyl chloride, $\text{CH}^2\text{Cl}-\text{CH}^2-\text{COCl}$, is produced, and decomposing this chloride with an alkali:

δ . By the action of silver oxide and water on β -iodopropionic acid, $\text{CH}^2\text{I}-\text{CH}^2-\text{COOH}$, produced by treating glyceric acid with iodine and phosphorus. Part of the paralactic acid is, however, converted by molecular transformation into ordinary lactic acid (Wichelhaus, *Ann. Ch. Pharm.* cxliv. 51; *Jahresb.* 1867, p. 402).

Beilstein (*Ann. Ch. Pharm.* cxxii. 369), by treating β -iodopropionic acid with recently precipitated silver oxide, obtained a tribasic acid, $\text{C}^2\text{H}^2\text{O}^{11}$, which he named hydracrylic acid. Moldenhauer (*ibid.* cxxxi. 330), by boiling this acid with silver oxide or alkalis, or by treating it with sodium-amalgam, obtained an acid having the composition of lactic acid; and this observation is confirmed by Wislicenus (*Zeitschr. f. Chem.* [2] iv. 684), who has moreover shown that the so-called hydracrylic acid, when simply neutralised with soda, likewise yields a sodium salt of lactic acid: hence he infers that the supposed hydracrylic acid has no existence, but that the acid formed by the action of moist silver oxide on β -iodopropionic acid is one of the modifications of lactic acid.

Hydracrylic acid may, however, be an anhydride of lactic acid, $4\text{C}^2\text{H}^2\text{O}^3 - \text{H}^2\text{O} = \text{C}^2\text{H}^2\text{O}^{11}$, and may be converted into lactic acid by the action of alkalis. Socoloff (*ibid.* v. 123), by treating β -iodopropionic acid with moist silver oxide, likewise obtains an acid of the composition $\text{C}^2\text{H}^2\text{O}^3$; but on account of certain peculiarities in the characters of the zinc, calcium, and barium salts, he regards this acid as different from either of the known modifications of lactic acid. He finds, moreover, that the calcium salt of this acid forms crystalline double salts with the acid sulphites of calcium and sodium, and hence he thinks it probable that the acid in question may be an aldehydic acid—in fact, the aldehyde of glyceric acid:

It is difficult, however, to imagine how β -iodopropionic acid, $\text{CH}^2\text{I}-\text{CH}^2-\text{CO}^2\text{H}$, can give rise, by substitution of OH for I, to anything but paralactic acid. Moreover,

Wislicenus (*ibid.* vi. 159) points out that the acid in question yields by oxidation, not glyceric, (but as first product) carbacetoxylic acid; that it is not converted into glycerin by nascent hydrogen; and when treated with hydriodic acid is easily transformed into β -iodopropionic acid. Sarcosalic acid appears to be a mixture of two acids, inasmuch as its zinc salt may be separated, by treatment with strong alcohol, into a sparingly soluble crystalline salt and an easily soluble amorphous salt. The acid of the latter appears to be identical with paralactic or β -oxypropionic acid; but that of the crystalline zinc salt is not identical with ordinary lactic acid, inasmuch as it exerts a strong dextrorotatory action on polarised light, whereas both ordinary lactic and paralactic acids are optically inactive. See further Heintz, *Ann. Ch. Pharm.* clvii. 291, 295;—Erlenmeyer, *ibid.* clviii. 262; also *Chem. Soc. J.* [2] ix. 361, 516.

Reactions.—1. Paralactic acid oxidised with *potassium dichromate*, or with dilute *nitric acid*, or by fusion with *potash*, is converted into malonic acid, $C^3H^2O^4$; but ordinary lactic acid treated with sulphuric acid and *potassium dichromate*, is converted into formic and acetic acids (Dossios, *Jahresb.* 1866, p. 381):

According to Chapman and Smith (p. 152), the products are acetic acid, carbon dioxide, and water: $C^2H^3O^3 + O^2 = C^2H^3O^2 + CO^2 + H^2O$.

2. Ordinary lactic acid heated for several hours to 130° with dilute *sulphuric acid* is converted into aldehyde and formic acid:

Ethylidene glycol. Aldelyde.
 Paralactic acid similarly treated would probably be resolved into formic acid and ethylene glycol (Erlenmeyer, *Zeitschr. f. Chem.* [2] iv. 343).
 ethylene glycol (Erlenmeyer, *Zeitschr. f. Chem.* [2] iv. 343).
 ethylene glycol (Erlenmeyer, *Zeitschr. f. Chem.* [2] iv. 343).

3. Lactic acid mixed with cupric sulphate forms a deep blue liquid without precipitation, whereas paralactic acid is almost completely precipitated (Dossion, *loc. cit.*).

4. Lactic acid heated to 160°–180° in a stream of gaseous hydrobromic acid, is converted into 100% in sealed tubes with saturated aqueous hydrobromic acid, is converted into bromopropionic acid, $C^3H^5BrO_2$ (Kekulé, *Ann. Ch. Pharm.* cxxx. 11).

100° in sealed tubes with $\text{C}_{12}\text{H}_{25}\text{BrO}_2$ (Kekulé, *Ann. Ch. Pharm.* cxxx. 11).
5. An ethereal solution of lactic acid treated with bromine in a well-cooled vessel, and afterwards heated to 100° in a retort with upright condenser, yields a liquid from which water throws down a gradually crystallising oil, while ordinary lactic acid remains dissolved. The crystalline product, which contains about 6.8 p. c. bromine, is neutral, melts at 83°–85°, dissolves easily in ether, separating therefrom in large acute rhombic prisms, and is decomposed by silver oxide and acetate, also by sodium-amalgam, yielding products not yet examined (Wichelhaus, *Jahresb.* 1867, p. 402).
6. *St. Pharm.* cxxxi. 287). calcium lactate yields by dry

According to Claus (*Ann. Ch. Pharm.* cxxxvi. 287), calcium lactate yields by dry distillation, acrylic acid, phenol, and a fetid oil varying in boiling point from 75° to 210°. Potassium lactate subjected to electrolysis yields large quantities of carbon dioxide and aldehyde-resin (Brester, *Jahresb.* 1866, p. 87). Ethyl lactate is converted by phosphorus trichloride into ethyl chloropropionate (Frankland & Duppa, *ibid.* 1866, p. 386):

$$3\text{C}_2\text{H}_5\text{O}^{\text{C}}\text{H} + \text{PCl}_3 \rightarrow 3\text{C}_2\text{H}_5\text{H}^{\text{C}}\text{Cl} + (\text{C}_2\text{H}_5\text{O})^{\text{C}}\text{Cl}.$$

Dibromolactic acid, $\text{C}^*\text{H}(\text{Br})\text{O}^*$, is formed by enclosing 1 mol. pyruvic acid, $\text{C}^*\text{H}(\text{O})^*$ (dried by standing over oil of vitriol and quick lime), with 1 mol. bromine in a sealed tube, and leaving the tube for several hours in ice-cold water. A viscid product containing capillary crystals is then formed, and the colour of the bromine disappears, without perceptible formation of hydrobromic acid. The product quickly absorbs moisture from the air, and decomposes with evolution of hydrobromic acid; it

is also decomposed by alcohol, and melts when heated, giving off hydrobromic acid. Its salts have not been prepared. When more than 1 mol. bromine is used, the excess remains free, and may be removed by a stream of dry air. Sodium-amalgam converts the product into ordinary lactic acid. It appears therefore to be dibromolactic acid formed from pyroracemic acid by a simultaneous process of addition and substitution:

Dibromolactic acid is converted by water, or by exposure to moist air, into crystalline monobromopyroracemic acid, $\text{C}^3\text{H}^3\text{BrO}^3$. In one experiment, in which considerable quantities of dibromolactic acid were dissolved in water, the crystallised product appeared to have the composition of dibromodilactic acid, $\text{C}^2\text{H}^2\text{Br}^2\text{O}^3$ (Wislicenus, *Ann. Ch. Pharm.* cxlviii. 208; *Zeitschr. f. Chem.* [2] v. 255. See also De Clermont a. Silva, *Deut. Chem. Ges. Berlin.* 1869, p. 40).

Benzolactic acid, $\text{C}^{10}\text{H}^{10}\text{O}^4 = \left\{ \begin{array}{l} \text{CH}^3 \\ \text{CHO}(\text{C}^2\text{H}^3\text{O}) \\ \text{COOH} \end{array} \right.$, which Strecker obtained by

heating lactic acid with benzoic acid (i. 561), is also produced by the action of benzoyl chloride on lactates, the calcium salt for example. When recrystallised from water, it always yields, besides the crystallised acid, $\text{C}^{10}\text{H}^{10}\text{O}^4$, an oily hydrate, $\text{C}^{10}\text{H}^{10}\text{O}^4 \cdot \text{H}^2\text{O}$, which in dry air is slowly converted into the crystallised acid. *Ethyl Benzolactate*, $\text{C}^{10}\text{H}^{10}\text{O}^4 \cdot (\text{C}^2\text{H}_5)^2$, formed by heating ethyl lactate to 100° with benzoyl chloride, or by the action of ethyl iodide on silver benzolactate, is a colourless oily liquid, insoluble in water, miscible in all proportions with alcohol and ether; boiling at 288° ; resolved by water at 150° into lactic acid and ethyl benzoate. Alcoholic ammonia converts it

into benzolactamide, $\text{C}^{10}\text{H}^{11}\text{NO}^3 = \left\{ \begin{array}{l} \text{CH}^3 \\ \text{CHO}(\text{C}^2\text{H}^3\text{O}) \\ \text{CONH}^2 \end{array} \right.$, which crystallises in white

sublimable nodules, melting at 121° , slightly soluble in water, easily in alcohol. By boiling with potash, it is resolved into lactic acid, benzoic acid, and ammonia; alcoholic ammonia converts it into benzamide and lactamide (Wislicenus, *Ann. Ch. Pharm.* cxxiii. 257; *Jahresb.* 1865, p. 363).

LACTIC ANHYDRIDES. 1. *Lactide*. $\text{C}^3\text{H}^2\text{O}^2$.—According to Krupsky (*Zeitschr. f. Chem.* [2] v. 179), this substance is formed very easily during the distillation of lactic acid, before the temperature rises to 200° , but the most favourable temperature for its production is from 210° to 215° . It may be obtained in splendid rhombic crystals by spontaneous evaporation of its alcoholic solution in a current of air.

2. *Dilactic Acid*. $\text{C}^6\text{H}^{10}\text{O}^5 = \left\{ \begin{array}{l} (\text{C}^3\text{H}^3\text{O})'' \\ (\text{C}^3\text{H}^3\text{O})'' \\ \text{H}^2 \end{array} \right\} \text{O}^3 = 2\text{C}^3\text{H}^3\text{O}^3 - \text{H}^2\text{O}$ (iii. 461).—

Wislicenus (*Ann. Ch. Pharm.* cxxviii. 1; cxxviii. 257) regards this compound as an ethereal derivative of two molecules of lactic acid, one of which acts as an acid, the other as an alcohol; thus:

This view has recently been corroborated by the experiments of N. von der Bruggen (*Zeitschr. f. Chem.* [2] v. 338), from which it appears that dilactic acid is produced by heating a mixture of equivalent proportions of bromopropionic acid and potassium lactate to 100° – 120° in a well-corked flask:

The portion of the product which was soluble in ether gave with dry ammonia the characteristic reaction of dilactic acid, viz. the formation of ammonium lactate and lactamide (p. 769).

A compound isomeric with the neutral ethylic ether of dilactic acid, $C^2H^4(C^2H^3)O^2$, is produced by heating ethylic sodio-lactate (iii. 463) with ethylic chloropropionate to 110° – 120° for twenty-four hours:

The resulting light brown viscid liquid may be freed from sodium chloride by washing with water, and from undecomposed chloropropionic ether by heating it to 110° in a rarefied distillatory apparatus. The distillate is a colourless oil having a faint ethereal odour, not decomposed by aqueous caustic soda even at the boiling heat, but completely, though slowly, by alcoholic soda, yielding lactic and ethyl-lactic acids. By heating it for 24 hours with a large excess of ethereal solution of ammonia, and distilling off the ether and excess of ammonia over the water-bath, there is obtained a non-distillable oil, which, after being left for some time over sulphuric acid in a vacuum, exhibits the composition of ethylic dilactamide, $C^2H^4NO^4$. It is not however converted into dilactamide by the further action of ammonia, and when heated with potash yields, not dilactic acid, but a mixture of lactic and ethyl-lactic acids (v. d. Bruggen, *Zeitschr. f. Chem.* [2] v. 250).

succinyl chloride to 100° with rather more than 2 mol. ethyl lactate, and removing the excess of the latter by heating the product to 170° in a stream of air. The compound, purified by solution in alcohol, precipitation by water, and distillation, is a colourless oily liquid, insoluble in water, miscible in all proportions with ether, and boiling between 300° and 304° (Wislicenus, *Ann. Ch. Pharm.* cxxxiii. 257). Wurtz a. Friedel (*Jahresh.* 1861, p. 378) obtained this ether in a less pure state, and with a lower boiling point, by heating neutral potassium succinate with ethylic chlorolactate.

LAETIMIDE, $C^2H^4NO = \left(\begin{array}{c} (C^2H^4O)^2 \\ H \end{array} \right)^2 N$, is produced by heating alanine in dry hydrochloric acid gas to 180° – 200° as long as water continues to form: $C^2H^4NO^2 = H^2O = C^2H^4NO$. The brown amorphous product, treated with lead hydrate and hydrogen sulphide, and recrystallised from absolute alcohol, yields laetimide in colourless needles, melting at 275° , subliming undecomposed when cautiously heated, having a bitter taste, easily soluble in water and in alcohol. The solution neither dissolves silver oxide, nor gives a precipitate with silver nitrate or zinc chloride. The quantity of laetimide obtained as above is but small, a large portion of the alanine being resolved into carbon dioxide and ethylamine (Preu, *Ann. Ch. Pharm.* cxxxiv. 372).

LACTONIC ACID. Syn. with ISODIGLYCOL-ETHYLENIC ACID (iii 414).

LACTOPROTEIN. See LACTALBUMIN (p. 769).

LEVULIN. A substance resembling dextrin, contained in the juice of the tubers of the Jerusalem artichoke, from which it may be separated by repeated treatment with alcohol. It has a sweetish taste; is soluble in water; does not reduce cupric oxide in alkaline solution till it has been boiled with acids; and is optically inactive in its natural state, but becomes strongly levogyrate by treatment with hydrochloric acid (Ville a. Joulie, *Bull. Soc. Chim.* [2] vii. 262).

LAMPFRANE. A sulphate, so called on account of its lustre, occurring at Langbanshytta in Wernmland, Sweden, in easily cleavable, white, nacreous masses having a sp. gr. = 3.07, and hardness = 3. Analysis gave

SO ³	PbO	MnO	CaO	MgO	K ² O; Na ² O	H ² O
11.17	28.00	7.90	24.65	5.26	14.02	8.35 = 99.35

(Igelström, *Ofv. af Kongl. Akad. Förh.* 1866, No. 4, p. 93).

LANGITE. A basic cupric sulphate occurring, together with others, in the clay-slate of Cornwall. (See SULPHATES.)

LANTHANUM. Zschiesche (*J. pr. Chem.* civ. 174) has determined the atomic weight of this metal by the decomposition of its sulphate, which at a white heat gives off the whole of its water and sulphuric acid, leaving the pure oxide. Six experiments gave values of La varying from 89.44 to 91.25: mean 90.18.

Cl. Winkler (*J. pr. Chem.* xcv. 410; *Jahresh.* 1865, p. 708) separates lanthanum

from didymium in a solution likewise containing cerium, by means of potassium permanganate and mercuric oxide. When a hydrochloric acid solution of the three metals, made as neutral as possible, is mixed with precipitated mercuric oxide, and a dilute solution of potassium permanganate is stirred into it till the colour of the latter disappears, the whole of the lanthanum (together with traces of didymium) remains in solution, whilst the resulting precipitate contains ceric oxide and didymium peroxide, together with mercuric oxide and manganese dioxide. This precipitate, freed from mercuric oxide by ignition, is dissolved in hydrochloric acid; the solution is concentrated by evaporation over sulphuric acid; and the sulphates of cerium and didymium are precipitated by means of solid potassium sulphate. These sulphates, after washing with a concentrated solution of potassium sulphate, are precipitated by ammonium oxalate, and the oxides of cerium and didymium obtained by igniting the precipitated oxalates are separated by known methods. The solution containing the lanthanum, after being freed from mercury by hydrogen sulphide, is precipitated with oxalic acid, and the washed lanthanum oxalate is ignited. The lanthanum oxide thus obtained contains only traces of didymium. This mode of separating lanthanum and didymium succeeds, however, only when cerium is present; in the contrary case only a small quantity of didymium oxide is precipitated.

For the separation of lanthanum and didymium from cerium, see also CERUM (p. 419).

LANTHOPINE. $C^{23}H^{23}NO^4$ (Hesse, *Ann. Ch. Pharm.* cliii. 57; *Chem. Centr.* 1870, 168).—A base homologous with papaverine, contained in small quantity, together with others, in the aqueous extract of opium. The mode of preparing it given under OPIUM-BASES (*q. v.*) is founded on the fact that lanthopine does not neutralise acetic acid, whereas the other bases present in the aqueous solution form neutral salts therewith: hence lanthopine is precipitated when the acetic solution of the whole of these bases is exactly neutralised with ammonia.

Lanthopine is a white powder consisting of microscopic prisms, or fan-shaped groups of prisms, sometimes a centimetre long; tasteless; does not alter the colour of litmus. Heated to 190° , it turns brown and gradually decomposes. It is insoluble in water, nearly insoluble in alcohol, very slightly soluble in ether and benzol, but dissolves pretty easily in *chloroform*, and separates therefrom on evaporation in small white prisms.

Lanthopine does not neutralise acids completely. It is precipitated from the solutions of its salts by *potash-ley* and *milk of lime*, and redissolved by an excess of the reagent; also by *sal-ammoniac*, like morphine and pseudomorphine; but it differs from these bases in not forming a blue solution with ferric chloride. *Chloroform* extracts it from the lime solution, but not from the potash solution till after addition of *sal-ammoniac*. Strong *nitric acid* dissolves it with orange-red colour; strong *sulphuric acid* with faint violet colour; acetic acid dissolves it with difficulty.

Sulphate of lanthopine forms extremely thin needles resembling *narceine* in appearance. The *hydriodide* is a white amorphous precipitate, melting, and ultimately dissolving, in hot water, easily soluble in alcohol. The *hydrochloride*, $C^{23}H^{23}NO^4 \cdot HCl + 6H^2O$, forms extremely thin needles resembling *narceine*, appearing like a jelly in mass, easily soluble in boiling water. The *platinochloride*, $2(C^{23}H^{23}NO^4 \cdot HCl) \cdot PtCl^4 + 2H^2O$, is a crystalline powder insoluble in water, alcohol, and hydrochloric acid.

LAUDANINE. $C^{20}H^{23}NO^3$ (Hesse, *Ann. Ch. Pharm.* cliii. 527).—A base homologous with morphine and codeine, also contained in the aqueous extract of opium. For its preparation, see OPIUM-BASES.

It crystallises from hot dilute alcohol in stollate groups of small, colourless, six-sided prisms, terminated at both ends by domes. Melts at 165° ; solidifies in the crystalline state on cooling; not sublimable. Tasteless. In the crystalline state it dissolves easily in *benzol*, *chloroform*, and boiling *alcohol*; sparingly in cold alcohol, still less in *ether* (1 pt. in 540° at ordinary temperatures); in the amorphous state, that is when recently precipitated, it is much more soluble.

The salts of laudanine have a bitter taste. From their solutions *potash* and *ammonia* precipitate the base in white amorphous flocks, which soon become crystalline and dissolve in excess of the precipitant; *chloroform* extracts it from the ammoniacal but not from the potassic solution. Laudanine dissolves in strong *sulphuric acid* with rose-red colour, in strong *nitric acid* with orange-red colour, and in *ferric chloride* with emerald-green colour.

Sulphate of laudanine forms concentric groups of needles very soluble in water. The *hydriodide* forms groups of white crystals, strung together like a necklace, easily soluble in boiling water. The *hydrochloride* crystallises in delicate colourless prisms, easily soluble in water and in alcohol, less soluble in solution of common salt. The

mercurochloride is a white precipitate, somewhat soluble in boiling water, and separating therefrom in spherical groups of crystals. The *platinochloride*, $2(\text{C}^2\text{H}^2\text{NO}^2 \cdot \text{HCl}) \cdot \text{PtCl}^4 + 2\text{H}^2\text{O}$, is a yellow amorphous precipitate, easily soluble in water, especially at the boiling heat. *Sulphocyanate of laudanine* forms white crystalline nodules moderately soluble in boiling water. The *oxalate* crystallises in delicate, concentrically grouped, colourless needles, somewhat sparingly soluble in cold water.

LAURENE or **LAUROL**. C^8H^{14} .—See BENZENE, HOMOLOGUES OF (p. 304).

LAURIC ACID, $\text{C}^{18}\text{H}^{34}\text{O}^2$, is one of the constituents of the crude oil of bay (Blas, *Ann. Ch. Pharm.* cxxiv. 1).

LAURITE. A sulphide of ruthenium and osmium, occurring in the platinum ore of Borneo. It forms very small grains or globules, of iron-black colour and strong lustre, and exhibiting faces of the regular octohedron, cube, and other forms of the regular system; very hard and brittle; with perfect octohedral cleavage and flat-conchoidal fracture; harder than quartz; sp. gr. greater than 6. Decrepitates like galena when heated; does not fuse before the blowpipe, but gives off the odour of sulphurous oxide and afterwards of osmic oxide. It is not attacked even by nitromuriatic acid, or by ignition with acid potassium sulphate, but when fused in a silver crucible with potassium hydrate and nitrate, it dissolves with greenish colour, and the product yields to water a solution containing ruthenium and osmium. The mineral ignited in a stream of hydrogen gives off hydrogen sulphide, but no water. Analysis gave 31.79 p. c. sulphur, 65.18 ruthenium, and 3.03 osmium, agreeing nearly with the formula $\text{Os}^4 \cdot 12\text{Ru}^2\text{S}^3$ (Wöhler, *Ann. Ch. Pharm.* cxxxix. 116; *Jahresb.* 1865, p. 913). Laurite is also contained in the platinum ore of Oregon (Wöhler, *Zeitschr. f. Chem.* [2] vi. 85).

LAUROXYLIC ACID, $\text{C}^8\text{H}^{10}\text{O}^2$.—An acid isomeric with xylic or xylylic acid (v. 1062), produced by the action of dilute nitric acid on laurene. It is nearly insoluble in cold, slightly soluble in boiling water, easily in alcohol, and separates from the hot aqueous solution as an indistinct crystalline powder, from alcohol in hard nodules. Melting point 135° . The *barium salt*, $(\text{C}^8\text{H}^8\text{O}^2)^2\text{Ba} + 4\text{H}^2\text{O}$, and the analogously constituted *calcium salt*, are easily soluble in water, and crystallise in concentrically grouped needles; the *silver salt*, $\text{C}^8\text{H}^8\text{O}^2\text{Ag}$, is a white precipitate, crystallising in small quantity from hot water.

Lauroxylic acid is further oxidised by chromic acid, the ultimate product being apparently acetic acid. Its constitution and relation to laurene are probably represented by the following equation:

(Fittig, Köbrich, a. Jilke, *Ann. Ch. Pharm.* cxlv. 129).

LAWROWITE. A mineral occurring near the river Sljudjanka in Russia, in emerald-green crystals, having the form of pyroxene, with cleavage parallel to the faces of a rhombic prism of $87^\circ 7'$. It contains silica, lime, and magnesia, with small quantities of alumina and iron, traces of manganese, and vanadium as colouring matter (Kokscharow, *Jahresb.* 1866, p. 927).

LAZULITE. A summary of the known facts relating to lazulite and ultramarine is given by Schützenberger (*Bull. Soc. ind. de Mulhouse*, mars 1865, p. 97; *abstr. Bull. Soc. Chim.* [2] iii. 455).

LEAD. On the physical properties of pure and impure lead, and on the impurities of commercial lead, see W. Baker (*Practical Mechanic's Journal*, 1864, April 7; *Report 33 of British Assoc., Notices and Abstracts*, p. 32; *Dingl. pol. J.* clxxiii. 119, 122; *Jahresb.* 1864, p. 474).

When granulated lead is boiled with pure water, a slow but continuous evolution of hydrogen takes place (1 to 2 c. c. in ten minutes when 10 to 20 grm. lead are used), the liquid becoming turbid from formation of hydrated lead oxide, and acquiring a strong alkaline reaction. Hydrochloric acid of sp. gr. 1.2 in contact with pure lead gives off hydrogen even at ordinary temperatures, more abundantly when heated, and with the finely divided metal. The evolution of hydrogen from the hydrochloric acid is greatly accelerated, especially at first, by placing metallic copper in contact with the lead. Sulphuric acid of 20 p. c. does not give off hydrogen under the same circumstances (Stolba, *J. pr. Chem.* xciv. 113).

According to Langlois (*J. Pharm.* [4] li. 320), the protection of lead from the action of ordinary water is chiefly due to the presence of calcium bicarbonate. The lead taken up by water which does not contain the carbonates of alkaline earths, such as distilled or rain water, is not dissolved, but suspended, in the form of basic carbonate, and, like the corresponding zinc compound, may be separated by a thick double paper filter, as effectually as by a charcoal filter. In river water, lead becomes covered with a compact film of suboxide, which protects the metal from further action.

From experiments by Stalman (*Dingl. pol. J.* clxxx. 366; *Jahresb.* 1866, p. 230), it appears that perfectly pure distilled water does not act upon lead, but that the action takes place when the water contains very small quantities of volatile substances (ammonia or nitric acid). The action on the lead requires, moreover, access of air and of free carbonic acid; if the air is completely excluded (as when the lead is placed in a bottle quite full of water), or if the carbonic acid is removed by an absorbing agent, no action takes place. The deposit formed is a mixture of basic carbonates of lead, and the water filtered therefrom is quite free from lead. According to Böttger, also (*Jahresb.* 1866, p. 232), the formation of this deposit is favoured by the presence of a very small quantity of ammonium carbonate in the water, while water perfectly purified by distillation with sulphuric acid has no action on pure lead.

According to Reichelt (*Dingl. pol. J.* clxxii. 155), pure lead immersed in a solution of common salt becomes covered with a crust of hydrate and carbonate of lead, a portion also being dissolved; common commercial salt acts in this manner more quickly than pure sodium chloride. Damp salt in contact with lead or plumbiferous tin also quickly takes up lead.

Estimation.—For the estimation of lead, either in soluble or in insoluble compounds, Stolba (*J. pr. Chem.* ci. 150) beats the compound in a platinum dish with dilute hydrochloric acid and pure zinc till the lead is completely reduced. The spongy lead thus separated is washed on the dish with water containing a drop of sulphuric acid, then dried at 150°–200° and weighed. The oxide thereby produced is dissolved out by cold water containing from 2 to 4 cub. cent. of standard nitric acid, and the quantity of lead thereby dissolved is determined by inverse titration of the remaining nitric acid.

For the *volumetric estimation* of lead, H. Schwarz (*Zeitschr. anal. Chem.* ii. 378, 392; *Jahresb.* 1863, p. 685) precipitates it with a solution of potassium dichromate containing 14·730 grm. of the salt in a litre, each cub. cent. of such a solution corresponding to 0·0207 grm. of lead, and determines the end of the precipitation by mixing a drop of the liquid from which the precipitate has separated with a drop of a solution of silver nitrate on a porcelain plate, whereby a red coloration is produced as soon as the chromate solution is in excess. For this excess a deduction of 1 c. c. is made from the volume of chromate solution used.

The separation of lead from *bismuth* may be effected by means of a solution of ammonio-thallic chloride (v. 748), which precipitates bismuth, but not lead, excepting from the basic acetate (Nicklès, *Bull. Soc. Chim.* [2] v. 49).

Lead may be detected in presence of *silver*, and separated from that metal, by the insolubility of lead chromate in sodium hyposulphite. When a solution containing a little lead and much silver is mixed with excess of sodium hyposulphite, and then with a small quantity of potassium chromate, the whole of the lead is precipitated as chromate (Chancel, *Jahresb.* 1866, p. 803).

The desilvering of lead is facilitated, according to Blagden (*Mechanic's Magazine*, Sept. 1867; *Dingl. pol. J.* clxxxvi. 474), by dissolving about $\frac{1}{4}$ p. c. zinc in the refined metal melted at 540°, and passing a galvanic current through it by means of copper wires for 10 to 30 minutes, or till all the zinc has risen to the surface. This crust of zinc contains the silver, and may be removed after the melted mass has cooled to 450°. For satisfactory desilverisation (to about $\frac{1}{500}$ p. c.) the operation must be repeated several times.

Compounds of Lead.

Chloride. PbCl_2 .—The solubility of this salt in water and in aqueous hydrochloric acid has been determined by J. C. Bell (*Chem. Soc. J.* [2] xvi. 350; *Chem. News*, xvi. 69): 1 pt. of lead chloride dissolves in 105·2 pts. water at 16·5°, the resulting solution containing 0·9414 p. c. PbCl_2 . The quantities dissolved by aqueous hydrochloric acid of various strengths are given in the following table:

Quantity of Hydrochloric acid of sp. gr. 1.1162 in 100 pts. of water	Quantity of PbCl ² dissolved at 17.7° by 100 pts. of liquid	Quantity of Hydrochloric acid of sp. gr. 1.1162 in 100 pts. of water	Quantity of PbCl ² dissolved at 17.7° by 100 pts. of liquid
1	0.347	15	0.090
2	0.201	20	0.111
3	0.165	30	0.161
4	0.145	40	0.216
5	0.131	50	0.356
6	0.107	60	0.559
7	0.100	70	0.933
8	0.099	80	1.498
9	0.096	90	2.117
10	0.093	100	2.900

It appears from this table that the dilute acid containing 1.5 p. c. of acid of sp. gr. 1.1162 exhibits a minimum power of dissolving lead chloride at the temperature above specified. For a more extended table see the paper in the *Chemical Society's Journal*.

It is commonly stated that lead chloride crystallises in needles, but according to Bell's observations, the needle-shaped crystals are obtained only from solution in weak hydrochloric acid, whereas from pure water the salt separates in wedge-shaped crystals, and from strong hydrochloric acid in rhombic crystals. The form of the crystals was, however, determined more exactly several years ago by Schabus (*Wien. Akad. Ber.* 1850, April, p. 456), who found that a solution of lead chloride in hydrochloric acid yields by spontaneous evaporation distinct crystals belonging to the rhombic system, and exhibiting the combination $P.2P.\infty P.\infty .4P.\infty .\infty P.\infty$, and often becoming needle-shaped by predominance of the faces $P.2P.\infty P$ lying in one zone. Angles $P:P$ in the terminal edges = $134^{\circ} 24'$ and $98^{\circ} 46'$; in the lateral edges = $98^{\circ} 31'$. Cleavage perfect parallel to ∞P . Sp. gr. = 5.802.

A solution of lead chloride mixed with the chloride of an alkali-metal, and especially with calcium chloride, absorbs a large quantity of chlorine gas, forming a deep yellow solution which may be preserved for a long time in a closed vessel, even if not protected from the solar rays, but in an open vessel is resolved into lead chloride and free chlorine. When added by drops to a large quantity of water, it yields a precipitate of lead dioxide and lead chloride. The dioxide is also precipitated from it by caustic alkalis and alkaline carbonates. With manganous chloride it forms a precipitate of lead chloride and manganese dioxide. It quickly dissolves copper, iron, zinc, gold-leaf, and finely divided platinum, and violently oxidises organic bodies, in all cases with separation of lead chloride, $PbCl_2$. The yellow solution probably contains an unstable tetrachloride of lead, which cannot exist in the separate state. On this supposition the reaction with water may be represented by the equation: $PbCl_4 + 2H_2O = 4HCl + PbO_2$ (Sobrero a. Selmi, *Ann. Ch. Pharm.* lxxvi. 234. Nicklès, *Compt. rend.* lxiii. 1118; *Jahresb.* 1866, p. 232).

Iodide. PbI_2 .—This compound in the dry state is not affected by light, and even when moist it undergoes decomposition only in direct sunshine and in contact with the air, iodine being separated, and carbonate and dioxide of lead produced. This decomposition is extremely slow with pure lead iodide, but is accelerated by all substances which absorb iodine. Lead chloride is not altered by light (W. Schmid, *Pogg. Ann.* cxvii. 493).

Oxide. PbO .—The hydrate, $3PbO.H_2O$, may be obtained in strongly refracting octohedral crystals, by mixing 100 vol. of an aqueous solution of the basic acetate, $3PbO.C^4H^3O^2 + H_2O$ or $2PbO.C^4H^3PbO^4 + H_2O$ (p. 11), with 50 vol. of deaerated water, and then with a mixture of 20 vol. ammonia and 30 vol. water, and leaving the solution exposed to a temperature of 25° – 30° . When a mixture of 100 vol. of the solution of the triplumbic acetate saturated at 15° to 16° , and 50 vol. water boiled for a short time and then left to stand in boiling water, is mixed with 3 vol. ammonia and 20 vol. water previously heated to 80° , anhydrous lead oxide is deposited in the course of a minute, in yellowish rhomboidal lamellæ which unite in radiate groups (Payen, *Ann. Ch. Phys.* [4] viii. 302).

An alkaline solution of lead oxide is precipitated by alkaline solutions of *chromic, stannic, stannous, antimonious, and arsenious oxides*. The precipitate formed under these circumstances by arsenious oxide is the triplumbic arsenite $Pb_3As_2O_7$ (Streng, *Ann. Ch. Pharm.* cxxix. 238).

Sulphide. PbS .—Hydrogen sulphide passed into lead solutions sufficiently acidulated with nitric acid, immediately forms a heavy pulverulent precipitate formed of

microscopic cubes resembling galena. A solution of 3 grms. lead nitrate in 250 c. c. 10 p. c. nitric acid, gave at 15° cubes measuring 0.19 mm.; at 40°-90° cubes of 0.025 to 0.028 mm. in the side. Solutions prepared in the same proportions, but with nitric acid of 1 p. c., yielded first a granular or amorphous precipitate; afterwards, when the quantity of free acid had increased in proportion to the lead salt, a crystalline precipitate. Lead solutions strongly acidulated with acetic acid give, on the other hand, with hydrogen sulphide, an amorphous precipitate. The iridescent film which is formed in the precipitation of neutral or slightly acid solutions by hydrogen sulphide, and dries up to shining spangles, is likewise non-crystalline. Roll-sulphur left for some time in a solution of lead oxide in caustic potash, produces, together with amorphous lead sulphide, cubes of this compound large enough to be distinguished by the naked eye (F. Muck, *Zeitschr. f. Chem.* [2] iv. 241).

LECANORIC ACID. $C^{16}H^{14}O^7$.—Hesse (*Ann. Ch. Pharm.* cxxxix. 22) prepares this acid from *Roccella fuciformis* or *R. tinctoria* by exhausting the lichen with ether, dissolving the greenish-white crystalline residue left on evaporation in milk of lime, precipitating the filtrate with sulphuric acid, washing the precipitate with water, and recrystallising it from hot alcohol. The exhaustion of the lichen in the first instance by milk of lime, Hesse finds less advantageous, because the acid separated from the gelatinous solution is contaminated with a yellow-brown colouring matter which can only be removed by repeated crystallisation from alcohol. In either case the purified acid must be treated with a quantity of ether less than sufficient to dissolve it, whereby a difficultly soluble substance is removed. The ethereal solution is then evaporated, and the residue again crystallised from hot alcohol.

The acid thus prepared has the composition $C^{16}H^{14}O^7$, H^2O assigned to it by Schunck, and easily gives off its water (5.35 p. c.) at 100°. 1 pt. of the acid dissolves in 24 pts. ether at 20° (according to Schunck in 80 pts. at 15°); it melts at 153° to a colourless liquid which quickly decomposes, with evolution of carbon dioxide. By passing this gas through a solution of the acid in baryta-water, a very stable solution of barium lecanorate is obtained; this reaction affords a means of separating lecanoric acid from erythrin. When the solution of this barium salt is boiled with excess of baryta till it no longer yields a gelatinous precipitate with hydrochloric acid, it deposits on cooling crystals of orsellinic acid. By boiling lecanoric acid with alcohol, ethyl orsellinate is produced:

but the quantity of this ether obtained is always less than the theoretical amount (57.6 instead of 61.6 p. c.), because part of the lecanoric acid is decomposed by the water in the alcohol, in the manner shown by the equation:

With amylc alcohol in like manner amyl orsellinate is produced.

Grimaux (*Bull. Soc. Chim.* [2] iii. 410), regarding orsellinic acid as a monobasic but trinitric acid, $\left\{ \begin{array}{c} C^8H^6O^4 \\ H^3 \end{array} \right\} O^3$ (inasmuch as it is converted by abstraction of CO^2 into the diatomic compound, orcin, $C^8H^6(OH)^2$), represents lecanoric acid by the formula $\left\{ \begin{array}{c} C^8H^6O^4 \\ C^8H^6O^4 \\ H^4 \end{array} \right\} O^3$.

Dibromolecanoric acid, $C^{16}H^{12}Br^2O^7$, is produced by mixing the ethereal solution of lecanoric acid by small portions with an ethereal solution of bromine, till the latter is but slowly absorbed. By washing the evaporation-residue with water, and recrystallising from hot alcohol with addition of animal charcoal, it is obtained in white crystals insoluble in water, less soluble in alcohol and ether than lecanoric acid, and producing in alcoholic solution a purple-violet colour with ferric chloride, blood-red with chloride of lime. It melts at 175°, with evolution of carbon dioxide, and is decomposed by boiling with baryta-water, yielding barium bromide and carbonate, and a yellow substance (Hesse).

Tetrabromolecanoric acid, $C^{16}H^{10}Br^4O^7$, is formed by dropping bromine into an ethereal solution of lecanoric acid, and crystallises from alcohol in pale yellow prisms melting at about 157°, easily soluble in alcohol, ether, ammonia, and baryta-water, and precipitated from the latter by acids in the form of a yellowish oil. Its alcoholic solution has an acid reaction, and reacts with ferric chloride and

chloride of lime like that of the dibrominated acid. Boiled with baryta-water it yields barium bromide and carbonate, together with a yellow resinous substance (Hesse).

LECITHINE (Diakonow, *Centralbl. f. die med. Wissensch.* 1867, No. 1 and 7; *Med.-chem. Unters.* ii. 221; *Zeitschr. f. Chem.* [2] iv. 154. Strecker, *Zeitschr. f. Chem.* [2] iv. 437).—This name was applied by Gobley to a phosphoretted fatty body which he supposed to exist in the yolk of eggs, the brain, bile, blood, &c., but did not succeed in isolating (iii. 567). Phosphoretted fats, existing in the brain and other parts of the animal organism, have also been described as *oleophosphoric acid* and *protagon*. These phosphoretted compounds were shown by Gobley to yield by saponification fatty acids and glycerophosphoric acid, and Liebreich obtained from his protagon a strong base, called neurine or choline (p. 448). More recently, Diakonow has obtained from the yolk of hens' eggs, and from the eggs of the sturgeon, a definite phosphoretted fat, having the composition $C^{51}H^{120}NPO^8 + H^2O$, and resolved by boiling with baryta-water into stearic acid, glycerophosphoric acid, and neurine. This substance, designated especially as lecithine, is regarded by Diakonow as a saline compound of neurine. In accordance with this view, Strecker finds that the ethereo-alcoholic extract of egg-yolk gives with an alcoholic solution of platine chloride containing free hydrochloric acid, a yellow flocculent precipitate consisting of a compound of platine chloride with lecithine. This precipitate decomposed by hydrogen sulphide yields a hydrochloride of lecithine; and on agitating the alcoholic solution of this salt with silver oxide, and treating the filtrate with hydrogen sulphide to remove dissolved silver, lecithine is obtained in the form of a waxy substance. The ethereo-alcoholic extract of egg-yolk also yields with cadmium chloride a precipitate of a double salt, from which lecithine may be obtained.

Lecithine thus prepared, when boiled with baryta-water, yields choline, together with glycerophosphoric, oleic, and palmitic acids, and probably small quantities of stearic acid. It appears, therefore, to contain, not merely a single fatty acid, but, like most animal fats, oleic acid, together with solid fatty acids, among which palmitic acid is the most abundant. There are probably, therefore, many varieties of lecithine and numerous mixtures of those varieties.

Strecker represents the lecithines by the general formula:

The particular lecithine examined by Strecker agreed nearly with the formula $C^{51}H^{120}NPO^8$, obtained by substituting, in the first term of the preceding formula, 1 mol. palmitic acid and 1 mol. oleic acid, whereby it becomes $\frac{C^{51}H^{120}O^{12}}{C^{51}H^{118}O^{12}}$. This formula agrees also nearly with Diakonow's analysis of lecithine:

	Cale.	Strecker	Diakonow
C ⁵²	64.8	64.6	64.3
H ⁸¹	10.6	10.7	11.4
N	3.9	4.0	3.8
P	1.8	—	1.8

Choline, which, as shown by Wurtz, may be obtained from ethylene oxide and trimethylamine hydrochloride (p. 448), may be regarded as an alcoholic base and represented by the formula

and lecithine may be regarded as a salt of this base, represented by the formula

containing the residues of palmitic acid, oleic acid, and glycerophosphoric acid:

Strecker has further pointed out that Liebreich's protagon, which also yields

choline by decomposition with alkalis, has the composition of a mixture of lecithine with a non-phosphoretted substance, probably cerebrin:

Lecithine (Diakonow)	Protagon (Liebreich)	Cerebrin (Müller)
64.37	66.2 to 67.4	68.45
11.40	11.1 „ 11.9	11.27
1.80	2.7 „ 2.9	4.61
3.80	1.1 „ 1.5	—
18.73	—	15.67
100.00		100.00

LECYTHIS. See SAPUCAIA (v. 195).

LEGUMIN. The composition of this proteide has recently been examined by Ritthausen (*Zeitschr. f. Chem.* [2] iv. 541). It was prepared by macerating the pulverised seeds of peas, beans, lentils, and vetches, with cold water (in some cases with addition of a little alkali); precipitating the strained liquid with acetic acid; washing the precipitate on a filter with alcohol of 49 to 50 p. c., which caused it to shrink and separate easily from the filter; again exhausting the separated lumps with alcohol, then with ether; removing the liquid as completely as possible by pressure; and finally drying the mass in a vacuum over sulphuric acid. The purity of legumin may be known by the three following characters taken together: 1. It dissolves completely in water.—2. Boiled for a few minutes with sulphuric acid diluted with an equal bulk of water, it forms a clear brown-yellow solution, which remains clear on addition of more water.—3. On dissolving it in water containing potash, adding a few drops of solution of cupric sulphate and then a few drops of potash-ley, a violet or reddish-violet colour is produced. Legumin which does not fulfil all these conditions may be purified by solution in weak aqueous potash (containing 1 to 2 p. c. KHO) and reprecipitation.

Legumin, free from ash, obtained from peas, lentils, vetches, and field-beans, gave by analysis in 100 pts.:

C	H	N	O	S
51.48	7.02	16.77	24.33	0.40;

that from garden-beans gave

51.48	6.92	14.71	26.35	0.45.
-------	------	-------	-------	-------

The phosphorus in legumin appears to be in the form of phosphoric acid. The possibility of extracting legumin from the seeds by water appears to depend on the presence of mineral substances, especially of tripotassic phosphate and free potash, both of which in aqueous solution easily dissolve pure legumin. Wheat-flour and soft peas do not contain basic phosphates, and from these the protein-substance cannot be dissolved out by water.

Legumin treated with sulphuric acid yields tyrosine, leucine, glutamic acid (p. 636), active aspartic acid (formerly regarded by Ritthausen as a peculiar acid, and called *legamic acid*), and brown amorphous substances.

Substances very closely allied to the legumin of peas, beans, &c., but exhibiting slight diversities in composition and physical properties, are obtained from almonds, the kernels of plums, apricots, and hazel-nuts, white mustard, the seeds of lupines, and oats. The legumin of almonds and lupines (Ritthausen's *conglutin*) is richer in nitrogen (16.65 to 18.93 p. c.) than that of pulse; it is also more glutinous and more soluble in acetic acid (Ritthausen, *J. pr. Chem.* ciii. 65, 78, 193, 273; *Zeitschr. f. Chem.* [2] iv. 528, 541; vi. 126; *Gmelin's Handbook*, xviii. 427–437).

LEPIDENE. $C^{20}H^{32}O$ (Zinin, *Ann. Ch. Phys.* [4] xii. 111; *Jahresb.* 1867, p. 416. Limpricht, *Zeitschr. f. Chem.* [2] v. 336. Dorn, *ibid.* 597).—This compound is formed, together with dibenzyl and an oily body, when benzoïn ($C^{14}H^{10}O^2$) is heated for several hours to 130° with 1½ pt. of fuming hydrochloric acid saturated at + 8°, whereby the benzoïn is converted into an oily body which floats on the surface, and on opening the tube immediately solidifies to a yellow laminar mass. More dilute acid acts only at 170°. The laminar mass is resolved by treatment with solvents into lepidene (28 p. c.), sparingly soluble in alcohol and ether, and partly remaining undissolved when the product is treated with ether, partly crystallising in white scales when the ethereal solution is mixed with alcohol and the ether is distilled off; benzyl (about 40 p. c.), which crystallises from the yellow solution; and a thick oil insoluble in water, but easily soluble in alcohol and ether.

Lepidene is insoluble in water, soluble in 170 pts. of boiling, scarcely soluble in

1,000 pts. of cold alcohol of 94 p. c.; soluble in 38 pts. of boiling and about 52 pts. of cold ether; in 28 pts. boiling and about 500 pts. cold glacial acetic acid; in 2 pts. hot and 1 pt. cold benzol. From solution in alcohol or acetic acid, it crystallises in feathery or laminated groups of flat needles; melts somewhat above 175° to a colourless liquid; and solidifies again in the crystalline form only when the temperature has not been raised above a certain point. At 220° it boils and may be distilled undecomposed in quantities not exceeding 10 grams. It is not decomposed by alcoholic pot. sh-solution or even by fusion with potassium hydrate. Nitric acid of sp. gr. 1.3 converts it into oxylepidene. When gently heated with phosphorus pentachloride, it forms a reddish liquid, which solidifies when washed with water, dissolves easily in alcohol and ether, and crystallises therefrom in needles (Ziinin).

Dibromolepidene, $C^{28}H^{18}Br^2O$, is formed on adding bromine in slight excess to a solution of lepidene in acetic acid, and separates in needle-shaped crystals insoluble in water, soluble in 410 pts. of hot alcohol, 66 pts. of boiling acetic acid, and 50 pts. of boiling ether, and crystallises therefrom in thin tables or laminae. It melts at 190° , and solidifies in the crystalline or amorphous state, according to the temperature to which it has been raised. With nitric acid it forms a needle-shaped body which reacts similarly to oxylepidene.

Oxylepidene, $C^{28}H^{16}O^2$, is most readily prepared by heating lepidene to the boiling point with 10 pts. of glacial acetic acid, and adding a mixture of 1 pt. nitric acid of sp. gr. 1.5 and 3 pts. glacial acetic acid, the oxylepidene then crystallising out on cooling. It forms yellow needles (4-sided prisms) insoluble in water, nearly insoluble in ether and cold alcohol, soluble in 200 pts. of boiling alcohol of 94 p. c., in 22 pts. of hot acetic acid, and easily in benzene. It melts at 220° and resolidifies in the crystalline form on cooling; but after being heated to its boiling point, it forms on cooling a yellow resinous substance, easily soluble in alcohol and ether, and separating therefrom with different properties. Oxylepidene dissolved in hot acetic acid is completely reduced by zinc to lepidene; by boiling with alcoholic potash-solution it is converted into a crystalline body, separable by water and differing in its properties from oxylepidene (Ziinin).

Lepidene and oxylepidene are analogous in composition to thionessal and tolalyl sulphide; thus:

Lepidene, $C^{28}H^{20}O$
Thionessal, $C^{28}H^{28}S$

Oxylepidene, $C^{28}H^{20}O^2$
Tolalyl sulphide, $C^{28}H^{28}S^2$

and may be formed from thionessal and tolalyl sulphide respectively by treatment with hydrochloric acid and potassium chlorate (Limpricht).

Oxylepidene is converted by the most various reducing agents into lepidene, but the latter cannot be deprived of any further portion of oxygen, even by passing it over heated zinc-powder. Oxylepidene heated with phosphorus pentachloride yields the same products as lepidene, namely, chlorinated derivatives of the latter. The following compounds have been obtained by Dorn:

Dichloroxylepidene, $C^{28}H^{18}Cl^2O^2$, is prepared by treating dichlorothionessal with hydrochloric acid and potassium chlorate. It forms white needles melting at 178° , and is converted by reducing agents into dichlorolepidene, $C^{28}H^{18}Cl^2O$, which forms white needles melting at 166° .

Oxylepidene heated in sealed tubes with phosphorus pentachloride, or (to diminish the pressure) with phosphorus oxychloride, yielded:

1. *Pentachlorolepidene*, $C^{28}H^{16}Cl^5O$, in white crystals melting at 186° , very slightly soluble in alcohol and ether.—2. *Hexachlorolepidene*, $C^{28}H^{14}Cl^6O$, a yellow amorphous substance, melting at 80° – 90° , easily soluble in alcohol and ether.—3. *Octachlorolepidene*, $C^{28}H^{12}Cl^8O$, an orange-yellow amorphous substance, softening at 70° , melting at 97° , easily soluble in alcohol and ether.

LEPIDOMELANE. This variety of mica, hitherto found only at one locality in Sweden (iii. 574), occurs, together with danalite, another variety of mica called *cryophyllite*, and a zircon-like mineral, in the granite of Rockport, Massachusetts. The lepidomelane occurs in black six-sided prisms with dark green streak, hardness about 3, and sp. gr. 3.169. Analysis gave:

SiO ²	SP ²	Al ² O ³	Mn ² O ³	Fe ² O ³	FeO	MgO	K ² O	Li ² O	H ² O
39.55	0.62	16.73	0.60	12.07	17.48	0.62	10.66	0.69	1.60 = 100.42,

agreeing with the general formula $(M'; M'')SiO_4$ (J. P. Cooke, jun., *Sill. Am. J.* [2] xliii. 217).

LEUCANILINE. On the methylated derivatives of this base, produced by the decomposition of iodine-green, see ANILINE (p. 164).

LEUCHTENBERGITE. According to an analysis of this mineral from the Chichime mountains in the Ural, by Duke Nicolas von Leuchtenberg (*N. Petersb. Acad. Bull.* ix. 188; *Jahresb.* 1865, p. 891), it appears to be a distinct mineral species allied to the chlorites.

LEUCIC ACID. $\text{C}^6\text{H}^{12}\text{O}^3 = \begin{array}{c} \text{C}^6\text{H}^{10}\text{OH} \\ | \\ \text{COOH} \end{array}$.—Geuther (*Jahresb.* 1867, p. 454) has

pointed out the following differences between the salts of this acid and those of its isomeride, diethoxalic acid (iv. 273). The ammonium salt of diethoxalic acid crystallises by spontaneous evaporation over sulphuric acid in large laminae; ammonium leucate is amorphous. Zinc diethoxalate forms wavelitic groups of needles, anhydrous, less soluble in alcohol than in water; zinc leucate crystallises in scales containing 1 mol. water, more soluble in hot alcohol than in water. Cupric diethoxalate is easily soluble and uncrystallisable; the leucate is a sparingly soluble precipitate. Silver diethoxalate contains 1 mol. water; silver leucate is anhydrous.

LEUCINE or AMIDOCAPROIC ACID. $\text{C}^6\text{H}^{13}\text{NO}^2 = \begin{array}{c} \text{C}^6\text{H}^{10}(\text{NH}^2) \\ | \\ \text{COOH} \end{array}$.—This

compound heated in a sealed tube with fuming hydriodic acid is decomposed, with formation of caproic acid and ammonium iodide, and separation of iodine:

Conversely it is produced synthetically by heating bromocaproic acid with strong aqueous ammonia to 120°–130° for five or six hours in a sealed tube:

(Hüfner, *Zeitschr. f. Chem.* [2] iv. 391, 616).

In the preparation of leucine by the action of hydrochloric and hydrocyanic acids on valeral-ammonia (iii. 581), the crystalline hydrochloride of the base $\text{C}^6\text{H}^{13}\text{N}^3$, discovered by H. Strecker (*Jahresb.* 1864, p. 417), is first produced, and this base, by prolonged contact with hydrochloric acid, is resolved into ammonia and leucine:

and

After the excess of hydrochloric acid has been removed by evaporation, the greater part of the leucine may be precipitated by ammonia; the portion remaining in solution may be recovered by evaporating, redissolving in hydrochloric acid, and again precipitating with ammonia. The removal of the sal-ammoniac by lead-hydrate, as in Limpricht's process (iii. 580), is not to be recommended, because leucine forms a sparingly soluble compound with lead oxide. Leucine solutions boiled with cupric acetate form a blue crystalline precipitate of copper-leucine.

Leucine melts at 210°, and when heated to 220°–230° is converted, with loss of weight amounting to about 20 p.c., into leucimide, $\text{C}^6\text{H}^{11}\text{NO} = (\text{C}^6\text{H}^{10}\text{O})^{\text{NH}}$, which after repeated crystallisation from alcohol, forms slender needles, subliming in white flocks without previous fusion. Sal-ammoniac and a small quantity of amylamine are formed at the same time as secondary products (Köhler, *Ann. Ch. Pharm.* cxxxiv. 36).

LEUCOPYRITE. This name is given by Zepharovich (*Jahresb.* 1867, p. 973) to an arsenide of iron, Fe^4As^4 , occurring, together with löllingite, (Fe^4As^4), in the siderite vein at Hüttenberg in Carinthia. It is found also in a sparry siderite in the Schwarzgrubner vein at Przibram.

LEUCOROSOLIC ACID. See ROSOLIC ACID.

LEVULIN. See LÄVULIN.

LIGHT. *Relations between Refractive Power and Chemical Composition.*—The researches of Gladstone and Dale, of which an account is given in the article LIGHT (iii. 624–631), showed: 1. That the specific refractive energy of a liquid—expressed by the formula $\frac{\mu-1}{d}$, in which μ is the index of refraction, and d the density—is nearly a constant quantity unaffected by change of temperature.—2. That the specific refractive energy of a mixed liquid is approximately the mean of the specific refractive energies of its constituents.—3. That isomeric bodies exhibit in many instances equal specific refractive energies.—4. That in compounds belonging to the same homologous

series, the specific refractive energy increases as the series advances, but that the amount of its variation is less between the higher than between the lower terms of the series.

Landolt (*Pogg. Ann.* cxxii. 545; cxxiii. 595; *Jahresb.* 1864, p. 101) simplifies the expression of these relations, especially of the last, by adopting, instead of the specific refractive energy, the product of this fraction by the molecular weight of the compound,

$P \cdot \frac{\mu - 1}{d}$; this is called the refraction-equivalent. In homologous series the refraction increases in all cases for a difference of CH_2 , by a nearly equal amount, the mean increment in the fatty acids, alcohols, &c., being 7.60. The first and third of the above laws remain true for refraction-equivalents to the same extent as for specific refractive energies. The expression of the second becomes: *The refraction-equivalent of a mixture or compound is the sum of the refraction-equivalents of its components.*

This last law gives the means of determining the refraction-equivalents of elements from those of their compounds. Landolt has shown, by comparison of the optical properties of a large number of organic compounds, that the refraction-equivalent is increased by addition of either carbon, hydrogen, or oxygen, but by somewhat different amounts according to the type to which the compound belongs, these values varying for C from 4.75 to 5.43, for H from 1.06 to 1.33, for O from 2.45 to 3.24. The mean refraction-equivalents of these three elements in the homologous fatty alcohols and acids are:

C	H	O*
5.00	1.30	3.00

By means of these values, the refraction-equivalent R of a compound of carbon, hydrogen, and oxygen may be calculated according to the formula,

$$R = nr + m'r' + m''r'',$$

where m, m', m'' denote the numbers of the atoms of the three elements, and r, r', r'' their refraction-equivalent: thus in the case of ethyl oxide, $\text{C}_2\text{H}_5\text{O}$:

$$4 \times 5.0 + 10 \times 1.3 + 3.0 = 36.0$$

Refraction-equivalent deduced from observation = 36.26.

The values above given for the refraction-equivalents of C, H, and O agree very nearly with those deduced from the experiments of Gladstone and Dale already cited. Gladstone has subsequently determined, by similar methods, the refraction-equivalents of chlorine, bromine, tin, iodine, and mercury; and Haagen (*Pogg. Ann.* cxxxi. 117), by examining a variety of liquid haloïd compounds, has deduced for several of these elements, refraction-equivalents agreeing with those found by Gladstone, together with those of arsenic, antimony, and silicon.

The fact, previously established by Gladstone and Dale, that a substance when dissolved retains the same specific refractive energy, and consequently the same refraction-equivalent, as in the solid state, affords the means of determining the refraction-equivalents of a great number of solid bodies which could not otherwise be ascertained. By determining the refractive indices of a series of chlorides, bromides, and iodides dissolved in water, Gladstone has shown that a chloride has, in each case, a refraction-equivalent about 6 less than the corresponding bromide, and about 17 less than the corresponding iodide; and that a potassium salt has, in each case, a refraction-equivalent about 3.2 greater than that of the corresponding sodium salt, about 4 greater than the lithium salt, and about 3.5 less than the ammonium salt. Hence it seems to follow: 1. That the different salts are really comparable with one another in this respect.—2. That each halogen and each metal retains its own refractive power, with whatever other elements it is combined.—3. That if the value of any one of these elements can be ascertained with certainty, all the rest may also be determined.

Experiments conducted on these principles have been extended by Gladstone to about 180 different salts, containing 28 inorganic salt-radicles and 33 metals. The results are tabulated in a paper recently communicated to the Royal Society (*Phil. Trans.* 1870, p. 9; *abstr. Proc. Roy. Soc.* 1868, p. 439).

The refraction-equivalents of the elementary bodies deduced from these results are given in the following table:

* These values differ but slightly from those of the free elements deduced by Landolt from the observations of Schraff, Dulong, and Regnault, viz. C = 4.85, H = 1.54, O = 3.04.

Refraction-equivalents of the Elementary Bodies.

Element	Atomic weight	Refraction-equivalent
Aluminium	27.4	8.4
Antimony	122	24.5
Arsenic	75	15.4 (other values?)
Barium	137	15.8
Bismuth	210	39.2
Boron	11	4.0
Bromine	80	15.3 In dissolved salts 16.9
Cadmium	112	13.6
Cæsium	133	13.7?
Calcium	40	10.4
Carbon	12	5.0
Cerium	92	13.6?
Chlorine	35.5	9.9 In dissolved salts 10.7
Chromium	52.2	15.9 In chromates 23?
Cobalt	58.8	10.8
Copper	63.4	11.6
Didymium	96	16.0?
Fluorine	19	1.4?
Glucinum	9.4	5.7
Gold	197	24.0
Hydrogen	1	1.3 In hydracids 3.5
Iodine	127	24.5 In dissolved salts 27.2
Iron	56	12.0 In ferric salts 20.1
Lead	207	24.8
Lithium	7	3.8
Magnesium	24	7.0
Manganese	55	12.2 In permanganate 26.2?
Mercury	200	21.3 In compound iodides 29.0
Nickel	58.8	10.4
Nitrogen	14	4.1 In high oxides 5.3
Oxygen	16	2.9
Palladium	106.5	22.2
Phosphorus	31	18.3 (other values?)
Platinum	197.4	26.0
Potassium	39.1	8.1
Rhodium	104.4	24.2?
Rubidium	85.4	14.0
Silicon	28	7.5? In silicates 6.8
Silver	108	13.5 (other values?)
Sodium	23	4.8
Strontium	87.5	13.6
Sulphur	32	16.0 (other values?)
Thallium	204	21.6?
Tin	118	27.0 In tetrachloride 19.2
Titanium	50	25.5?
Uranium	120	10.8
Vanadium	51.2	25.3?
Zinc	65.2	10.2
Zirconium	89.6	22.3?

The sign ? in the above table indicates that the equivalent has been deduced from only one compound, or that the different determinations are not fairly accordant.

It will be seen that many of these elements have a double value. An element usually exerts the same influence on transmitted rays in all analogous compounds, and in many that are not analogous; but there are differences of composition which do affect this quality, and in some cases at least these are coincident with a change of atomicity. Thus iron in all the ferrous salts examined has the equivalent 12.0, but in the ferric salts 20.1. The knowledge of this can be applied to the examination of other compounds of the same element, such as the ferricyanide of potassium. The

refraction-equivalent of this body gives for iron 11.7, suggesting that the metal is in the same condition as in the ferrous salts.

Again, in most of the vegetable acids, as in other organic compounds, hydrogen has a refraction-equivalent of 1.3, but in hydrochloric, hydrobromic, and hydriodic acids it exerts a far greater influence on light, its refraction-equivalent in these compounds being 3.5.

The bodies of the aromatic group, two series of nitrogenised bases, viz. the pyridine series and chinoline series, and certain oxidised essential oils, exhibit refraction-equivalents considerably higher than those calculated from the values of the elements in the preceding table; for example:

Substance	Formula	Refraction-equivalent		Difference
		Observed	Calculated	
Benzene	C^6H^6	43.7	37.8	5.9
Anilino	C^6H^5N	51.1	43.2	7.9
Salicylol	C^7H^6O	58.9	48.6	10.3
Pyridine	C^5H^5N	40.1	35.6	4.5
Chinoline	C^8H^7N	66.7	58.2	8.5
Naphthalene	$C^{10}H^8$	75.0	60.4	14.6
Anethol	$C^{10}H^{12}O$	81.4	68.5	12.9
Eugenol	$C^{10}H^{12}O^2$	81.1	71.4	9.7
Anthracene	$C^{14}H^{10}$	100.3	83.0	17.3

(Gladstone, *Chem. Soc. J.* [2] viii. 117).

The specific refractive energies, $\frac{\mu-1}{d}$, of the metals are for the most part greater as their combining proportions are less. This will be seen from the following numbers extracted from Gladstone's table (*ibid.* p. 113):

Combining proportion	H	Li	Mg	Fe	Pt	Pt	Pb	Th
Sp. refr. energy	1	4.7	12	28	26.6	49.3	103.5	204
$\frac{\mu-1}{d}$	1300	540	292	211	208	132	120	103

There are, however, many exceptions to this rule.

On the application of specific refractive energies to the quantitative analysis of mixtures of organic liquids, such as methyl and ethyl alcohol, which cannot be accurately separated by chemical methods, see Landolt (*Ann. Ch. Pharm. Suppl.* iv. 1; *Zeitschr. anal. Chem.* iv. 390; *Jahresb.* 1865, p. 680).

On the relations between refracting power and chemical composition, see also Schrauf (*Pogg. Ann.* cxviii. 359; cxix. 461, 553; cxxvi. 177; cxxvii. 175, 344; *Jahresb.* 1863, p. 98; 1865, p. 84); J. Regnault (*J. Pharm.* [3] xliii. 187; xlv. 187); Fouqué (*Compt. rend.* lxiv. 121; *Phil. Mag.* [4] xxxiii. 655; *Jahresb.* 1867, p. 96).

Fluorescence.—When, instead of observing fluorescence directly, a pure linear spectrum of the fluorescent light is subjected to prismatic analysis, it is found that, for each fluorescent substance, the fluorescence begins at a distinct prismatic colour, and is not excited by any rays of lower refrangibility. When sunlight is used, both the limit of the fluorescence and its maximum intensity, for each particular substance, are situated (with slight variations) at the same part of the spectrum, and are therefore characteristic of that substance. Throughout the whole extent of the fluorescent portion of the spectrum, the predominant tints in the secondary spectrum are the same, so that the composition of the fluorescent colour is independent of the nature of the colour which excites it, and is likewise characteristic of each fluorescent substance. In light from artificial sources, or light which has passed through coloured media, the beginning and maximum of the fluorescence may be situated at points of the spectrum different from those at which they are placed in sunlight.

Composite fluorescences, such as those of tincture of litmus and alcoholic tincture of quassia, exhibit, by prismatic analysis of the linear spectrum, several secondary spectra. Mixtures of fluorescent substances, on the other hand, exhibit either a composite fluorescence (which may be resolved by prismatic analysis into simple fluorescences), or a fluorescence which cannot be recognised as composite. In the latter case, therefore (e.g. in a mixed solution of æsculin and fraxin), the fluorescence is no longer characteristic. In substances which fluoresce in solution, the solvent

exerts an influence, either on the intensity alone, or likewise on the nature of the fluorescence. Thus the aqueous solution of æsculetin-red exhibits a fluorescence different from that of the alcoholic solution. The fluorescence of some substances is strengthened, and sometimes also modified, by addition of acids, that of others by addition of alkalis. Solutions of æsculin, æsculetin, fraxin, and similar compounds, fluoresce more strongly on addition of ammonia or a fixed alkali; less strongly and in a different manner on addition of acids; in this latter case, the original fluorescence is restored by saturation with an alkali. The feeble fluorescence of neutral quinine salts is converted, by addition of most acids, into the strong and totally different fluorescence of the acid salts; but hydrochloric and hydriodic acids destroy it almost completely (V. Pierre, *Wien. Akad. Ber.* liii. (2. Abth.), 704; *Jahresh.* 1866, p. 79).

Fluorescence is developed in an aqueous solution of quinine by the addition of an oxygen-acid, such as sulphuric, phosphoric, nitric, iodic, acetic, benzoic, tartaric, &c., whereas hydracids, such as hydrochloric, hydriodic, hydroferrocyanic, hydroplatinocyanic, &c., not only do not develop fluorescence in the quinine solution, but destroy it when previously developed by an acid of the former class. Hyposulphurous acid resembles the hydracids in its effect on the fluorescence of a quinine solution; but this acid, though usually classed with the oxygen-acids, nevertheless exhibits many of the chemical characters of a hydracid (Stokes, *Chem. Soc. J.* [2] vii. 174). See HYPOSULPHUROUS ACID, under SULPHUR.

According to C. B. Greiss (*Pogg. Ann.* cxxxiii. 171), fluorescent substances are found in all parts of plants and animals. Many organic compounds not occurring in nature (amyl alcohol, acetone, croosote) likewise exhibit weak fluorescence.

On the alteration of the fluorescence of certain vegetable tinctures, produced by filtration through animal charcoal, see J. E. Loughlin (*Sill. Am. J.* [2] xliii. 239; *Jahresh.* 1867, p. 104).

The conversion of rays of lower into rays of higher refrangibility—the opposite of the change which takes place in fluorescence—was designated by Emmismann (*Pogg. Ann.* civ. 651 [1861]) as ‘negative fluorescence.’ An example of it is afforded by the incandescence of a platinum wire or of a piece of lime held in a hydrogen flame, the dark ultra-red rays which constitute the greater part of the spectrum of this flame being then converted into rays of higher refrangibility, and so becoming luminous. This phenomenon has been further studied by Akin (*The Reader*, Sept. 1863; *Phil. Mag.* [4] xxviii. 554; xxix. 28, 136) and Tyndall (*ibid.* xxviii. 329; xxix. 44, 218, 241; *Proc. Roy. Soc.* xiv. 33, 476). When the luminous and calorific rays from an electric lamp are passed through a sufficiently thick stratum of a solution of iodine in carbon bisulphide, which absorbs all the visible rays, and gives passage only to the invisible ultra-red rays, and these rays, which are the least refrangible of all, are then made to pass through a system of lenses, a focus of invisible but very hot rays is produced, which easily sets fire to inflammable substances, and raises metals and other solid bodies held in it to a state of vivid incandescence, causing them to emit rays of every degree of refrangibility (Tyndall). The same exaltation of refrangibility may be more simply exhibited by placing a piece of fluor-spar (chlorophane) in the flue of an ordinary stove, so that it may be heated by the dark rays radiated from the moderately hot walls of the flue; the mineral then becomes luminous in a few minutes (G. Bohn, *Jahresh.* 1867, p. 103). As fluorescence properly so called—i.e. the lowering of the refrangibility of rays—takes place at ordinary temperatures, whereas the phenomena just noticed, designated by Emmismann as negative fluorescence, take place only at high temperatures, Tyndall prefers to denote them by the term calorescence. Akin uses the word calescence.

Circular Polarisation.—The rotatory power of volatile substances is not constant, but varies with the temperature, its variation being represented by the general formula $a + bt + ct^2$, in which c is very small and sometimes equal to nothing. For any given temperature, the rotations of the different rays are not exactly in inverse proportion to the wave-lengths, the variation being different in different substances. The proportion of the rotations of any one ray at different temperatures holds good likewise for all other rays, in the case of any given substance. This last law applies also to the vapours of camphor and certain volatile oils, the rotation of which is moreover the same in direction, and equal or nearly equal in amount to that which would be produced by the solid or liquid substance at the same temperature (Gernez, *Compt. rend.* lviii. 1108).

LIGHT, MEASUREMENT OF THE CHEMICAL ACTION OF.

According to the method described on p. 689 of vol. iii. (which consists in the exact estimation of the tint which standard sensitive paper assumes when exposed for a given length of time to the action of daylight), a regular series of measurements was

continued for two years at Kew Observatory (Roscoe, *Phil. Trans.* 1867, 555), proving that a continued series of such daily observations can be effectually and satisfactorily carried out. The curves (figs. 31, 32) show the rise and fall of monthly chemical intensity with the hour of the day at Kew for the year 1866, whilst the numbers in the following table give the mean monthly integrals of chemical intensity for the same period.

FIG. 31.

FIG. 32.

(Light of the Intensity 1.0 acting for 24 hours = 1,000.)

January .	15.0	May .	78.9	September .	70.1
February .	24.3	June .	92.3	October .	29.5
March .	34.5	July .	106.9	November .	15.6
April .	78.9	August .	94.5	December .	14.0

From these curves, as from the observational numbers, it is seen that the chemical intensity for hours equidistant from noon is the same. Thus

					Chemical intensity
The mean action, from 552 morning observations in 1865-67 at 9.41 A.M. is	=	0.105,			
" " " 529 afternoon " " " 2.27 P.M. is	=	0.107.			

So that we may conclude that when the disturbing causes of cloud, &c., are eliminated, the daily maximum of chemical intensity corresponds to the maximum of sun's altitude, and that the chemical intensity exhibits no sign of a post-meridian maximum, as is observed in the measurements of hourly temperature. Although the curves of mean daily chemical intensity, showing the variation from hour to hour, are symmetrical, this relation appears by no means to hold good for the curves of yearly chemical intensity. This is distinctly seen by comparing the monthly means for the two months about the vernal with the two about the autumnal equinox, for 1865, '66, and '67:

1865, 7	Mean C. I.	1866	Mean C. I.
March 1867 .	30.5	March 1866 .	34.5
April 1865 .	97.8	April 1866 .	52.4
September 1865 .	107.8	September 1866 .	70.1
August 1865 .	88.9	August 1866 .	94.5

Or for 100 chemically active rays falling in the months of March and April 1865, '66, '67, at Kew, there fell, in the months of August and September 1865, '66, '67, 167 rays, the sun's mean altitude being the same in both cases. The curve (fig. 33) shows

FIG. 33.

the biennial variation of chemical intensity at Kew for the two years ending April 1, 1867. The yearly integral for the twelve months, January to March 1867, and April to December 1866, is 55·7 per diem, whilst that for the 12 months of 1866 is 54·7. From careful comparison of the other meteorological elements it appears that the difference in chemical intensity between spring and autumn cannot be ascribed to a greater amount of cloud at one of these seasons over that at the other, but rather to the variation in the transparency of the atmosphere, partly caused by variation in the humidity of the air, and partly by the presence of finely divided solid particles, which, floating about, produce the phenomenon of atmospheric opalescence.

Our knowledge concerning the distribution of the chemically active rays on the earth's surface is as yet but limited. It has been frequently stated (Golding Bird, *Nat. Phil.* 5th edit. 622) that the chemical intensity of light on snowy peaks and in tropical climates is much less than that in our own latitudes, and that photographers in Mexico have found it impossible, amidst the glaring rays of a tropical sun, to obtain a picture which, in the gloomier atmosphere of England, would need an exposure of only one minute.

A series of experiments made according to the above-described method (proposed by the writer of this article) by Dr. Thorpe at Pará on the Amazons (long. 48° 30' W., lat. 1° 28' S.) prove that any difficulties which a photographer may have in the tropics cannot be ascribed to an insufficient supply of the sun's chemically active rays. The following table gives the mean daily chemical intensities at Kew and Pará for 15 days in April 1866:

Date	Daily mean Intensity		Ratio
	Kew	Pará	
April 4, 1866	—	269·4	
" 6 "	28·6	242·0	8·46
" 7 "	7·7	301·0	39·09
" 9 "	5·9	326·4	55·25
" 11 "	25·4	233·2	9·18
" 12 "	55·8	203·1	3·66
" 13 "	52·2	337·8	6·40
" 14 "	38·5	265·5	6·89
" 18 "	39·8	350·1	8·80
" 19 "	75·2	352·3	4·68
" 20 "	38·9	385·0	9·90
" 23 "	80·4	350·1	4·35
" 24 "	83·6	362·7	4·34
" 25 "	73·7	307·8	4·17
" 26 "	39·1	261·1	6·67
Mean intensity	46·66	302·2	

The changes in chemical intensity, as observed from hour to hour, or even from minute to minute, are very sudden and remarkable. These sudden variations, seen in figs. 34, 35, 36, are caused by the passage of enormous thunder-clouds, which during the rainy season spread quickly over the sky; the chemical action sinks down to zero, and as the clouds pass away, with torrents of deluging rain, the chemical intensity again rises. If the observations made when the sun's disc was unobscured are tabulated, and a curve plotted from these numbers, we get a good idea of the march of daily chemical intensity under the equator during sunshine. This curve (fig. 36) is a symmetrical one, and exhibits a maximum at noon. The dotted line is the curve of mean chemical intensity for April at Kew, and the relation of the two intensities is as 52·4 to 313·3, or as 1 to 5·98.

A very exact series of experiments (Roscoe & Thorpe, *Proc. Roy. Soc.* 1870, 301) has been subsequently made in Portugal, when the sky was cloudless, for the purpose of determining the relation existing between the sun's altitude and the chemical intensity of total daylight. This relation is shown to be graphically represented by a straight line for altitudes above 10°; this fact had previously been observed in a less complete way at Kew, Heidelberg, and Pará. Hence we learn that, although the chemical intensity for the same altitude at different places and at different times of the year varies according to the varying transparency of the atmosphere, yet the relation at the same place between altitude and intensity is always represented by a

straight line. This variation in the direction of the straight line is due to the opalescence of the atmosphere, and it has been invariably observed that, for equal altitudes, the higher intensity is always found where the mean temperature of the air is greater, as in summer, when observations at the same place at different seasons are compared, or as the equator is approached, when the actions at different places are examined. The differences in the observed actions for equal altitudes (which may amount to more than

FIG. 34.

FIG. 35.

FIG. 36.

100 p. c. at different places, and to nearly as much at different seasons of the year) serve as exact measurements of (1) the transparency and (2) the reflecting power of the atmosphere.

One important conclusion to which these determinations have led is the fact that at altitudes below 10° the direct sunlight is robbed of almost all its chemically active powers. This has been noticed in Manchester, Heidelberg, Kew, Pará, and Lisbon. Thus at Manchester, when the sun was $12^\circ 3'$ above the horizon, it was found that of 100 chemically active rays falling on the horizontal surface, less than 6 were due to the direct sunlight, whilst 95 came from the diffused light of the heavens, even when the sky was unclouded. At the same instant, of 100 rays of visible light as affecting the eye, 60 came directly from the sun, and only 40 from the diffuse skylight. This same preponderance of the chemical activity of the diffuse light exists at higher altitudes. Thus at $25^\circ 16'$ the ratio of the chemical intensities of diffuse to direct sunlight was as 100 to 23, whilst the ratio of their visible intensities was as 100 to 400. The following table gives the results of the Lisbon experiments arranged according to the sun's altitude:

No. of Observations	Mean Altitude	Chemical Intensity		
		Sun	Sky	Total
15	$9^\circ 51'$	0.000	0.038	0.038
18	$19^\circ 41'$	0.023	0.063	0.085
22	$31^\circ 14'$	0.052	0.100	0.152
22	$42^\circ 13'$	0.100	0.115	0.215
19	$53^\circ 9'$	0.136	0.126	0.262
24	$61^\circ 8'$	0.195	0.132	0.327
11	$64^\circ 14'$	0.221	0.138	0.359

This cutting off of the chemically active (most refrangible) rays is due to the *opalescence of the atmosphere* (Roscoe).

The small particles of floating solid and liquid matter which are seen dancing in the sunbeam, and are present in all natural air, reflect the blue rays and transmit the red, giving rise to the ruddy tints of sunrise and sunset. That mere traces of finely divided particles completely cut off the chemically active rays can be shown by a simple experiment. If we take a very slightly milky liquid, such as water containing $\frac{1}{10}$ of a grain of finely divided suspended sulphur in the gallon—which produces so slight an opalescence that we can scarcely detect it—and then endeavour to explode a bulb of mixed chlorine and hydrogen gases by a bright flash of light when the opalescent

solution is placed between it and the bulb, no combination occurs; but the bulb explodes immediately when pure water is used instead of the opalescent solution. In opal glass we have a good illustration of the action of the atmosphere upon the chemically active rays. The opalescence of the glass is caused by the presence of very minute particles of bone-phosphate or arsenious acid disseminated throughout the mass. By reflected light the glass appears white or bluish-white, by transmitted light it appears orange. If a bright source of light be placed behind the glass, the direct rays are seen to be red, whilst the general diffused light reflected from the particles of the finely divided matter suspended throughout the glass is bluish-white.

Basis of a Quantitative Photography.

Relative Sensitiveness of various Photographic Papers.—A. Macdougall (*Chem. Soc. J.* [2] iii. 183) has measured accurately the relative sensitiveness of various silvered papers, salted with solutions of different strengths of sodium chloride, potassium chloride, ammonium chloride, and potassium bromide, and afterwards floated on a strong silver nitrate bath of constant composition. From these experiments it appears that the sensitiveness of a photographic paper depends solely upon the quantity of the halogen (chlorine and bromine) contained in the salting solution, and that it is not influenced by the metal (K, Na, NH⁺, Ba) with which the halogen is combined. The following table gives the relative sensitiveness of papers prepared in solutions of chloride of sodium containing in 100 parts quantities varying from 0.25 to 20.0 parts of salt, and all silvered in a bath containing 12 p. c. of nitrate:

p. c. of NaCl	Relative sensitiveness	p. c. of NaCl	Relative sensitiveness
0.25	0.448	6.0	4.45
0.50	0.782	7.0	4.75
1.0	1.000	8.0	4.98
1.5	1.29	9.0	5.24
2.0	1.79	10.0	5.69
3.0	2.33	15.0	6.81
4.0	3.19	20.0	7.20
5.0	3.85		

That the sensitiveness depends solely upon the quantity of chlorine and bromine present is seen from the following numbers:

	Relative sensitiveness		Relative sensitiveness
Chloride of sodium	1.50	Bromide of sodium	1.43
Chloride of potassium . . .	1.53	Bromide of potassium . . .	1.56
Chloride of ammonium . . .	1.53	Bromide of ammonium . . .	1.41
Chloride of barium	1.56	Bromide of barium	1.40
		Bromide of quinine	1.43

C. R. Wright (*Chem. Soc. J.* [2] iv. 33) has continued these experiments, determining the relative sensitiveness for an equal number of atoms of chlorine, bromine, and iodine, or mixtures of these halogens, present in the paper. He finds that in all cases the darkening of these differently prepared photographic papers obeys the law of Bunsen and Roscoe, viz. that the same tint is always produced when the product of the intensity into the time of exposure is constant. It was however proved that papers prepared with different halogens do not all darken at the same relative rates; in other words, if standard paper (see vol. iii. p. 688) be exposed to a constant source of light, it assumes a definite series of tints in the relative times 1, 2, 3, 4 . . . ; if, however, bromide paper be exposed to the same source of light, the relative times in which it assumes the same series of tints are not 1, 2, 3, 4 . . . , but are in some other proportion.

It has further been shown that this proportion remains constant for a paper salted with the same halogen, whatever the strength of the salting solution may be; thus the *relative* rates of darkening of the 10 p. c., the 3 p. c., the 0.5 p. c. sodium-chloride papers are identical; and the same was found to hold good with the papers salted in bromide of potassium. Hence it is clear that if the relative sensitiveness of papers salted with different halogens is to be compared, some particular tint must be taken as a standard of reference. In order to determine the relative times taken by papers prepared with various halogens to gain the same definite series of tints, solutions were prepared containing a quantity of bromine, and mixtures of chlorine, bromine, and iodine, equivalent to the quantity of chlorine in a 4 per cent. potassium-

chloride solution. The relative sensitiveness of papers prepared in each of these solutions was accurately determined, and tables are given in which are found the relative times for which pieces of these papers must be exposed to a constant source of light in order to gain a given series of tints, and, therefore, the relative intensities of light to which they must be exposed for a constant time to gain the same series of tints. From this table the relative sensitiveness of any of these papers with respect to any tint can be calculated when their relative sensitiveness with respect to some one given tint is known. The following numbers give the relative sensitiveness of 5 papers with respect to the normal tint :

Chloride . . . 1.000	Chlorobromide . . . 4.022	Bromiodide . . . 4.060
Chloriodide . . 1.078	Bromide . . . 2.396	

Photometer for Photographic Purposes

H. Vogel (*Ber. d. deutsch. Chem. Ges.* 1868, 62) has described the arrangements of a simple photometer. It consists of a semi-transparent paper scale, of which the tints vary in regular gradation; under this scale is placed a paper sensitised with chromate of potash, which becomes darkened on exposure to light. In order to recognise the effect of the light, black letters are painted on the scale, and the portions of the paper under these letters remain unacted on. No numerical results of the working of this instrument have yet appeared.

Chemical Decomposition of the Vapour of Volatile Organic Bodies by the Action of Light.

Tyndall (*Proc. Roy. Soc.* xvii. 92, 223, 317; *ibid.* xviii. 176), by subjecting the vapours of volatile liquids to the action of concentrated sunlight, or to the concentrated beam of the electric light, has shown that a remarkable decomposition is brought about, which is rendered visible by the formation of singular cloud-like forms. These clouds disappear when the experimental tube through which the rays pass from end to end, is again rendered vacuums. The substance which was first experimented upon was nitrite of amyl (boiling from 91° to 96°); when the slightest trace of this vapour was introduced into the tube, and the electric beam allowed to shine through it, the tube at first appeared *optically empty*; nothing whatever was seen within it; but before a second had elapsed, a shower of liquid spherules was precipitated on the beam, thus generating a cloud within the tube. Dry oxygen, hydrogen, or nitrogen can be equally well used as a diluent, and the effect is, therefore, not due to any interaction between the nitrite and its vehicle. The seat of the observed action is in the vapour itself, but Tyndall does not attempt to determine strictly the character of the decomposition. Brown nitrous fumes were however noticed, and it is probable that amyl nitrate was formed. The more refrangible rays are those which especially produce these singular decompositions, though the effect was observed, but to a very much diminished degree, with the red rays. A solution of yellow chromate of potash, made of such a strength as to be identical in colour with that of the liquid nitrite of amyl, was found to stop the active rays more effectually than red glass; but by far the most complete mode of arresting the rays which produce these changes is to allow them to pass through a screen of the vapour of the nitrite itself: a layer of vapour $\frac{1}{2}$ of an inch in thickness, although scarcely affecting the luminous intensity, was sufficient to absorb the whole of the chemical energy of the beam of the electric light. A blue cloud of decomposing nitrite of amyl can also be obtained by greatly diluting the vapour. Other organic liquids, such as iodide of isopropyl and iodide of allyl, as well as hydriodic acid, gave singularly beautiful cloud-forms of varying tints when subjected to a similar treatment.

H. E. R.

LIGNOSE. See GLYCOLIGNOSE (p. 640).

LIGNUM COLUBRINUM, said to be used with good results as a remedy for intermittent fever, contains a somewhat considerable proportion of brucine, together with a little strychnine (B. van Berlekom, *Zeitschr. f. Chem.* [2] ii. 442).

LINOLEIC ACID. $C^{18}H^{32}O^2$ (iii. 700).—The ethereal solution of the lead salt of this acid, left to evaporate on a glass plate, leaves a white amorphous residue consisting of the lead salt of oxylinoleic acid, $C^{18}H^{30}O^2$. The acid separated from this salt by hydrogen sulphide and dissolved in alcohol, remains on evaporation as a nearly colourless viscid mass, which becomes blood-red, but without alteration

of composition, when heated to 100° or treated with acids or alkalis. Its colourless alcoholic solution is not altered by alkaline carbonates at the boiling heat, but caustic alkalis turn it red even at ordinary temperatures. When linoleic acid is exposed to the air in a thin film till its weight becomes permanent, a colourless resinous substance is formed, having the composition of a hydrate of oxylinoic acid, $C^{18}H^{28}O^5 \cdot H^2O$. Heated to 100° it gives off 6.7 p. c. water, and becomes blood-red. By prolonged contact with the air, more quickly when frequently moistened with ether, colourless oxylinoic acid loses its viscid consistence, and is converted into linoxyn, $C^{18}H^{27}O^4$ or $C^{32}H^{54}O^{11}$, a neutral, amorphous, elastic, non-hygroscopic body, heavier than water, insoluble in water, dilute acids, alcohol, and ether, but soluble in a mixture of alcohol and chloroform. In warm aqueous potash, and more slowly in ammonia, it dissolves to a red liquid, which, when supersaturated with an acid, yields a yellowish-red flocculent precipitate, soluble in alcohol, and still more in ether, and exhibiting the composition and properties of oxylinoic acid. Linoxyn is also formed in the drying of linseed or poppy oil exposed to the air (G. W. Mulder, *Scheikund. Verhandl. en Onderzoek.* iv. (1 Stuk), 1; *Jahresb.* 1865, p. 324).

LINOXYN. See the last article.

LINSEED OIL contains, according to Mulder (*loc. cit.*), 77.0 p. c. carbon, 11.2 hydrogen, and 11.8 oxygen. Besides linolein (about 80 p. c.), it contains elain (*i.e.* a fat yielding sebic acid by dry distillation), palmitin, and myristin (the two latter amounting to about 10 p. c. of the oil). By dry distillation it gives off sebic, palmitic, and myristic acids, together with acrolein, and leaves a substance insoluble in ether and resembling caoutchouc, from the analysis of which Mulder infers that it is an anhydride of linoleic acid, $C^{18}H^{27}O^4$, or $C^{32}H^{54}O^3$.

LITHIUM. The following method of preparing a lithium salt from lepidolite is given by Mierzinski (*Zeitschr. f. Chem.* [2] v. 349). Twenty-five pounds of pulverised lepidolite are digested for twenty-four hours with 30 pounds of strong sulphuric acid, and then fused in a crucible till all excess of sulphuric acid is driven off. On exhausting the residual mass with hot water, the whole of the silica remains undissolved. The iron, manganese, and aluminium are precipitated from the solution by ammonium carbonate, and the sulphuric acid from the filtrate by barium chloride. The liquid, which contains only the chlorides of the alkali-metals, is evaporated to dryness; the residue is digested with alcohol, which dissolves only the lithium chloride; the syrupy lithium solution which remains on distilling off the alcohol is precipitated by ammonium carbonate; and the precipitate is washed with alcohol. See also Lunglmayr, *Dingl. pol. J.* clxxi. 293; *Jahresb.* 1863, p. 182;—Reichardt, *Dingl. pol. J.* clxxii. 447; *Jahresb.* 1864, p. 186;—Schröter, *J. pr. Chem.* xciii. 27; also the article RUBIDIUM in this Dictionary, v. 128;—v. Hauer, *J. pr. Chem.* xciv. 148.

Rammelsberg (*Pogg. Ann.* cxxviii. 311; *Jahresb.* 1865, p. 167; 1866, p. 157) has examined the crystalline form and composition of several lithium salts, with the view of ascertaining whether they are isomorphous with the corresponding salts of potassium or sodium. The sulphate, $Li^2SO^4 + H^2O$, crystallises in monoclinic prisms having the clinodiagonal, orthodiagonal, and principal axis in the proportion 0.8278 : 1 : 1.2021, and the angle of the inclined axes = $70^{\circ} 29'$. A solution of potassium sulphate and lithium sulphate in equivalent proportion, first deposits the former salt, then *potassio-lithic sulphate*, $KLiSO^4$, in double hexagonal pyramids having the secondary to the principal axis as 0.6006 : 1; they agree with the crystals of sodio-potassic sulphate only in their general symmetry, not in the ratio of their axes or the inclinations of their faces. The mother-liquor ultimately yields very small crystals having the form of the hydrated lithium sulphate above described, and the composition $(K^2SO^4 \cdot H^2O) + (4Li^2SO^4 + H^2O)$ or $K^2Li^4(SO^4)^3 + 2H^2O$. A solution of the sulphates of lithium and sodium in equivalent proportions yields by evaporation hexagonal crystals (combinations of a rhombic prism having a terminal angle of $102^{\circ} 28'$ with the end-face and the second hexagonal prism). The first crop of these crystals had the composition $Na^2Li(SO^4)^2 + 6H^2O$, the second crop $Na^2Li^2(SO^4)^3 + 9H^2O$. Finally, crystals were obtained having the form of the hydrated lithium sulphate, but containing the sodium salt in isomorphous combination. The *hyposulphate*, $Li^2S^2O^6 + 2H^2O$, obtained by decomposing barium hyposulphate with lithium sulphate, crystallises in rhombic combinations of prisms and pyramids having the axes $a : b : c$, as 0.5985 : 1 : 1.0355, isomorphous with the sodium salt. The crystals become moist in the air and dissolve very easily in water. The *neutral chromate*, $Li^2CrO^4 + H^2O$, forms rhombic prisms having the axes $a : b : c$ as 0.6619 : 1 : 0.4663; very soluble in water. The *dichromate*, $Li^2CrO^4 \cdot CrO^3 + 2H^2O$,

separates from a solution evaporated to a syrup, in deliquescent brown-black crystals having some of their faces curved. *Ammonio-lithic chromate*, $\text{Li}(\text{NH})^4\text{CrO}^4 + 2\text{H}^2\text{O}$, separates from a solution of acid lithium chromate supersaturated with ammonia, in slender red-brown non-deliquescent needles. The *arsenate*, $\text{Li}^2\text{AsO}^4 + \frac{1}{2}\text{H}^2\text{O}$, is precipitated by ammonia in the pulverulent form, from a solution of arsenic acid saturated with lithium carbonate. A solution of this salt in arsenic acid yields, by spontaneous evaporation, transparent deliquescent rhombic prisms (of about 142°), consisting of *acid lithium arsenate*, $\text{LiH}^2\text{AsO}^4 + \frac{1}{2}\text{H}^2\text{O}$, which is resolved by water into the neutral salt and free arsenic acid. *Lithium molybdate*, $\text{Li}^2\text{MoO}^4 + \frac{1}{2}\text{H}^2\text{O}$, is obtained by heating molybdic acid with ammonium carbonate and water, and evaporating the solution, in small nodular groups of crystals permanent in the air, and moderately soluble in water.

LÖLLINGITE. This name is given by Zepharovich (*Jahresb.* 1867, p. 973) to the iron arsenide, FeAs^2 , occurring in the vein of siderite at Lölling, near Hüttenberg in Carinthia, the mineral Fe^2As^2 , originally thus designated by Kennigott, being called *leucopyrite*.

LOPHINE. $\text{C}^{20}\text{H}^{16}\text{N}^2$.—This base may be separated by boiling alcohol from the black-brown residue of the distillation of di- and tri-benzylamine (p. 338), and crystallises from the resulting solution in colourless silky needles melting between 260° and 270° . Dry hydrochloric acid gas passed over lophine converts it into the dihydrochloride, $\text{C}^{20}\text{H}^{16}\text{N}^2 \cdot 2\text{HCl}$; and by dissolving lophine in alcohol mixed with hydrochloric acid, the monohydrochloride, $\text{C}^{20}\text{H}^{16}\text{N}^2 \cdot \text{HCl}$, is obtained in small crystalline nodules melting at 155° . The alcoholic solution of this salt mixed with platinum chloride yields a yellow precipitate of the platinumchloride, $2(\text{C}^{20}\text{H}^{16}\text{N}^2 \cdot \text{HCl}) \cdot \text{PtCl}^4 + 5\text{H}^2\text{O}$ (Brunner, *Ann. Ch. Pharm.* cli. 135).

LUTEOLIN. $\text{C}^{20}\text{H}^{14}\text{O}^2$.—Rochleder (*J. pr. Chem.* xcix. 433) prepares this substance by boiling weld with water mixed with $\frac{1}{8}$ pt. of alcohol of 50 p. c., straining the decoction at the boiling heat, and heating it to remove the alcohol. The impure luteolin, which separates in grey flocks on cooling, is dissolved in a small quantity of hot alcohol, the solution filtered into water, the turbid liquid heated to the boiling point, and the colouring matter which separates on cooling is further purified by Moldenhauer's process (iii. 736). A mixture of water and glycerin is well adapted for recrystallising it.

Luteolin fused with potash is resolved, with evolution of carbon dioxide, into phloroglucin and protocatechuic acid:

LUXULIAN. A mineral thus designated, from the parish of Luxulion, near Lostwithiel in Cornwall, is, according to Pisani (*Compt. rend.* lix. 913), a porphyritic granite in which the mica is replaced by dark green radiate needles of tourmalin.

LYCOTONINE. A base contained, together with acolyctine (p. 54), in wolfsbane (*Aconitum Lycotonum*), and separated from the latter by its solubility in ether. It separates in warty groups of crystals, easily soluble in alcohol, sparingly soluble in ether and in water; has an alkaline reaction, a strong bitter taste, and is coloured red by strong sulphuric acid (Hübschmann, *Jahresb.* 1866, p. 483).

LYDINE. A violet dye produced by the action of potassium ferricyanide on aniline: 100 grms. of aniline are dissolved in 100 grms. of fuming hydrochloric acid diluted with 120 c. c. water; this liquid is poured into a solution of 90 grms. potassium ferricyanide in 850 c. c. water, and the whole is heated to boiling for an hour and a half. It is then left to cool, and the precipitate, after being washed by decantation, is dissolved in water nearly saturated with tartaric or oxalic acid. The violet solution leaves on evaporation a pasty product called extract of lydine. The solution of the colouring matter in the organic acid may be used directly for dyeing wool, silk, or mordanted cotton. It may be precipitated from the solution by alkalis, and purified with aid of alcohol or wood-spirit. Sodium hyposulphite precipitates it as a mass of a very fine violet colour; alumina, as a red-violet lake. Pure lydine is a powder having a beautiful violet colour, soluble in alcohol, slightly soluble in ether and in benzol, insoluble in water and in fatty oils, but very soluble in fatty acids. Tissues dyed with lydine are not altered by alkaline carbonates or ammonia. Lydine exerts a poisonous action when taken internally or allowed to come into direct contact with the blood (Guyot, *Compt. rend.* lxi. 829).

M

MACHROMIN. See the next article.

MACLURIN. $C^{12}H^{10}O^4$. *Morintannic Acid* (iii. 1049) (Hlasiwetz a. Pfaundler, *J. pr. Chem.* xciv. 65; *Jahresb.* 1864, p. 558).—A moderately concentrated solution of this substance boiled with sulphuric acid and zinc, becomes deep red and ultimately yellow, and then contains, together with phloroglucin, a substance which, from its variations of colour, is called machromin. To separate this substance, the yellow liquid decanted from the zinc is mixed with $\frac{1}{3}$ vol. alcohol, and agitated with ether as long as the latter becomes coloured; the ethereal solution is evaporated; and the residue diluted with water is precipitated with lead acetate, the phloroglucin then remaining in solution. The yellowish precipitate, which quickly becomes green on exposure to the air, is decomposed with hydrogen sulphide; the lead sulphide is washed with boiling dilute alcohol; the resulting liquid is evaporated in a vacuum; and the granular crystalline mass thereby separated is repeatedly crystallised from boiling dilute alcohol.

Machromin thus obtained forms colourless crystalline spangles, appearing under the microscope as tufts or stars of slender needles, very sparingly soluble in water and in alcohol, somewhat more easily in ether. The crystals exposed to air and light, or dried by heat, gradually acquire a dark blue colour. The hot-prepared aqueous solution also acquires a deep violet-blue colour on exposure to the air, and then yields with hydrochloric acid an amorphous indigo-blue precipitate; ferric chloride produces (best in a very dilute alcoholic solution) a violet-red colour, afterwards changing to blue; the solution of machromin in dilute ammonia, or a caustic fixed alkali, likewise turns blue on exposure to the air. Silver nitrate and mercuric chloride produce a violet coloration, the former with reduction of the metal. An alkaline cupric solution is also reduced by heating with machromin. The solution of machromin in strong sulphuric acid is orange-red at first, then becomes yellow, and after warming (or dilution) emerald-green, and after supersaturation with alkalis, violet.

Hlasiwetz a. Pfaundler give, as the most probable expression of the composition of machromin, the formula $C^{12}H^{10}O^5 \cdot 3H^2O$, and suppose it to be formed from protocathechuic acid (resulting from decomposition of the maclurin), according to the equation:

Machromin is not however produced by the action of nascent hydrogen on readily-formed protocathechuic acid.

When a solution of maclurin in 10 pts. water is heated with sodium-amalgam, and the resulting yellow liquid is saturated with sulphuric acid, keeping it as much as possible excluded from the air, it yields to ether, on agitation, phloroglucin and an amorphous substance, which has nearly the composition $C^{12}H^{12}O^5$, and may therefore also be formed from protocathechuic acid by addition of hydrogen: $2C^{12}H^{10}O^4 + H^4 = C^{12}H^{12}O^5 + 3H^2O$. This compound is soluble in water and in alcohol; easily turns brown; is precipitated by lead acetate; forms with ferric chloride a grass-green liquid, turning red on addition of sodium carbonate; reduces silver solutions and alkaline cupric solutions; and yields by dry distillation crystals having the composition of pyrocatechin.

Acetyl-maclurin, $C^{12}H^8(C^2H^3O)O^5 + 1\frac{1}{2}H^2O$, is formed by heating maclurin to 100° in a sealed tube with acetyl chloride. It is a viscid oil, precipitated by water from the alcoholic solution.

MAGNESIUM. From experiments by Woods (*Phil. Mag.* [4] xxx. 49), the calorific equivalent of magnesium appears to be higher than that of any other metal. The oxidation of $1\frac{1}{3}$ grm. magnesium develops heat sufficient to raise the temperature of 1,000 grms. of water 10.67° , whereas the heat produced by oxidation of an equivalent quantity of zinc raises it by only 5.35° , and of an equivalent quantity of potassium or sodium, 9.72° . The quantities of heat produced by the combination of equivalent quantities of zinc, potassium, and magnesium are as the numbers 6.42, 12.78, and 14.0, or as 1 : 1.99 : 2.17. According to Ditte (*Compt. rend.* lxxiii. 108), the calorific equivalents of zinc and magnesium are as 1 : 1.61.

Magnesium in the finely divided state unites at determinate temperatures with

sulphur, phosphorus, and arsenic, and at a red heat decomposes the oxides of carbon, sulphurous oxide, most metallic oxides, and many hydrocarbons (Parkinson, *Chem. Soc. J.* [2] v. 125). According to Phipson (*Proc. Roy. Soc.* xiii. 217), iodine and sulphur may be distilled over magnesium without altering it; silica and boric oxide are easily reduced by it; from sodium carbonate at a red heat it separates a large quantity of carbon. Ammonia and the fixed caustic alkalis do not act upon it at ordinary temperatures. It precipitates nearly all metals from their neutral solutions (even iron and manganese from ferrous and manganous salts) in the metallic state; aluminium and uranium, and perhaps also chromium, as oxides. Roussin (*J. Pharm.* [4] iii. 413) regards magnesium as particularly well adapted for the precipitation of poisonous metals in toxicological investigations, and is of opinion that it might be advantageously used as a substitute for zinc in voltaic combinations, on account of its great electromotive power. On the precipitation of metals by magnesium, see also Commaille (*Bull. Soc. Chim.* [2] vi. 257; *Jahresb.* 1866, p. 171).

Reactions of Magnesium Salts.—According to Pribram (*Jahresb.* 1866, p. 174), the ordinary statement that only half the magnesia is precipitated from magnesium salts by excess of ammonia is erroneous, 58 p. c. being immediately precipitated, 61 p. c. after three hours, and from 84 to 92 p. c. after fifteen hours.

According to R. Warrington (*Chem. Soc. J.* [2] iii. 27), magnesia is dissolved by the salts of the fixed alkalis, as well as by ammonia, though in much smaller quantity. Hence the precipitation of ammonia by fixed alkalis is never complete, unless a very large excess of the precipitant is used. The clear solution obtained by mixing a magnesium salt with ammonia and the exact quantity of ammoniacal salt required to prevent precipitation, deposits magnesia on dilution with water, whereas addition of strong ammonia within certain limits causes no precipitation. This appears to be the cause of the turbidity produced when the clear slightly ammoniacal wash-water of ammonio-magnesian phosphate runs into a filtrate containing a considerable quantity of magnesia.

Potassium sulphide and sodium sulphide added to solutions of magnesium salts, precipitate magnesium hydrate and form a sulphhydrate of the alkali-metal:

A solution of 1 pt. magnesium chloride in 6,000 pts. water is immediately and distinctly clouded by sodium sulphide, the precipitate being soluble in excess of the magnesium salt (Pelouze, *Jahresb.* 1866, p. 174).

Fresenius (*Zeitschr. anal. Chem.* vii. 310) confirms his former observation, that in separating calcium from magnesium by means of ammonium oxalate, it is necessary to redissolve the precipitated calcium oxalate in hydrochloric acid, and reprecipitate with ammonia and ammonium oxalate, inasmuch as the first precipitate always carries down with it a certain quantity of magnesium salt.

On the separation of magnesia from the alkalis by means of ammonium phosphate (iii. 754), see further Reynoso (*Compt. rend.* lvi. 873; *Jahresb.* 1863, p. 755); Chancel (*ibid.* 1866, p. 796).

Alloys of Magnesium.—With potassium and sodium, magnesium forms malleable alloys, which decompose water at ordinary temperatures: 15 pts. magnesium and 85 pts. tin form a hard brittle lavender-coloured alloy, which decomposes water like the preceding. Mercury does not amalgamate with magnesium at ordinary temperatures (Phipson, *Proc. Roy. Soc.* xiii. 217). Alloys of magnesium and thallium are formed by melting the two metals together in any proportions, and may be drawn out into wire or ribbon. The alloy containing 5 p. c. thallium is stable, and more malleable than magnesium; those containing larger proportions of thallium oxidise more readily. All these alloys burn less quickly and less brightly than pure magnesium; the flame is smaller, and of a pure white colour even when the alloy contains 50 p. c. thallium (S. Mellon, *Chem. News*, xv. 245).

Parkinson (*Chem. Soc. J.* [2] v. 125) has prepared a considerable number of magnesium alloys, by fusing the metals together in a glass tube in a stream of hydrogen, or on a larger scale, and with the less fusible metals, by fusion in an earthen crucible under a flux composed of equal parts of fluor-spar and cryolite, or of 1 pt. of fluor-spar and 2 pts. sodium chloride, the magnesium, on account of its small specific gravity, being attached to the end of an iron rod and stirred into the fused metal. In this manner alloys have been obtained with sodium, aluminium, cadmium, zinc, lead, bismuth, tin, antimony, mercury, silver, gold, and platinum; also triple alloys of magnesium with bismuth and copper, with copper and gold, and with copper and nickel. Iron, cobalt, and nickel do not appear to form alloys with magnesium; zinc, only by fusion in hydrogen; aluminium, only by fusion in a crucible

lined with magnesia. All these alloys are very brittle, somewhat harder than the component metals, resemble them in colour, and have a granular or crystalline fracture; they appear to be too easily alterable to be available in the arts. An *arsenide of magnesium* is formed by slowly heating 3 pts. magnesium-filings and about 6·2 pts. arsenic to dull redness in a stream of hydrogen; it has a chocolate-brown colour, faint metallic lustre, and fine-grained fracture, is very brittle, very difficult to fuse, and quickly crumbles to a brown powder on exposure to the air (Parkinson).

Magnesium Fluoride.—The slag obtained in heating magnesium with sodium silicofluoride (*infra*) leaves, when exhausted with boiling water, a sodio-magnesium fluoride, $\text{NaF} \cdot \text{MgF}_2$, crystallised in cubes resembling common salt; they are contaminated with free silicon, but may be purified by treatment with a mixture of hydrofluoric and nitric acids. The same double fluoride is obtained by fusing magnesium chloride with excess of sodium fluoride and chloride (Geuther, *Jahresb.* 1865, p. 173); also in the amorphous state by boiling a solution of sodium fluoride with magnesia: $3\text{NaF} + \text{MgH}_2\text{O} = 2\text{NaHO} + \text{NaF} \cdot \text{MgF}_2$ (Tissier, *Compt. rend.* lvi. 848).

Oxides.—Magnesia, prepared by igniting the nitrate, is converted by prolonged immersion in water into a hydrate, MgH_2O_2 , having the density and toughness of marble, but harder and more translucent. A hydrate having the same properties, but containing also alumina, ferric oxide, magnesium carbonate, and sand, is obtained by the action of water on the residue left on igniting commercial magnesium chloride. Pure magnesia possesses the property of hardening with water only when prepared by igniting the nitrate or chloride at a moderate red heat; by exposure for 12 hours to a white heat, it loses this property altogether. Magnesia prepared from the basic carbonate yields under similar circumstances a hydrate having only the hardness of talc (H. Sainte-Claire Deville, *Compt. rend.* lxi. 975). According to H. Schwarz (*Bull. Soc. Chim.* [2] ix. 78), magnesia prepared by igniting native magnesite (MgCO_3) at the lowest possible temperature, exhibits the hydraulic properties of the hydrate obtained as above by Deville. The paste prepared from it with water hardens in about twelve hours, afterwards withstands the action of water, and by prolonged immersion therein, acquires the hardness of the best Portland cement. According to Sorol (*Compt. rend.* lxx. 102), a mixture of magnesia with a concentrated solution of magnesium chloride (of sp. gr. 1·16 to 1·26) hardens in a short time to a compact mass of hydrated basic chloride, which resists the action of water. The pasty mixture is very plastic, and capable of binding more than twenty times its weight of sand or other inert powders. Cements or mortars of similar character may be prepared with other chlorides, especially chloride of calcium.

A *suboxide of magnesium* appears to be formed when a solution of sodium or ammonium chloride is electrolysed with poles formed of magnesium wire, the positive pole becoming covered with a black deposit, which exhibits the characters of an oxide (W. Beetz, *Pogg. Ann.* cxxvii. 43; *Jahresb.* 1866, p. 172).

Phosphide.—When melted phosphorus is made to flow upon magnesium-filings heated to dull redness in a stream of hydrogen, combination takes place attended with vivid combustion. The same compound is obtained by heating magnesium-filings with red phosphorus in a narrow-necked flask. It forms a very hard brittle mass, not fusible even at a red heat; has a dark brown colour; and exhibits a semi-metallic lustre on its crystalline fracture. It decomposes water and hydrochloric acid, with evolution of hydrogen phosphide; is permanent in dry air, but is decomposed by moist air in the same manner as by water. Its composition is represented by the formula P^2Mg^2 (Parkinson, *Chem. Soc. J.* [2] v. 309). F. P. Blunt (*ibid.* iii. 106), by passing phosphorus-vapour over magnesium-filings heated to dull redness in a stream of carbon dioxide, obtained a black coherent mass, which was not attacked by dilute hydrochloric acid, scarcely by dilute sulphuric acid, and very slowly even by hot nitromuriatic acid; when intimately mixed with metallic magnesium, however, it was decomposed by hydrochloric acid, with copious evolution of hydrogen phosphide. Parkinson regards this black product as a mixture of charcoal and magnesia with only a small quantity of magnesium phosphide, inasmuch as magnesium is scarcely attacked at a dull red heat by phosphorus-vapour, which, however, easily decomposes carbon dioxide at that temperature.

Silicide, Mg^2Si^2 (?).—This compound, first obtained by Wöhler (v. 266), is prepared by strongly igniting sodium silicofluoride with magnesium in a crucible filled up with common salt, and may be purified from unaltered magnesium by boiling with solution of sal-ammoniac, and from adhering silica by friction on smooth paper and levigation. It forms lead-grey crystals, apparently regular octohedrons, heavier than water. It is

decomposed by hydrochloric acid, with evolution of hydrogen and siliciuretted hydrogen, and formation of white silicon oxide (v. 274), which retains the form of the crystals; also by sal-ammoniac solution, though very slowly at ordinary temperatures, with evolution of the same gases and formation of silica. Heated to low redness in a stream of nitrogen, it is converted into a black mixture of magnesium nitride and silicon (Geuther, *J. pr. Chem.* xcv. 424; *Jahresb.* 1865, p. 187).

MALEIC ACID. $C^4H^2O^4$.—According to V. von Richter (*Zeitschr. f. Chem.* [2] v. 453), the best way of preparing this acid is to distil deliquesced maleic acid quickly in a very small retort, only a very small residue of fumaric acid being then obtained.

According to J. Loschmidt (*Wien. Akad. Ber.* li. [2] 385), maleic acid crystallises in rhombic prisms $\infty P : \bar{P}\infty$, having the angle $\infty P : \infty P = 67^\circ 4'$ and $112^\circ 56'$; $P\infty : P\infty$ at the principal axis = $125^\circ 32'$; $\infty P : \bar{P}\infty = 112^\circ 12'$, and consequently the axes a (maer.) : $b : c$ (principal) in the ratio 1:5089 : 1:0:51167 or 1:0:66273 : 0:34100. The crystals cleave perfectly parallel to $P\infty$; they become turbid and like porcelain by keeping.

On the isomeric relations between fumaric and maleic acids, see ACIDS, ORGANIC (p. 48).

Maleic acid is decomposed by the electric current in the same way as fumaric acid, yielding acetylene, succinic acid, and a small quantity of fumaric acid. Sodium bromomaleate yields by electrolysis, at the positive pole, chiefly carbon monoxide, with a small quantity of carbon dioxide:

(Kekulé, *Ann. Ch. Pharm.* cxxx. 1).

Zinc dissolves in cold aqueous maleic acid without evolution of hydrogen. The resulting solution deposits large well-defined triclinic crystals of acid zinc maleate, and the liquid filtered therefrom contains succinic acid:

By prolonged action of zinc, the acid maleate is converted into succinate. Acid zinc maleate is also produced by boiling maleic acid with zinc carbonate, and adding to the filtered solution an equal quantity of maleic acid (v. Richter, *loc. cit.*).

Bromomaleic Acids (Carius, *Ann. Ch. Pharm.* cxlix. 265).—*Monobromomaleic acid*, $C^4H^3BrO^4$, and *isomonobromomaleic acid* (iii. 786) are produced, together with a small quantity of isodibromosuccinic acid, by heating phenaconic acid, dissolved in at least 20 times its weight of water, with bromine in a sealed tube:

On agitating the product with ether, the bromomaleic acids dissolve, and on distilling off the ether, and leaving the viscid residue to evaporate over oil of vitriol, isobromomaleic acid separates in crystalline crusts, which may be purified by recrystallisation. It dissolves easily in water, alcohol, and ether, and crystallises from water in acuminate (but not needle-shaped) monoclinic prisms. It melts at 165° , and distils at a higher temperature, being resolved at the same time into water and an anhydride, which is oily at first, but afterwards solidifies in the crystalline form. The barium salt, $C^4HBrBaO^4 + 4H^2O$, crystallises in prisms, pointed but not needle-shaped; the silver salt in short rhombic prisms easily soluble in warm water. The acid agrees very nearly in its properties with the isobromomaleic acid which Kekulé obtained by decomposition of isodibromosuccinic acid; its melting point is however 5° higher, Kekulé's acid melting at 160° , and its silver salt is but slowly decomposed by boiling even in ammoniacal solution, whereas that of Kekulé's acid is described as decomposing easily when boiled with water.*

The thick mother-liquor of the isobromomaleic acid yields an isomeric acid agreeing nearly in most of its properties with Kekulé's monobromomaleic acid. When purified by conversion into a barium salt, and separation therefrom, it crystallises in long prisms and needles, more soluble in water than isobromomaleic acid, melts at about 120° (Kekulé's acid at 125° – 126°), and decomposes at about 150° into water and an anhydride, which sublimes in beautiful needles melting at 108° – 110° . The anhydride of Kekulé's monobromomaleic acid (obtained by decomposition of

* As the two modifications of bromomaleic acid obtained from phenaconic acid (a derivative of benzene) do not quite agree with those described by Kekulé, Carius proposes to distinguish them as *isozotic bromomaleic acids*.

dibromosuccinic acid) is liquid and boils at 212° . The barium and silver salts of bromomaleic acid crystallise in needles; the latter dissolves easily in water without decomposition, and is but slowly decomposed by boiling in ammoniacal solution.

The two bromomaleic acids above described are also formed, together with dibromosuccinic and isodibromosuccinic acids and bromoform, when phenaconic acid is heated with bromine and a quantity of water smaller than that which was used in the experiments above described. (See PHENACONIC ACID.)

Chloromaleic acid, $C^4H^3ClO^4$, apparently identical with that described by Perkin a. Duppa (iii. 788), is obtained by the action of baryta-water on an amorphous chlorinated acid formed, together with trichlorophenomaleic acid, by the action of chlorous acid on benzene. (See PHENOMALIC ACID.) It is separated from the resulting solution—after removal of baryta and hydrochloric acid—by half neutralising with potash, leaving the acid potassium salt to crystallise, and decomposing this salt with an acid; and is finally purified by recrystallisation. The chloromaleic acid thus obtained crystallises in groups of small white needles, easily soluble in water, alcohol, and ether, and melting at 171° – 172° . By prolonged fusion, especially at 180° , it is resolved into water and an oily anhydride which is reconverted into the acid by contact with water. Chloromaleic acid is reduced by hydriodic acid to ordinary succinic acid. It is bibasic; the neutral chloromaleates of alkali-metal are easily soluble in water. The acid potassium salt, $C^4H^2ClKO^4 + H^2O$, forms hard crystals; the barium salt, $C^4HClBaO^4 + 5H^2O$, chalky crusts composed of small laminae. The soluble salts form with ferric chloride a white flocculent precipitate, with lead acetate a white amorphous precipitate = $C^4HClPbO^4$, and with silver nitrate a white microscopically crystalline precipitate = $C^4HClAg^2O^4$ (Carius, *Deut. Chem. Ges. Ber.* 1870, 334).

MALIC ACID. $C^4H^4O^5$.—This acid exists, according to Gintl (*Zeitschr. f. Chem.* [2] v. 377), in the leaves of the common ash. Reinsch (*ibid.* [2] 221) recommends the preparation of it from the fruits of the common sumach (*Rhus coriaria*). The expressed cold aqueous infusion of these leaves, precipitated with lead acetate and then boiled, yields a large quantity of lead malate. Crystallised calcium malate may also be obtained by boiling the juice with chalk, and evaporating the still acid solution.

Malic acid treated with sodium in alcoholic solution is converted into an acid resembling hydrocitric acid (p. 473), the calcium salt of which has the composition $C^4H^3CaO^5 + 2\frac{1}{2}H^2O$ (Kämmerer, *Jahresb.* 1866, p. 403).

Neutral potassium malate subjected to *electrolysis* is decomposed as follows: *a.* Fundamental reaction: $C^4H^4O^5K^2 = C^4H^4O^4 + O + K^2$.—*b.* Part of the anhydride $C^4H^4O^4$ is reconverted into malic acid; another portion is oxidised, yielding aldehyde and carbon dioxide: $C^4H^4O^4 + O = C^4H^4O + 2CO^2$.—*c.* Acetic acid is formed as a secondary product. A mixture of 4 mol. of the neutral malate with 1 mol. potassium hydrate yields the same products. Free malic acid is for the most part converted into aldehyde and carbon dioxide (Burgoin, *Bull. Soc. Chim.* [2] ix. 429).

Dry malic acid heated in the water-bath for three or four days with an equal volume of cold-saturated aqueous *hydrobromic acid* is converted into monobromosuccinic acid:

With a larger quantity of fuming hydrobromic acid, the malic acid is converted at 100° into fumaric acid, $C^4H^2O^4$, and at 110° – 120° carbon dioxide and carbon monoxide are formed by more complete decomposition (Kekulé, *Ann. Ch. Pharm.* cxxx. 11).

Detection and Separation of Malic Acid.—1. Malic acid in the free state may be recognised by evaporating its aqueous solution in a test-tube, and then heating the tube in a sand-bath to 160° – 170° till the crystalline sublimate no longer increases; the maleic or fumaric acid thus produced may be recognised by its usual characters.—2. Calcium malate precipitated by alcohol from a solution of malic acid mixed with calcium chloride, shrinks together when the liquid is warmed, and forms on cooling a mass easily pulverised by pressure. As the solution with the precipitate bums very violently when heated, it is best to pour off the alcohol, dissolve the precipitate in water, boil the solution, and mix it with pure alcohol.—3. The well-known lead reaction (iii. 791) is for the most part best exhibited by liberating the malic acid from its salts, and then precipitating it with lead acetate. It is only when lead malate is present in a liquid unmixed with other salts that it exhibits the characteristic reaction when heated.—4. When a solution containing free malic acid is neutralised with magnesia, and the filtered solution is mixed with alcohol, a precipitate of magnesium malate is obtained, which behaves like the calcium salt when heated (Barfoed, *Zeitschr. anal. Chem.* [2] v. 402).

Separation from other acids.—Malic acid may be detected, in presence of *oxalic*

and *tartaric acids*, as follows: The two latter are precipitated by calcium chloride, the liquid is filtered (after some time if tartaric acid is present); the filtrate precipitated with alcohol; the aqueous solution of the precipitate mixed with lead acetate; the lead malate decomposed by hydrogen sulphide; and the liberated malic acid again precipitated by lead acetate, or otherwise tested as above. To separate malic acid from *citric acid*, advantage may be taken of the greater facility with which calcium citrate is precipitated by alcohol. After the greater part of the citric acid has been precipitated by calcium chloride at the boiling heat, the filtrate is mixed with a small quantity of alcohol to throw down the rest of the citric acid; and the liquid filtered therefrom is treated with a large quantity of alcohol to precipitate the malate of calcium. When tartaric, oxalic, and citric acid are present in solution together with malic acid, it is best to convert all the three acids into ammonium salts, and mix the solution with 8 or 9 times its volume of alcohol, which dissolves only the malate. From *tannic acid*, malic acid may be separated by precipitating the former with animal membrane; or the tannic acid may be precipitated from the slightly ammoniacal solution by calcium chloride. The filtrate, which still contains a little tannic acid, may be precipitated with alcohol, and the calcium malate dissolved out of the precipitate by water; or the filtrate may be acidulated with hydrochloric acid, the tannic acid decomposed by chlorine-water, and the calcium malate precipitated by alcohol, after addition of ammonia. *Gallic acid* is separated from malic acid by calcium chloride in ammoniacal solution, the liquid being agitated with air frequently renewed. The filtrate from the black precipitate is acidulated with hydrochloric acid, mixed with chlorine-water, and the malic acid then precipitated as above. When *succinic* and malic acids are present together in the free state, the malic acid may be directly precipitated with lead acetate. But if both acids are present as metallic salts, lead acetate precipitates them both. If, however, the precipitate be dissolved in ammonium acetate, and the solution mixed with twice its volume of alcohol, only the malate of lead is precipitated. This precipitate must be washed with a mixture of 2 pts. alcohol and 1 pt. water, decomposed by hydrogen sulphide, and the free malic acid tested as above. Or the solution of the alkali-metal salts may be strongly concentrated; the malate precipitated by alcohol; the precipitate dissolved in water; and the malic acid precipitated as lead-salt. *Benzoic, acetic*, and *formic acids* remain in solution when malic acid is precipitated by calcium chloride and alcohol; the quantity of alcohol added must not however exceed 1 to 2 volumes, as otherwise the formic acid will also be precipitated. From *sulphuric* and *phosphoric acids*, malic acid may be separated by precipitating the two former acids with barium chloride, and the malic acid from the filtrate with calcium chloride and alcohol (Barfoot, *loc. cit.*).

For the quantitative estimation of malic (and tartaric) acid, Juetto (*Zeitschr. f. Chem.* [2] iv. 373) makes use of the power possessed by those acids to hold ferric oxide, alumina, and manganous oxide in solution in presence of alkalis. For a description of the method, see TARTARIC ACID.

Acetyl-malic Acid. $C^2H^3(C^2H^3O)O^2 = \left. \begin{matrix} (C^2H^3O) \\ H^2 \end{matrix} \right\} O^2$.—Produced by treating

diethyl-malate, $C^2H^3O^2$. $(C^2H^3)^2$, with 2 mol. acetyl chloride, and after the first violent reaction is over, heating the mixture to 100° for an hour. The product treated with water yields diethyl-acetylmalate, $C^2H^3O^2 = C^2H^3O^2 \cdot (C^2H^3)^2$, as an oily liquid, which may be purified by repeated solution in alcohol, precipitation with water, and final rectification. This ether is a heavy colourless oil, having a faint ethereal odour and bitter taste, insoluble in cold water, but miscible in all proportions with alcohol and ether. Boils at 258° (corr. 265.7°). When boiled with potash it yields acetic and malic acids (Wislicenus, *Ann. Ch. Pharm.* cxxix. 175; *Jahresb.* 1864, p. 387).

Sulphomalic acid, $C^2H^3O^4S$, is formed as a tripotassic salt, by heating 1 mol. neutral potassium monobromosuccinate to 110° with a concentrated solution of 2 mol. potassium sulphide:

The product of the reaction is acidulated with acetic acid; neutralised exactly with ammonia, after driving off the hydrogen sulphide; then precipitated with lead acetate; the precipitate decomposed with hydrogen sulphide; the filtrate repeatedly evaporated to expel hydrobromic acid; and the solution decolorised with animal charcoal. The colourless liquid evaporated at a temperature not exceeding 40° , and finally under the air-pump, leaves sulphomalic acid as an indistinctly crystalline,

deliquescent, strongly acid substance, which becomes brown at 100° , and gives off stinking vapours at higher temperatures. The solution of the acid is not precipitated by barium acetate, and only imperfectly by lead acetate. The barium salt, $C^4H^4BaO^4S$, is obtained, by supersaturating the acid with baryta-water, as a flocculent precipitate somewhat soluble in water. The *lead salt* is soluble in acetic acid. The *silver salt*, $C^4H^4Ag^2O^4S$, is a white precipitate which easily turns black. When a solution of sulphomalic acid in 20 pts. water is carefully evaporated with excess of nitric acid, sulphosuccinic acid, $C^4H^4O^4S$, is formed, together with small quantities of oxalic and sulphuric acids (Carius, *Ann. Ch. Pharm.* cxxix. 6).

MALOBIURIC ACID. $C^3H^3N^3O^4 = N^3 \left\{ \begin{array}{l} (CO)^2 \\ (C^3H^2O^2)^2 \\ H^3 \end{array} \right\}$.—An acid analogous in

constitution and mode of formation to biuret, $N^2(CO)^2H^4$, produced as an ammonium salt by heating barbituric acid to 150° – 170° with urea:

The acid is prepared by dissolving the crude ammonium salt in potash and supersaturating the solution with hydrochloric acid, and purified by repeating this treatment several times. It is distinguished from dibarbituric acid (the product of the action of heat on barbituric acid) by its granular character, by its greater solubility in water, and by dissolving completely when treated with bromine and water, instead of yielding a yellow bromide (v. 962). Nitric acid converts it into diluturic acid. Its salts are amorphous or finely crystalline precipitates (Baeyer, *Ann. Ch. Pharm.* cxxv. 312).

MALONIC ACID. $C^3H^4O^4 = \begin{array}{c} COOH \\ | \\ CH^2 \\ | \\ COOH \end{array}$.—The formation of this acid from cyanacetic acid (or cyanacetic ether, iii. 799) is represented by the equation:

It is also produced: α . By oxidation of paralactic acid, CH^2OH-CH^2-COOH (p. 771).— β . By oxidation of allylene, C^3H^4 , with an alkaline solution of permanganic acid (Berthelot, *Jahresb.* 1867, p. 335).— γ . By boiling barbituric acid with potash (Baeyer, v. 962; see also Heintzel, *Ann. Ch. Pharm.* cxxxix. 129; *Jahresb.* 1866, p. 397):

Finkelstein (*Ann. Ch. Pharm.* cxxxiii. 338) prepares malonic acid by boiling crude cyanacetic acid with excess of strong potash-ley; neutralising the diluted solution with acetic acid; precipitating with lead acetate; decomposing the lead malonate with dilute sulphuric acid; evaporating the filtrate; and recrystallising the crystalline residue from a larger quantity of ether, in order to free it from an adhering syrupy substance. The ethereal solution when left to evaporate yields malonic acid in slightly coloured laminae, or in large prisms having a laminated structure. When recrystallised from water, it is obtained, according to Knop's measurements, in triclinic combinations of ∞P . ∞, P . mP . ∞ . P , with two faces bevelling the acute prismatic edges. Cleavage distinct parallel to P . Angles ∞P : $\infty P = 113^{\circ}$ and 67° ; ∞P : $\infty P = 110^{\circ}$; ∞P : $\infty P = 86^{\circ} 30'$; ∞P : $P = 115^{\circ} 30'$.^{*} Malonic acid is therefore not isomorphous with succinic acid (which crystallises in the rhombic system). It forms acid and neutral salts, all of which, except those of the alkali-metals, are but sparingly soluble; in free malonic acid, acetic acid, or nitric acid they dissolve more readily. The following have been examined:

Potassium salt (acid)	$C^3H^3KO^4 + \frac{1}{2}H^2O$,	colourless prisms.
Sodium salt	$C^3H^3NaO^4 + \frac{1}{2}H^2O$,	well-defined crystals.
Barium salt $\left\{ \begin{array}{l} a \\ b \end{array} \right.$	$C^3H^2BaO^4$,	white precipitate.
	$C^3H^2BaO^4 + H^2O$,	white needles.
Calcium salt	$C^3H^2CaO^4 + \frac{1}{2}H^2O$,	tufts of needles.

^{*} On account of imperfect reflection, these angular measurements are only approximate.

Magnesium salt	$\left\{ \begin{array}{l} a. \text{C}^6\text{H}^2\text{MgO}^4 + 2\text{H}^2\text{O} \\ b. \text{C}^6\text{H}^2\text{MgO}^4 + 4\text{H}^2\text{O} \\ c. \text{C}^6\text{H}^2\text{MgO}^4 + 11\text{H}^2\text{O} \end{array} \right\}$	crystalline powder.
Manganous salt	$\text{C}^6\text{H}^2\text{MnO}^4 + 2\text{H}^2\text{O}$	pale red prisms.
Cobalt salt	$\text{C}^6\text{H}^2\text{CoO}^4 + 2\text{H}^2\text{O}$	brown-red powder.
Nickel salt	$\text{C}^6\text{H}^2\text{NiO}^4 + 2\text{H}^2\text{O}$	blue-green powder.
Zinc salt	$\text{C}^6\text{H}^2\text{ZnO}^4 + \frac{5}{2}\text{H}^2\text{O}$	small crystals.
Cadmium salt	$\text{C}^6\text{H}^2\text{CdO}^4$	amorphous, deliquescent.
Cupric salt	$\left\{ \begin{array}{l} a. \text{C}^6\text{H}^2\text{CuO}^4 + 3\frac{1}{2}\text{H}^2\text{O} \\ b. \text{C}^6\text{H}^2\text{CuO}^4 \cdot \text{CuO} \end{array} \right\}$	blue crystals. blue-green precipitate.
Lead salt	$\text{C}^6\text{H}^2\text{PbO}^4$	crystalline powder.
Silver salt	$\text{C}^6\text{H}^2\text{AgO}^4$	crystalline powder.
Ethylie ether	$\text{C}^6\text{H}^2(\text{C}^2\text{H}^5)^2\text{O}^4$	oil boiling at 195°.

The neutral potassium salt and the acid ammonium salt are deliquescent, partially crystalline masses. The barium salt *b* crystallises from the solution of the salt *a* in a large quantity of hot water, and does not give off its water of crystallisation at 150°. The calcium salt gives off $\frac{1}{2}$ mol. water at 100°. The magnesium salt *a* gives off $\frac{1}{2}$ mol. water at 110°; the salt *b*, which separates from more dilute solutions, gives off all its water at that temperature. The manganese and cobalt salts become anhydrous at 150°; the nickel salt at 170°; the copper salt *a* gives off 2 $\frac{1}{2}$ mol. water at 100° (Falkenstein).

Oxymalonic acid, $\text{C}^3\text{H}^4\text{O}^5$, is formed in small quantity, together with oxalic, acetic, and formic acids, and Reichardt's gum (ii. 955), by oxidising glucose with cupric oxide in alkaline solution. It crystallises in very deliquescent prisms, and forms barium and calcium salts having the composition $\text{C}^6\text{H}^2\text{M}^2\text{O}^5$ (Claus, *Zeitschr. f. Chem.* [2] v. 152).

MALTIN. A nitrogenous ferment existing, according to Dubrunfaut, in malt (*Compt. rend.* lxxi. 274; *Zeitschr. f. Chem.* [2] iv. 351), and much more active than diastase. It is precipitated from extract of malt by addition of 2 mol. alcohol of 90 p. c.; and if the addition of alcohol to the solution be continued as long as any precipitate is thereby produced, a substance is obtained, not flocculent like maltin, but syrupy, perfectly soluble in water, and having much less fermentative power than maltin, and containing only a small proportion of nitrogen. As continued treatment with alcohol is recommended by Page and Persoz for the purification of diastase, Dubrunfaut is of opinion that this substance is merely a product of the decomposition of maltin, and that the latter is the really active principle of malt. He further states that maltin is present in all cereal grains, and in the water of rivers and brooks; the well-water of Paris does not however contain it.

MAMANITE. A triple sulphate, $\text{K}^2\text{SO}^4 \cdot 2\text{MgSO}^4 \cdot 3\text{CaSO}^4 + 3\text{H}^2\text{O}$, occurring as a deposit on the carnallite of Maman in Persia (Göbel, *Jahresb.* 1865, p. 900).

MANDELAMIDE. See the next article.

MANDELIC ACID. $\text{C}^8\text{H}^8\text{O}^3$. *Formobenzoic acid* (iii. 799).—This acid has the constitution of phenyl-glycollic acid, $\text{C}^6\text{H}^5 \cdot \text{C}^2\text{H}^2\text{O}^3$ or $\text{C}^6\text{H}^5 \cdot \text{CHOH} \cdot \text{COOH}$. When dissolved in fuming hydrobromic acid, and left in sealed tubes for some weeks at ordinary temperatures, or for a few hours at 120°–130°, it is converted into phenyl-bromacetic or α -bromotoluic acid:

The last acid, heated in concentrated alcoholic solution with alcoholic potash, gives up bromine, and is converted into phenyl-ethyl-glycollic or ethyl-mandelic acid:

On neutralising the product with hydrochloric acid, filtering from potassium bromide, and evaporating, ethyl-mandelic acid is obtained as a yellow oil, which when purified

by conversion into a barium salt, separation by sulphuric acid, and evaporation, forms a viscid mass resembling bird-lime. Its salts are likewise amorphous (Glaser a. Radziszewski, *Zeitschr. f. Chem.* [2] iv. 140).

When the compound of benzoic aldehyde and hydrogen cyanide, $(C^6H^5O)^2.CNH$ (produced by treating bitter almond oil with hydrocyanic and hydrochloric acids, p. 329), is heated to 180° with water or alcohol, it is completely resolved into benzoic aldehyde and mandelamide, $C^6H^5O.NH^2$:

Mandelamide crystallises in rhombic or hexagonal tables, soluble in water and in boiling alcohol, slightly soluble in ether, melting at 131° , and not wholly volatile without decomposition. Heated with baryta-water to 180° , it is converted into barium mandelate, $(C^6H^5O^2)^2Ba$, which crystallises in small rhombic tables soluble in 6·17 pts. of boiling water, and in 12·3 pts. water at 23° (Zinin, *Zeitschr. f. Chem.* [2] iv. 709).

MANGANESE. This metal is precipitated by sodium-amalgam from acidulated solutions as an amalgam, which when distilled in a stream of hydrogen leaves the metal in form of a pulverulent sponge (*Bull. Soc. Chim.* [2] vi. 93).

Detection and Estimation.—For the detection of manganese in solid bodies, C. D. Braun (*Zeitschr. anal. Chem.* vi. 73) heats the substance in the oxidising flame for two or three minutes in a bead of sodium pyrophosphate, and moistens the bead, after cooling, with nitric acid, whereupon the presence of manganese is indicated by the reddish-violet colour of manganic pyrophosphate, either immediately, or after renewed heating in the oxidising flame. The formation of manganic pyrophosphate may also be made available for the detection of manganese in solution. A moderately concentrated solution of sodium pyrophosphate is mixed with the liquid to be tested for manganese, till the resulting precipitate no longer dissolves, after which a small quantity of lead dioxide is added, and the liquid is boiled and filtered. If manganese is present, the brown filtrate will assume a violet-red to violet-brown colour when mixed with a little hydrochloric acid and gently heated. To detect manganese in vegetable substances, they are gradually added to a melting mixture of 5 pts. nitre and 1 pt. sodium pyrophosphate. The blue-green mass repeatedly evaporated with nitric acid, and finally heated to fusion, assumes a lilac colour (Braun).

According to W. Gibbs (*Sill. Am. J.* [2] xlv. 216), manganese may be estimated, like magnesium, as *ammonio-manganous phosphate*. The manganous solution is mixed with a considerable excess of sodium phosphate; the white gelatinous precipitate is dissolved in hydrochloric acid; the liquid then heated to boiling, and ammonia added in excess. The ammonio-manganous phosphate, which separates in pale rose-coloured nacreous scales, is collected on a filter after a quarter of an hour, washed with hot water, and ignited. If it acquires a darker red colour during washing, it must be redissolved in hydrochloric acid, and precipitated at the boiling heat by ammonia, with addition of sodium phosphate.

On the precipitation and estimation of manganese by *ammonium sulphide*, see *Classes* (*Zeitschr. anal. Chem.* 1869, p. 416; *Zeitschr. f. Chem.* [2] vi. 285).

For the estimation of manganese in iron and iron ores, the following method is given by Eggertz (*Zeitschr. f. Chem.* [2] iv. 506; *Jahresb.* 1868, p. 872). The iron having been dissolved in hydrochloric acid, with addition of a little nitric acid, the solution is evaporated to dryness to separate silica; the dry mass is boiled with chlorine-water till no more red powder is visible; the solution is diluted with water and filtered; and the separated silica, if still red, is treated with strong hydrochloric acid. The acid solution is then nearly neutralised with sodium carbonate, and boiled with sodium acetate to precipitate ferric oxide and alumina, the precipitate being redissolved and again thrown down with sodium acetate, to separate any manganese that may have been precipitated with it in the first instance. The manganese solution is then concentrated and mixed with bromine, till it becomes yellow, whereby the whole of the manganese is precipitated as hydrated dioxide. The liquid is heated on the water-bath to expel dissolved bromine, then filtered, and the precipitate is washed with weak hydrochloric acid (1 p. c.), to remove alkali more quickly. The precipitate dried at 100° consists of $3MnO^2.H^2O$, containing 59·18 p. c. manganese; by heating it is converted into $MnO.MnO^2$, containing 69·62 manganese.

Iron ores are pulverised and fused with an alkaline carbonate, and the fused mass is treated as above.

Manganese may be separated from the *alkaline earth-metals* by mixing the warm hydrochloric acid solution with caustic soda or sodium carbonate till a permanent precipitate is formed, dissolving this precipitate in the smallest possible quantity of hydrochloric acid, adding a quantity of crystallised sodium acetate nearly equivalent to the hydrochloric acid, and precipitating the manganese at the boiling heat as dioxide by means of sodium hypochlorite, added in such quantity as to leave the liquid slightly acid (E. Reichardt, *Zeitschr. anal. Chem.* v. 60). Rubie (*ibid.* iv. 241) boils the nearly neutralised solution for two hours with excess of recently precipitated mercuric oxide. The whole of the manganese is then thrown down as dioxide, together with ferric oxide and alumina, while calcium and magnesium remain in solution.

On the separation of manganese from *cobalt*, *nickel*, and *zinc*, see Gibbs (*Sil. Am. J.* [2] xxxix. 58; *Jahresh.* 1865, p. 712). Manganese salts are easily purified from *cobalt*—which occurs in many varieties of the native dioxide—by passing hydrogen sulphide through the solution of the chloride or sulphate, the liquid being kept neutral by suspending manganese carbonate in it. The cobalt is then wholly precipitated as sulphide (Muck, *Zeitschr. f. Chem.* [2] v. 626).

The precipitation of manganese by *ammonium sulphide* is often prevented by the presence of organic ammonium salts. When a solution of manganous chloride is mixed with a large quantity of oxalic acid, then with excess of ammonia and a little ammonium sulphide, no manganese sulphide is precipitated, but needles of manganous oxalate separate after a while. A solution of manganous chloride, to which chloride, oxalate, and sulphide of ammonium are added in succession, yields after a short time a mixed precipitate of manganous sulphide and oxalate. When a solution of manganous oxalate in dilute hydrochloric acid is treated successively with oxalic acid, ammonia, and ammonium sulphide, no precipitate is formed, but crystals (probably of a double salt) separate after some time. When tartaric or citric acid is dissolved by warming in a solution of manganous chloride, and ammonia and ammonium sulphide are then added, no precipitate is formed even after 24 hours. The other metals of the same group, cobalt, nickel, zinc, &c., are precipitated under similar circumstances by ammonium sulphide, either immediately or after some time (How, *Chem. News*, xix. 137).

Volumetric Estimation.—1. When a manganous solution mixed with ferric chloride is treated with excess of a strongly alkaline solution of *potassium ferri-cyanide*, manganous dioxide (mixed with ferric oxide) is precipitated, while *potassium ferro-cyanide* remains in solution:

To apply this reaction to the volumetric estimation of manganese, the acid manganous solution is mixed with ferric chloride (1 mol. MnO to 1 mol. Fe^3O^2), and the mixture is added to a solution of the ferri-cyanide made strongly alkaline with caustic soda. The solution when quite cold is filtered; the brown-black precipitate is washed; the filtrate is concentrated to a definite volume, and acidulated; and the quantity of ferro-cyanide in it is determined by titration with *potassium permanganate* (Lønsen, *J. pr. Chem.* lxxx. 408). According to Fresenius (*Zeitschr. anal. Chem.* iii. 209), this method is especially useful when a considerable number of determinations have to be made, and the quantity of manganese present is not very small.

2. When a solution of a manganous salt (containing all other metals in their highest forms of oxidation) is mixed with *potassium permanganate*, the latter is decolorised, and a violet-brown precipitate of hydrated dioxide, $MnO^2 \cdot H^2O$, is formed, insoluble in dilute inorganic acids. The reaction is:

1 mol. of permanganate used corresponding to 5 at. manganese in the solution. A gram or two of the manganese-compound under examination is dissolved in boiling nitromuriatic acid; the solution nearly neutralised with an alkali is made up to a litre with boiling water, and a titrated solution of permanganate is poured into it (the temperature of the liquid being kept up to 80°) till the supernatant liquid retains its colour even after stirring. The permanganate solution is titrated with pure manganous sulphate, so that 30 c. c. of it shall correspond to about 1 grm. of metallic manganese (A. Guyard, *Bull. Soc. Chim.* [2] vi. 89).

The separation of manganese from the metals of the alkalis and alkaline earths, and from nickel, cobalt, and uranium, may also be effected by means of *potassium permanganate* in the manner above described, the slight excess of the latter being decomposed by ammonia. If a non-titrated solution of permanganate is used, the precipitate must be ignited, and three-fifths of its weight reckoned as manganese (Guyard).

According to Habich (*Zeitschr. anal. Chem.* iii. 474), Guyard's volumetric acid gives exact results when applied to neutral solutions, but not when free sulphuric or hydrochloric acid is present. The presence of ferric or chromic oxide likewise interferes with the correctness of the result.

For Mittenzwey's method of estimating manganese and other substances by oxidation in presence of an alkali, see ANALYSIS, VOLUMETRIC (p. 155).

On the valuation of commercial manganese, see Teschemacher and Denham Smith (*Zeitschr. anal. Chem.* 1869, 314, 509; *Zeitschr. f. Chem.* [2] vi. 287).

Compounds of Manganese.

Chlorides. According to Nicklès (*Ann. Ch. Phys.* [4] v. 161; *Jahresb.* 1865, p. 225), a chloride, MnCl^4 , analogous to the dioxide, is produced by passing hydrochloric acid gas into a well-cooled mixture of the dioxide with ether. A solution is then obtained of a fine green colour, very unstable, and easily decomposed by reducing agents. It appears to contain ether, water, and the tetrachloride in variable proportions; in one instance its analysis gave results agreeing with the formula $\text{MnCl}^4 \cdot 12(\text{C}^2\text{H}^5)^2\text{O} \cdot 2\text{H}^2\text{O}$. Green unstable solutions are likewise obtained with manganese dioxide, ether, and hydrobromic or hydriodic acid; also when the sesquioxide of manganese is used instead of the dioxide.

Fluorides. The tetrafluoride, MnF^4 , is produced by treating the ethereal solution of the tetrachloride with aqueous hydrofluoric acid, the colour changing from green to brown; also by treating the dioxide with aqueous hydrofluoric acid. It does not appear to have been obtained pure. It dissolves in alcohol, and, in absence of water, also in ether. The aqueous solution acts as an oxidising agent, and in the dilute state decomposes easily, especially in presence of alkalis or alkaline chlorides, depositing the hydrated dioxide. With potassium fluoride it yields a rose-coloured precipitate which when dried at 100° has the composition $2\text{KF} \cdot \text{MnF}^4$; with ammonium fluoride a similar but more soluble precipitate; the still more soluble sodium double salt is precipitated only on addition of alcohol. These double fluorides dissolve with violet colour in concentrated aqueous phosphoric acid. In dilute aqueous solution they decompose as easily as the free tetrafluoride of manganese, but become more permanent in presence of an excess of alkaline fluoride. They are fusible, acquiring a transient blue colour while melted, and are decomposed by prolonged fusion, with formation of a basic double fluoride, e.g. $8\text{KF} \cdot \text{MnF}^4$. A similar basic salt is formed by fusing manganese dioxide with potassium fluoride. A few double fluorides of manganese and other heavy metals have been obtained by double decomposition, and similar but very unstable compounds containing organic bases by saturating the aqueous solution of manganese tetrafluoride with the corresponding bases. When manganese tetrachloride is added by drops to a boiling solution of potassium or ammonium fluoride, a rose-coloured powder separates, consisting, according to Nicklès, of an oxyfluoride, MnOF^2 , and forming with potassium fluoride the double salt $2\text{KF} \cdot \text{MnOF}^2$. The tetrafluoride and oxyfluoride of manganese are obtained in ethereal solution by treating their potassium salts with anhydrous ether saturated with silicon fluoride. The solutions are brown and give up manganese tetrafluoride or oxyfluoride to water when agitated therewith. *Manganese trifluoride*, Mn^2F^3 (ii. 808), also yields double fluorides and oxyfluorides when similarly treated with solutions of alkaline fluorides, e.g. the salt $4\text{KF} \cdot \text{Mn}^2\text{F}^3\text{O}$. A potassium salt belonging to one of these groups is formed, with elimination of ozone, by the action of aqueous hydrofluoric acid on potassium permanganate (Nicklès, *Bull. Soc. Chim.* [2] viii. 408).

In treating manganese dioxide with hydrofluoric acid for the preparation of the tetrafluoride as above, there are sometimes obtained, especially when heat is applied (perhaps also only when the manganese dioxide is mixed with manganoso-manganic oxide, Mn^2O^3), brown crusts of *manganoso-manganic fluoride*, $\text{Mn}^2\text{F}^3 + 10\text{H}^2\text{O}$ or $\text{MnF}^2 \cdot \text{Mn}^2\text{F}^3 + 10\text{H}^2\text{O}$. This compound dissolves with brown colour in a small quantity of water, but is decomposed by a large quantity, with separation of brown oxide, and more completely by alkaline carbonates. It forms a rose-coloured precipitate both with potassium fluoride and with manganic fluoride. Its solution takes up large quantities of metallic silver, being converted at the same time into colourless manganous fluoride. Potassium fluoride added to this solution throws down a precipitate of variable composition (containing about 1 p. c. manganese and 50 p. c. silver); lead precipitates the silver, but is not itself dissolved (Nicklès, *Bull. Soc. Chim.* [2] xi. 411).

Oxides. Analyses of manganite and pyrolusite from Nova Scotia are given by How (*Phil. Mag.* [4] xxxi. 165; *Jahresb.* 1866, 923). E. Schmid (*Pogg. Ann.* cxxvi. 151; *Jahresb.* 1865, 878) has analysed psilomelino from Oehrenstock, from Elgersburg, and from Nadabula in Hungary. For the mineral from Elgersburg, he deduces the formula $(\text{BaO} + \text{MnO}) \cdot 4\text{MnO}_2 + 6\text{aq}$.

Respecting the regeneration of manganese dioxide from waste chlorine-liquors, see CHLORINE (p. 435).

Manganates.—A pigment called *Cassel green* is prepared by igniting 14 pts. manganese dioxide with 80 pts. nitrate and 6 pts. sulphate of barium, or 24 pts. manganous oxide with 40 pts. nitrate and 30 pts. sulphate of barium. The green fritted mass is triturated with water and mixed in the moist state with gum or dextrin (*Schad, Bull. Soc. Chim.* [2] v. 477; see also Rosenstichl, *Dingl. pol. J.* clxxvii. 409).

Permanganates.—To avoid the loss arising in the preparation of potassium permanganate from the separation of hydrated dioxide, Städeler (*J. pr. Chem.* ciii. 107) effects the conversion of the manganate into permanganate by means of chlorine gas:

The crude pulverised manganate is left to soften for some hours in contact with water; an equal quantity of water is then added; and chlorine is passed into the liquid till it turns red. The solution is then diluted with four times its bulk of water; and after clarification by subsidence, or filtration through pounded glass, is evaporated to one-fifth of its volume. The greater part of the permanganate then separates out, and may be purified by recrystallisation. The product amounts on the average to 90 p. c. of the manganese dioxide used.

Potassium permanganate is reduced by hydrogen dioxide, with formation of potassium hydrate, and precipitation of hydrated sesquioxide and dioxide of manganese, the proportion of these oxides in the precipitate varying according as the solution of hydrogen dioxide is neutral or acid (*Weltzien, Compt. rend.* lxii. 642; *Ann. Ch. Pharm.* cxxviii. 140. Swionkowski, *ibid.* xli. 205; *Jahresb.* 1867, p. 248).

According to Linder (*Zeitschr. f. Chem.* [2] v. 442), soluble iodides are converted by dilute potassium permanganate into iodates; bromides in acid solution react like iodides; but in neutral or alkaline solution they do not reduce the permanganate; chlorides do not reduce it either in alkaline or in acid solution.

A solution of potassium permanganate is easily decomposed at ordinary temperatures by metallic mercury, with formation of mercurous oxide, manganic hydrate, and potassium hydrate; more quickly at the boiling heat, with immediate formation of mercuric oxide. Silver appears also to be attacked by the permanganate; on zinc and copper it does not act (*W. B. Giles, Chem. News*, xv. 201). Thallium is oxidised by the permanganate solution at ordinary temperatures; magnesium and aluminium only at the boiling heat, and even then but slowly (*Crookes, ibid.*).

Cane-sugar, milk-sugar, starch, and gum are completely oxidised by potassium permanganate in acid solution, to carbonic acid and water; equal quantities of starch and gum reduce nearly equal quantities of the permanganate. Tartaric acid and naphthalene are likewise oxidised (*Langbein, Zeitschr. f. Chem.* [2] v. 350).

Ammonium salts heated to 150° in sealed tubes, with about 40 times their weight of potassium permanganate, and a 50 p. c. solution of potash, give off no nitrogen, and yield only traces of ammonia. Acetamide reacts in a similar manner. The nitrogen must therefore be converted, under these circumstances, into nitric or nitrous acid, as formerly found by Schönbein, Cloez, and Guignet (*Jahresb.* 1858, p. 174), also by Wöhler (*ibid.* 1865, p. 150). Urea heated in sealed tubes to 160°–200°, with a strongly alkaline solution of permanganate, gives off part of its nitrogen in the free state, while nearly all the rest is converted into nitric acid, with only a trace of ammonia; but when the urea is distilled for some time in an open vessel with dilute potash containing permanganate, 22 p. c. of the nitrogen appears as ammonia (*Wanklyn a. Gamgee, Chem. Soc. J.* [2] vi. 25). Asparagine, piperine, piperidine, amylamine, diamylamine, hippuric acid, narcotine, and diphenyl-tartramide, heated with a strongly alkaline solution of potassium permanganate, give off nearly the whole of their nitrogen as ammonia; morphine, codeine, papaverine, strychnine, isomethyl-strychnine, brucine, quinine, cinchonine, nicotine, loluidine, and roscinine, only about half; creatine about a third; caffeine about a fourth; uric acid about a fifth; gelatin 12.7 p. c.; albumin about 10 p. c.; casein 6.6 p. c. Picric acid thus treated yields no ammonia (*Wanklyn a. Chapman, Chem. Soc. J.* [2] vi. 161). On the action of permanganate on quinine, see that base.

Sulphides. Manganous sulphide is formed, together with a polysulphide of potassium, by heating potassium manganate in vapour of carbon bisulphide:

A similar product is obtained with barium manganate (W. Müller, *Pogg. Ann.* cxxvii. 404).

By heating the amorphous sulphide in a stream of hydrogen sulphide, it is obtained in yellow-green hexagonal prisms. At the same time very small shining laminar crystals of unknown composition are formed, grouped in squares or crosses (Sidot, *Compt. rend.* lxvi. 1257).

On the behaviour of flesh-coloured manganese sulphide with various reagents, see Muck (*Zeitschr. f. Chem.* [2] vi. 6).

MANNITE. $C^6H^{11}O^8 = \left(\begin{smallmatrix} C^6H^8 \\ H^6 \end{smallmatrix} \right)^4 O^8$.—Respecting its constitution, see ALCOHOLS (p. 72).

The compounds of mannite with the alkaline earths which Ubaldini obtained by triturating mannite with hydrate of barium, calcium, &c., and water, and precipitating with alcohol (*Gmelin's Handbook*, xv. 365), have been further examined by Hirzel (*Ann. Ch. Pharm.* cxxxi. 50; *Jahresh.* 1864, p. 581), who finds for the barium compound the formula $2C^6H^{11}O^8 \cdot BaO$; for the calcium compound, $4C^6H^{11}O^8 \cdot 3CaO$; and for the strontium compound, $4C^6H^{11}O^8 \cdot SrO$.

Silver nitrate, mercurous nitrate, auric chloride, and mercuric chloride are not reduced by mannite even at the boiling heat; silver acetate or silver oxide heated with mannite, or left in contact with it at ordinary temperatures, yields a speculum of silver. Hydrogen dioxide converts mannite into an acid substance, which reduces an alkaline cupric solution.

Acetyl-mannites.—Mannite heated with acetic anhydride containing 10·15 p. c. glacial acetic acid gradually dissolves, the liquid solidifying on cooling to a crystalline mass surrounded by a syrupy liquid. On filtering this mass in an imperfect vacuum through asbestos, and washing the residue with absolute alcohol, a white very light mass is obtained, having the composition of acetyl-dimannitan, $C^{12}H^{22}(C^2H^3O)_{10}$. It has a bitter taste, is very slightly levogyrate, nearly insoluble in boiling alcohol, insoluble in ether, very soluble in water and in acetic acid; melts at 120° ; yields mannitan by saponification. By prolonged action of the acetic anhydride, a thick syrup is obtained, from which water separates white crystalline grains; and the mother-liquor yields, when evaporated over the water-bath, a colourless, transparent, nearly solid, very sweet syrup, having a strong levogyrate power, $[\alpha] = -22\cdot6^\circ$. The white crystalline precipitate exhibits, after recrystallisation from alcohol, the composition of hexacetyl-mannite, $C^6H^6(C^2H^3O)^6O^8$. It is optically inactive, melts at about 100° and resolidifies in the crystalline form on cooling. The syrupy compound above-mentioned appears to have the composition $C^6H^6(C^2H^3O)^7O^8$, and is probably identical with Berthelot's so-called diacetyl-mannitan (E. Grange, *Compt. rend.* lxxiii. 1326; *Zeitschr. f. Chem.* v. 448).

MARACAIBO BALSAM. } See COPAIBA.
MARANHAN BALSAM. }

MARCELIN. This mineral, from St. Marcel in Piedmont, has, according to G. Rose (*Pogg. Ann.* cxi. 318), the composition $MnO \cdot MnO^2 \cdot SiO^2$; sp. gr. 4·752.

MARCYLITE. This mineral, from the Red River in the neighbourhood of Mount Wichita, has, according to S. W. Tyler (*Sill. Am. J.* [2] xli. 209), essentially the composition $CuS \cdot CuO + H^2O$, the ferrous sulphide and gypsum contained in it being regarded as adventitious.

MARGARYLENE. $C^{11}H^{12}$.—One of the hydrocarbons obtained by the dry distillation of Menhaden oil soap (p. 814). Boils at 193° – 196° .

MAUVANILINE. $C^{10}H^{11}N^3 = \left(\begin{smallmatrix} C^6H^8 \\ C^2H^3 \\ H^3 \end{smallmatrix} \right)^2 N^3$ (De Laire, Girard, a. Chapoteaut,

Compt. rend. lxiv. 416; *Bull. Soc. Chim.* [2] vii. 366; *Jahresh.* 1867, p. 507, 962).—A base produced by the action of dehydrogenising agents on a mixture of aniline and toluidine:

It may be prepared by heating 100 pts. of commercial aniline (boiling at 183° – 188° , and consisting of a mixture of 2 mol. phenylamine and 1 mol. toluidine) with 115 pts. dry arsenic acid, or 164 pts. of a solution containing 70 p. c. arsenic

anhydride, to 170° for some hours, in the same way as for the preparation of rosaniline, treating the product with boiling water to dissolve any salts of chrysotoluidine and rosaniline that may have been formed, and decomposing the remaining arsenite and arsenate of mauvaniline with caustic soda. The impure base, after being separated and washed, is dissolved in dilute hydrochloric acid, and the solution is precipitated by sodium chloride, the rest of the chrysotoluidine then remaining dissolved; or the crude base may be treated with ether and benzol to dissolve the mauvaniline and chrysotoluidine, which may then be separated by solution in hydrochloric acid and precipitation with sodium chloride as above. The residue insoluble in dilute acids, and in ether or benzol, consists chiefly of violaniline. All other oxidising agents used for the preparation of rosaniline may also be applied to that of mauvaniline. This base occurs, in fact, in the residues of the industrial preparation of rosaniline, and is perhaps the cause of the violet tint sometimes exhibited by commercial aniline-red.

Mauvaniline forms light brown crystals, which give off their water ($\frac{1}{2}$ mol.), with decomposition, above 130° . It is soluble in ether, benzol, and alcohol, very slightly in hot water, insoluble in cold water. Its salts (especially the acetate and hydrochloride) crystallise readily, and exhibit a bronze-green reflex like those of rosaniline. They are somewhat soluble in cold, more easily in hot or acidulated water, and dye silk and wool a fine mallow-red.

Triphenyl-mauvaniline, $C^{19}H^{14}(C^6H^5)^3N^1$, produced by the action of aniline on mauvaniline, is a yellowish-white crystalline mass, insoluble in water, soluble in ether and in alcohol; its salts have a splendid blue colour.

Triethyl-mauvaniline, prepared like the corresponding derivative of rosaniline, is white, crystalline, soluble in alcohol and ether; its salts impart a fine blue-violet colour to silk and wool.

MAUVEINE, the base of mauve or aniline purple (iv. 466), is now regarded by Perkin as consisting of $C^{20}H^{14}N^4$ or $(C^{10}H^{12})^{10}H^1N^4$ (*Lecture delivered at the Royal Institution*, May 14, 1869).

MECONIC ACID. $C^7H^4O^7$.—This acid suspended in water is converted by sodium-amalgam into hydromeconic acid, $C^7H^6O^7$, which when separated from its lead salt by hydrogen sulphide and evaporated, remains as a strongly acid syrup, easily soluble in water, less soluble in alcohol, and precipitated therefrom by ether in deliquescent flocks. It is completely decomposed by heat, but not attacked by bromine or nitric acid. The following hydromeconates have been examined:

Barium salt, $C^7H^4BaO^7 + 2H^2O$, amorphous precipitate, soluble in water, insoluble in alcohol.

Lead salt, $C^7H^4PbO^7 + 1\frac{1}{2}H^2O$, amorphous precipitate.

Silver salt, $C^7H^4Ag^2O^7 + \frac{1}{2}H^2O$, white granular precipitate.

Meconic acid is not further reduced by hydriodic acid, but resolved, as by hydrochloric acid, into carbon dioxide and comenic acid. Hydriodic acid does not act upon hydromeconic acid. Meconic acid forms with aniline a beautifully crystallised salt, $C^7H^4O^7 \cdot 2C^6H^5N$, which is converted by heat into comenate, $C^6H^4O^6 \cdot C^6H^5N$ (J. v. Korff, *Ann. Ch. Pharm.* cxxxvii. 191).

MECONIDINE. $C^{21}H^{22}NO^4$ (Hesse, *Ann. Ch. Pharm.* cliii. 47; *Chem. Centr.* 1870, 167).—A base contained, together with others, in the aqueous extract of opium, and remaining in solution after the codamine (p. 480) has crystallised out. When the crystals of the latter no longer appear to increase, the mother-liquor is decanted, the bases contained in it are combined with dilute acetic acid, and the acid solution is saturated with common salt, whereby hydrochloride of meconidine is thrown down, whilst the salts of a fourth base (x) remain for the most part in solution. The meconidine precipitate, which is of resinous consistence, is redissolved in cold water, with addition of a little acetic acid, and again precipitated with common salt, which operation is once more repeated. Lastly the salt thus purified is dissolved in a small quantity of cold water; the solution is mixed with excess of sodium bicarbonate and agitated with ether; the ethereal solution is filtered through animal charcoal; and the ether is left to evaporate, whereupon the meconidine remains as a yellowish varnish, very easily dried at 90° .

Meconidine forms a brownish-yellow transparent amorphous mass, which when touched splits up into innumerable small laminae, and may be ground to a yellowish powder. Melts at 58° ; not sublimable; burns away completely when heated in the air. It is tasteless; insoluble in water, but very soluble in alcohol, ether, benzol, chloroform, and acetone. The alcoholic solution blues reddened litmus, and neutralises sulphuric, hydrochloric, and acetic acids.

Meconidine is easily decomposed by strong acids, especially if heated. Its solution in dilute sulphuric acid becomes rose-coloured in a few minutes, purple-red in a few hours; at the boiling heat these changes of colour take place immediately. With acetic acid the change is much slower. Ammonia produces in the purple-red solution a dirty-white, very changeable precipitate. Strong sulphuric acid dissolves meconidine with olive-green colour; strong nitric acid colours it orange-red.

The salts of meconidine are very unstable. Their dilute solutions have an intensely bitter taste. From the acetic acid solution the meconidine is precipitated by potash or soda in white flocks, but is redissolved by excess of the reagent, and may be separated from the alkaline solution, after addition of sal-ammoniac, by ether, chloroform, and other solvents; acids precipitate it from the alkaline solution, but redissolve it when added in excess. Ammonia likewise precipitates the base, redissolves it when added in very large excess, but gives it up to ether or chloroform when agitated therewith. Lime reacts in a similar manner. The reaction with potash distinguishes meconidine from rheadine, the salts of which give with potash a permanent crystalline precipitate.

Platinochloride of meconidine, $2(C^2H^2NO^4).PtCl_4$, is a yellow amorphous precipitate, which soon turns reddish. The aurochloride is a dingy yellow amorphous precipitate; the mercuriochloride is a white amorphous precipitate, which in contact with hydrochloric acid soon acquires a rose colour.

MELACONITE. Native cupric oxide found at Copper Harbour, Lake Superior, in monoclinic crystals (Maskelyne, *Br. Assoc. Reports*, 35; *Notices and Abstracts*, 33; *Jahresb.* 1867, p. 979).

MELAMINE. $C^3H^6N^4$.—Syn. with CYANURAMIDE (ii. 287).

Triethyl-melamine, $C^3H^9(C^2H^5)^3N^4$, is produced by desulphuration of ethyl-sulphocarbamide. (See SULPHOCARBAMIDES.) By prolonged contact with cold hydrochloric acid, or by boiling for a short time with the same acid, it is converted into ammonia and triethyl-ammelide:

The platinochloride of triethyl-ammelide, $2[C^3H^9(C^2H^5)^3N^4O.HCl].PtCl_4$, crystallises in beautiful four-sided prisms, very easily soluble in water, less soluble in alcohol, not decomposed at 100° (Hofmann, *Zeitschr. f. Chem.* [2] vi. 158).

MELAPHYR. Analysis of this rock from Norheim near Kreuznach and Kokos in the Dobrudscha, are given by Laspeyres (*Jahresb.* 1865, p. 922) and Sommaruga (*ibid.* 1866, p. 978).

MELLILOTIC ACID. Syn. with HYDROCOUMARIC ACID (p. 715).

MELISSIN. C^3H^6O .—This alcohol occurs in Canaüba wax (p. 391).

MELLITIC ACID. $C^{12}H^6O^{12}$ (Bayer, *Ann. Ch. Pharm. Suppl.* vii. 1; Preliminary Notice, *Berl. Akad. Ber.* 1866, p. 77; *Ann. Ch. Pharm.* cxli. 271; further, *Deut. chem. Ges. Ber.* 1871, 273; *Chem. Soc. J.* [2] ix. 372).—This acid, formerly represented by the formula $C^6H^2O^6$, and regarded as bibasic, has been shown by Bayer's investigations to be sexbasic, and to have the constitution of benzene-hexarbonic acid, $C^6(CO^2H)^6$ —that is, to consist of benzene in which all the six carbon-atoms are replaced by carboxyl.

The composition of the salts and ethers of mellitic acid, according to the six-carbon formula, may be illustrated by the following examples:

Neutral.	Acid.
$C^{12}O^{12}(NH^4)^6$	$C^{12}O^{12}H^6(NH^4)^2$
$C^{12}O^{12}(CH^3)^6$	$C^{12}O^{12}H^6K^2$
$C^{12}O^{12}(C^2H^3)^6$	$C^{12}O^{12}H^6(C^2H^3)^2$
$C^{12}O^{12}Ba^3$	$C^{12}O^{12}H^6Ca^3$
$C^{12}H^{12}(Al^2)^4$	

Mellitic chloride, obtained by H. Müller (iii. 874) by the action of phosphorus pentachloride on mellitic acid, has the composition $C^6(COCl)^6$. Müller described it as non-volatile, but Bayer finds that, on distilling the product in a stream of air, the mellitic chloride passes over (after the $POCl^3$ and excess of PCl^3) as a colourless oil, which solidifies to a crystalline mass on cooling. It dissolves easily in pure ether, is insoluble in water, and is slowly converted by boiling therewith into mellitic acid.

Mellitic acid is capable of yielding a large number of amidogen derivatives. Between mellitamide, $C^6(CONH^2)^6$, and mellitic acid, $C^6(COOH)^6$, there may exist

five amidated acids, admitting of several isomeric modifications. Mellitimide by giving up ammonia is converted into a tri-imide, viz. paramide, $C^6\left(\begin{smallmatrix} CO > NH \end{smallmatrix}\right)^3$.

Between this compound, the amide, and the acid, there may further exist numerous intermediate compounds, two of which are known, viz. paramic acid and euchroic acid (ii. 601), which are probably related as follows. When paramide is dissolved in ammonia, and the solution immediately treated with hydrochloric acid, it deposits paramic acid:

one of the bivalent imidogen groups, $(CO)^2NH$, of the paramide being converted by assumption of water into the two univalent groups $CONH^2$ and $COOH$. If now the amidogen group $CONH^2$ takes up H^2O and gives off ammonia, a second acid group $COOH$ will be formed, and the result will be euchroic acid, $C^6\left\{ \begin{array}{l} [(CO)^2NH]^* \\ (COOH)^2 \end{array} \right.$.

Acids derived from Mellitic Acid.

Mellitic acid heated with lime is completely resolved into carbon dioxide and benzene:

It is in fact the last term of the series of aromatic acids derived from benzene by substitution of CO^2H for H —the first term being benzoic acid—all of which are resolved in like manner by distillation with lime into carbon dioxide and benzene. The formulae of these acids are as follows:

The first and fifth, and mellitic acid itself, are not susceptible of isomeric modifications; but the second, third, and fourth, each admit of three modifications, accordingly as the carboxyl occupies, in the second, the places (1, 2), (1, 3), or (1, 4); in the third the places (1, 2, 3), (1, 2, 4), or (1, 2, 5); and in the fourth the places (1, 2, 3, 4), (1, 2, 3, 5), or (1, 2, 4, 5): in all twelve different acids. (See AROMATIC SERIES, p. 197.)

One modification of the fourth acid of the series (pyromellitic acid, $C^4H^2O^4$) is produced by distilling mellitic acid alone at a moderate heat; and by heating mellitic acid to duly regulated temperatures, either alone or with bases, it is possible that the other acids of the series might also be obtained.

All the twelve acids above enumerated are known, except the fifth. They are produced by the following series of processes:

Mellitic acid treated with sodium-amalgam takes up 6 atoms of hydrogen—one for each atom of carboxyl—and is converted into hydromellitic acid, $C^6H^6(CO^2H)^6$. This acid heated with strong sulphuric acid loses 6 atoms of hydrogen, and at the same time 2 mol. carbon dioxide, and is converted into two isomeric quadribasic acids, called prehnitic and mellophanic acids:

In like manner, prehnitic acid treated with sodium-amalgam, takes up an atom of hydrogen for each of its atoms of carboxyl, forming hydroprehnitic acid, $C^6H^4(CO^2H)^4$, and this acid heated with strong sulphuric acid is converted into tribasic trimelic acid:

This last compound can in like manner take up 3 at. hydrogen, and the resulting acid, $C^6H^3(CO^2H)^3$, heated with sulphuric acid, will yield bibasic isophthalic acid, $C^6H^4(CO^2H)^2$; but the latter may be obtained more directly by simply heating hydroprehnitic acid.

Mellophanic acid undergoes similar transformations, resulting in the formation of hemimellitic and phthalic acids.

In the chain of reactions just described, the carboxyls are removed from mellitic acid in a certain order; this however is not the only method of passing from the sexbasic to the monobasic acid. Mellitic acid when heated yields pyromellitic acid,

$\text{C}^6\text{H}^2(\text{CO}^2\text{H})^4$; and this acid treated with sodium-amalgam takes up 4H and is converted into hypopyromellitic acid, $\text{C}^6\text{H}^6(\text{CO}^2\text{H})^4$, which when heated with strong sulphuric acid yields trimellitic acid, $\text{C}^6\text{H}^2(\text{CO}^2\text{H})^3$, isomeric with hemimellitic acid; and this again would doubtless take up hydrogen, yielding a product decomposable by sulphuric acid. In the formation of trimellitic acid, isophthalic acid is obtained as a secondary product.

Hydromellitic Acid. $\text{C}^{12}\text{H}^{12}\text{O}^{12} = \text{C}^6\text{H}^6(\text{CO}^2\text{H})^6$.—Mellitic acid is easily hydrogenised by sodium-amalgam, especially in presence of ammonia. The resulting hydromellitic acid may be purified by precipitating the neutralised solution with lead acetate, and decomposing the precipitate with hydrogen sulphide. On evaporating the filtrate, the hydromellitic acid remains as a syrup, which gradually solidifies to indistinct crystals like those of grape-sugar. It is colourless, very hygroscopic, but not actually deliquescent; dissolves very easily in water, forming a strongly acid liquid; also in alcohol, but sparingly in ether. When heated it melts, with loss of water, to a colourless liquid, which decomposes at a higher temperature, giving off carbon dioxide and leaving a large quantity of charcoal.

The hydromellitates of the alkali-metals are easily soluble in water; of those of the earth-metals and heavy metals, some are soluble, others insoluble. Many are precipitated from their solutions by heat, like calcium citrate, and redissolve on cooling; this is the case with the *calcium* and *manganese* salts. The *silver* salt contains $\text{C}^{12}\text{O}^{12}\text{H}^6\text{Ag}^6$; the *lead* salt $\text{C}^{12}\text{O}^{12}\text{H}^6\text{Pb}^6$. The ethylic ether, $\text{C}^{12}\text{O}^{12}\text{H}^6(\text{C}^2\text{H}^5)^6$, formed by passing hydrochloric acid gas into the alcoholic solution of the acid, is a viscid oil insoluble in water, and decomposing when heated, giving off gas, and yielding a distillate consisting of a liquid and a solid body. The solid body crystallises in large prisms soluble in alcohol, melting between 128° and 130° , and yielding by analysis numbers intermediate between those required by the formulæ $\text{C}^6\text{H}^2(\text{CO}^2\text{C}^2\text{H}^5)^4$ and $\text{C}^6\text{H}^4(\text{CO}^2\text{C}^2\text{H}^5)^3$. The liquid portion of the distillate consists of the ethers of acids richer in hydrogen, one of which, judging from the odour, is hydrobenzoic acid.

Hydromellitic acid heated for some time with *phosphorus pentachloride* and excess of the *oxychloride*, apparently yields hydromellitic chloride. Oxidising agents, e.g. *permanganates* and *nitric acid*, act but slowly on hydromellitic acid; in a mixture of strong nitric and sulphuric acids, it dissolves without apparent alteration. By heating or by prolonged contact with *hydrobromic acid* it is converted into isohydromellitic acid. Heated to 130° in a sealed tube with 6 at. *bromine*, it is partly converted into hydrobromic acid and brominated benzocarbonic acids, and perhaps also yields a small quantity of benzocarbonic acids containing smaller proportions of carboxyl. At the same time the hydrobromic acid converts part of the hydromellitic into isohydromellitic acid.

Respecting the difference of constitution between mellitic and hydromellitic acids, see p. 814.

Isohydromellitic acid, $\text{C}^{12}\text{H}^{12}\text{O}^{12}$, is obtained as above described in tufts of short thick needles, easily soluble in water, but precipitated from the concentrated solution by hydrochloric acid. It crystallises immediately from the aqueous solution in rather large, hard, thick, four-sided prisms, without first becoming syrupy like hydromellitic acid. The crystals are anhydrous, and melt with intumescence when heated, giving off a small quantity of acid water, and leaving a large quantity of charcoal. It is a very stable compound, not being altered by heating to 300° with fuming hydrochloric acid, or by heating with a mixture of sulphuric and fuming nitric acids. It is slowly oxidised by potassium permanganate, rapidly by chromic acid mixture, giving off carbon dioxide and yielding acetic acid, together with a small quantity of trimesic acid.

Isohydromellitic acid yields with *barium acetate* a flocculent precipitate slightly soluble in acetic acid, the solution becoming turbid when heated; with *manganous acetate* no precipitate in the cold, but a flocculent precipitate when heated, which redissolves on cooling; with *silver nitrate* a white granular precipitate easily soluble in ammonia and in nitric acid; with *lead acetate* a flocculent precipitate of the salt $\text{C}^{12}\text{O}^{12}\text{H}^6\text{Pb}^6$, nearly insoluble in water, and very slightly soluble in warm dilute acetic acid. *Methylic isohydromellitate* is easily formed by the action of methyl iodide on the silver salt, and crystallises in needles insoluble in water, easily soluble in alcohol, melting at 125° , and often remaining liquid for a long time after evaporation of the alcoholic solution.

Hydromellitic or isohydromellitic acid heated with five times its weight of strong *sulphuric acid* to about the boiling point of the latter, gives off carbonic and sulphurous anhydrides, and yields a brown liquid, which when mixed with a sufficient quantity of water to redissolve the precipitate first formed, then agitated with ether, and

freed from ether by distillation, yields a reddish nodular crystalline mass easily soluble in water, excepting a small portion. The soluble substance is isopyromellitic acid; the insoluble, trimelic acid. Their formation is represented by the following equations:

and

These two acids are purified by converting them into lead salts, separating with hydrogen sulphide, evaporating to a small bulk, adding a little sulphuric acid, and exhausting with ether. The same mode of purification is applicable to all the corresponding acids to be further described.

Trimelic Acid. $\text{C}^6\text{H}^4\text{O}^6$.—Fittig (*Ann. Ch. Pharm.* cxli. 129; *Jahresb.* 1866, p. 607) obtained this acid by the action of potassium dichromate and sulphuric acid on mesitylenic acid:

It is moderately soluble in water and ether, easily in alcohol, and crystallises from hot water in hard, thick, colourless prisms, which volatilise at a very high temperature without previous fusion, and sublime in needles. The *barium salt*, $(\text{C}^6\text{H}^4\text{O}^6)^2\text{Ba}^2 + 2\text{H}^2\text{O}$, separates on mixing the slightly ammoniacal solution of the acid with barium chloride, as a crystalline pulp composed of rather large needles; it is but slightly soluble in water, even at the boiling heat, and is easily decomposed by hydrochloric acid, with separation of trimelic acid. The *silver salt*, $\text{C}^6\text{H}^4\text{O}^6\text{Ag}^3$, is an amorphous precipitate insoluble in hot water (Fittig). The acid obtained by the action of sulphuric acid on hydromellitic acid exhibits exactly the same characters.

Prehnitic acid, $\text{C}^6\text{H}^4\text{O}^8 = \text{C}^6\text{H}^4(\text{CO}^2\text{H})^4$, is readily soluble in water, and crystallises from its concentrated solution in large prisms resembling the mineral prehnite. They contain 2 mol. water of crystallisation, which escapes on heating; the anhydrous acid melts at 237° – 250° , with further loss of water and formation of the anhydride; the fused mass solidifies quickly at 220° into a crystalline mass, which resembles sal-ammoniac, and melts again at 239° . The aqueous solution of the acid gives with barium chloride a precipitate of small octohedral crystals, having the composition $(\text{C}^6\text{H}^4\text{O}^8)^2\text{Ba}$, and containing 3 or 4 mol. water of crystallisation. The methyl-ether of prehnitic acid crystallises in small thick concentrically grouped prisms, which melt at 104° – 108° , solidify at 81° – 70° , and sublime without decomposition. By the action of sodium-amalgam, the acid is converted into hydroprehnitic acid, a syrupy liquid, which on heating yields isophthalic acid, besides regenerated prehnitic acid.

Mellophanic acid, $\text{C}^6\text{H}^4\text{O}^8$, isomeric with prehnitic acid, is also readily soluble in water, and forms anhydrous crystalline crusts. From a solution containing a little hydrochloric acid it crystallises in fine prisms. Its aqueous solution is not precipitated by barium chloride. At 215° it begins to soften and to shrink together, and at 238° forms a clear liquid, the anhydride, which on cooling solidifies into crystals resembling frost-flowers and melting afterwards at 164° .

Prehnomalic acid, $\text{C}^6\text{H}^4\text{O}^8$, is formed in varying quantity, together with the two preceding, when the action of the sulphuric acid on hydromellitic acid is not carried on too long. It has the composition of prehnitic acid + water, and is easily transformed into the latter acid, by the further action of hot sulphuric acid, by the action of bromine-water, and by the action of methyl-iodide on its own silver salt, the methylic ether of prehnitic acid being then formed.

Prehnomalic acid is quadribasic; its aqueous solution evaporated over the water-bath leaves an amorphous mass, $\text{C}^6\text{H}^4\text{O}^{12}$, very soluble in water. The resulting solution soon solidifies to a magma of bulky needles having the composition $\text{C}^6\text{H}^4\text{O}^{12} \cdot 4\text{H}^2\text{O}$, only sparingly soluble in water. Prehnomalic acid dried at 100° melts at 210° , with loss of water, to a colourless liquid, and distils at a higher temperature, the distillate solidifying to a varnish-like mass which melts at 180° .

Hemimellitic acid, $\text{C}^6\text{H}^4\text{O}^8 = \text{C}^6\text{H}^4(\text{CO}^2\text{H})^3$, is isomeric with trimelic acid, and is so called because it behaves when heated like mellitic acid, and contains only half as many atoms of carboxyl as the latter. To obtain it, the precipitate formed by adding baryta-water to the aqueous solution of the product resulting from the action of sulphuric acid on hydro-isopyromellitic acid is exhausted with cold water; the solution, containing barium hemimellitate mixed with small quantities of isopyromellitate

and isophthalate, is mixed with sulphuric acid; the aqueous solution is again precipitated with baryta-water; and the filtered liquid is mixed with hydrochloric acid, which throws down hemimellitic acid in fine colourless needles, while isopyromellitic acid remains dissolved.

Hemimellitic acid melts at 185° , and if kept for some time at that temperature solidifies to a crystalline mass which melts at 125° . During the fusion long needles of phthalic anhydride sublime, together with a small quantity of benzoic acid. It is rather difficultly soluble in water, and crystallises slowly therefrom, a character by which it is distinguished from phthalic acid, which is also but slightly soluble, but crystallises quickly. It also differs from phthalic acid in being precipitated from its concentrated aqueous solution by hydrochloric acid.

The ammonium salt of hemimellitic acid is easily soluble in water, and crystallises in a radiate mass when evaporated on a watch-glass. A very dilute solution of the acid is not precipitated by baryta-water, but a strong solution gives a precipitate, thereby affording another distinction from phthalic acid, which is not precipitated by baryta-water. The solution of the ammonium salt gives with barium chloride a precipitate of microscopic needles consisting of the neutral salt, $(C^6H^3O^6)^2Ba^2 + 5H^2O$, which gives off 3 mol. water at 160° . The ammonium salt is not precipitated by calcium chloride, but alcohol added to the solution throws down floccs; its concentrated solution is precipitated by cupric sulphate. Lead acetate forms with the acid a flocculent precipitate sparingly soluble in excess of acetic acid. With silver nitrate in excess, the acid forms a flocculent precipitate which dissolves when heated, and separates in the granulo-crystalline form on cooling; this silver salt dried at 120° has the composition $C^6H^3Ag^2O^6$.

Pyromellitic Acid. $C^6H^2O^8 = C^6H^2(CO^2H)^4$ (iv. 762).—The anhydride of this acid, $C^{12}H^2O^{12}$, is produced by the dry distillation of mellitic acid:

and when boiled with water or alkalis, is converted, by assumption of water, into pyromellitic acid. Erdmann's method of preparing the acid by distilling sodium mellitate with sulphuric acid yields good results when only small quantities are operated on at once.

Pyromellitic acid bears a strong resemblance to phthalic acid. By distillation it yields the anhydride $C^{12}H^2O^8$, as an oil which quickly solidifies in large crystals and sublimes in long needles by slow evaporation. It dissolves easily in hot water, and is at the same time converted into the acid, much more easily than phthalic anhydride into phthalic acid. It melts at 286° , the acid at 264° ; phthalic anhydride, on the other hand, melts at a lower temperature than phthalic acid.

Pyromellitic chloride, $C^6H^2(CO^2Cl)^4$, is produced by heating the acid for a considerable time with a slight excess of phosphorus pentachloride, and may be purified by redistillation in a stream of air at 180° . It then solidifies to a soft crystalline mass, which after a while becomes hard and brittle. It dissolves easily in pure ether, and when boiled with water is gradually reconverted into pyromellitic acid.

Ethyl pyromellitate, $C^6H^2(CO^2C^2H^5)^4$, obtained by heating the silver salt to 100° with ethyl iodide, crystallises from alcohol in short flat needles, insoluble in water, melting at 53° , and subliming in needles at a higher temperature. It is probably also one of the products of the dry distillation of ethylic hydromellitate (p. 810).

Hydropyromellitic acid, $C^6H^4O^8 = C^6H^4(CO^2H)^4$, is produced by the action of sodium-amalgam on the ammonium salt of pyromellitic acid, the reduction, if assisted by a gentle heat, being complete in three or four weeks. It remains on evaporation as a colourless syrup, which gradually solidifies in the crystalline form. The presence of alkali interferes with its crystallisation. It is hygroscopic, but not deliquescent; very soluble in water. When heated, it melts with intumescence to a colourless liquid, which decomposes when further heated. With barium acetate, the acid forms no precipitate in the cold; but on heating, a flocculent powder is precipitated, which quickly disappears on cooling. Baryta-water forms an amorphous precipitate which shrinks together to some extent when heated. Manganous acetate forms no precipitate in the cold, but at the boiling heat a flocculent precipitate which disappears immediately on cooling. Altogether hydropyromellitic acid reacts just like hydromellitic acid, excepting that its salts are somewhat more soluble.

Hydropyromellitic acid heated with 5 pts. of strong sulphuric acid gives off large quantities of carbonic and sulphurous anhydrides, yields a small sublimate of benzoic acid, but no phthalic anhydride, and a residue consisting of pyromellitic acid, trimellitic acid, isomerie with hemimellitic acid, and isophthalic acid. To separate these acids, the residual mass is diluted with water and exhausted

with ether, and the aqueous solution of the ethereal extract is precipitated with boiling baryta-water, whereby pyromellitic and trimellitic acids are precipitated, while isophthalic acid remains in solution. The precipitate is decomposed by sulphuric acid, the filtrate concentrated, and the crystalline mass which separates on cooling is fused and digested with pure ether, which dissolves the trimellitic acid, leaving the pyromellitic acid undissolved.

The decomposition of hydroypyromellitic acid by sulphuric acid may be represented by the following equation :

Trimellitic Acid. $\text{C}^8\text{H}^6\text{O}^8 = \text{C}^8\text{H}^2(\text{CO}^2\text{H})^3$.—This acid, dissolved as above by ether, is purified by conversion into a lead salt in the manner already described (p. 811). It is moderately soluble in water and ether, and crystallises from aqueous solution by slow evaporation in nodular groups of indistinct crystals. It melts at 216° , and when more strongly heated does not sublime, but distils in oily drops, which solidify on cooling to nodular groups of concentric needles. In this respect it bears considerable resemblance to isopyromellitic acid, which however melts at 238° , and solidifies from the oil obtained on distilling it, in needles and isolated crystals. These characters, however, are distinctly exhibited only when the respective acids are pure. The two acids are further distinguished by the different solubilities of their barium salts, isopyromellitic acid giving a precipitate with barium chloride, whereas this reagent does not produce a precipitate even with the ammonium salt of trimellitic acid.

Ammonium trimellitate is easily soluble in water, and crystallises in concentric needles from the concentrated solution. The *barium salt* is sparingly soluble, and separates on mixing the ammonium salt with barium chloride, especially on heating, in crystalline nodules, exhibiting, after drying over sulphuric acid, the composition $(\text{C}^8\text{H}^6\text{O}^8)^2\text{Ba} + 3\text{H}^2\text{O}$. With *lead acetate*, trimellitic acid forms a flocculent precipitate nearly insoluble in acetic acid. *Silver nitrate* forms, especially on addition of ammonia, a granular precipitate, which dissolves when heated, and reappears on cooling.

The acids above described belong to two classes, the benzocarbonic and the hydrobenzocarbonic acids. Of the benzocarbonic acids, as already observed, twelve are possible, and eleven have actually been obtained. These are arranged by Baeyer as ortho-, meta-, and para- compounds (AROMATIC SERIES, p. 197) as follows :

	<i>Ortho-series.</i>	<i>Meta-series.</i>	<i>Para-series.</i>
$\text{C}^6(\text{CO}^2\text{H})^6$	1 2 3 4 5 6 Mellitic acid.		
$\text{C}^8\text{H}(\text{CO}^2\text{H})^5$	1 2 3 4 5 Unknown.		
$\text{C}^8\text{H}^2(\text{CO}^2\text{H})^4$	1 2 3 4 Mellophanic acid.	1 2 3 5 Prehnitic.	1 2 4 5 Pyromellitic acid.
$\text{C}^8\text{H}^3(\text{CO}^2\text{H})^3$	1 2 3 Hemimellitic acid.	1 2 4 Trimesic acid.	1 3 5 Trimellitic acid.
$\text{C}^8\text{H}^4(\text{CO}^2\text{H})^2$	1 2 Phthalic acid.	1 3 Isophthalic acid.	1 4 Terephthalic acid.
$\text{C}^8\text{H}^5\text{CO}^2\text{H}$	1 Benzoic acid.		

Of the hydrobenzo-carbonic acids, two were previously known, viz. hydrobenzoic acid, $\text{C}^7\text{H}^{10}\text{O}^2$, and hydrophthalic acid, $\text{C}^7\text{H}^8\text{O}^4$; and four more have been added to the list by Baeyer's recent investigations, viz. hydromellitic acid, $\text{C}^{12}\text{H}^{10}\text{O}^{12}$, hydroypyromellitic, hydroprehnitic, and hydromellophanic acids, $\text{C}^{10}\text{H}^{10}\text{O}^8$. The difference of structure of mellitic and hydromellitic acid may be represented by the following formulæ, in which the symbol X stands for CO^2H :

Mollitic.

Hydromellitic.

In the first, the nucleus C^6 consists, as in most aromatic compounds, of three pairs of carbon-atoms united by two affinities, while each pair is united with the next by only one affinity. In the second the six carbon-atoms are united together by only one affinity.

The stability of the hydro-acids increases in a remarkable manner with the number of the carboxyl groups; for whereas hydrobenzoic acid loses its hydrogen by mere exposure to the air, and hydrophthalic acid is so unstable that it reproduces phthalic acid and benzoic acid under the influence of almost all reagents, isohydromellitic acid is so stable that it is not oxidised even by a mixture of strong sulphuric and fuming nitric acids.

MENAPHTHOXYLIC ACID. Syn. with NAPHTHALENE-CARBOXYLIC ACID.

MENAPHTHYLAMINE. $C^{11}H^{10}NH^2$.—A base produced by treating menaphthothiamide, $C^{11}H^8NS$, in alcoholic solution with hydrochloric acid and zinc, as long as hydrogen sulphide is given off. It is a liquid boiling at 290° – 298° , and rapidly absorbing carbonic acid from the air. The hydrochloride, $C^{11}H^{10}NH^2 \cdot HCl$, crystallises in long, sparingly soluble needles; the platinochloride, $2(C^{11}H^{10}NH^2 \cdot HCl) \cdot PtCl_4$, is a yellow crystalline precipitate. The sulphate and nitrate crystallise well. With carbon bisulphide the base forms a white crystalline mass. With alcoholic soda and chloroform it forms the strongly smelling compound formomenaphthyl nitrile (Hofmann, *Deut. chem. G. Berlin*, 1868, p. 100; *Zeitschr. f. Chem.* [2] iv. 503).

MENECHINITE. $4PbS \cdot Sb^2S$.—According to G. vom Rath (*Pogg. Ann.* clxxxii. 372; *Jahresb.* 1867, 974), the crystalline form of this mineral is not trimetric, as found by Sella (iii. 879), but monoclinic. In the primary form the ratio of the clinodiagonal: orthodiagonal: principal axis = $0.361639 : 1 : 0.116825$. Angle of inclined axes = $92^\circ 19' 42''$.

MENHADEN OIL (Warren a. Storer, *Mem. Amer. Acad.* [new series] ix. 177; *Zeitschr. f. Chem.* [2] iv. 228).—The oil obtained from *Alosa Menhaden*, a species of herring, forms a lime-soap which, when distilled with excess of lime, yields the following volatile hydrocarbons:

		Boiling point of the fraction	Amount in the crude oil
Amylene	C^6H^{10}	35° – 37°	0.8 p. c.
Quintane or Amyl hydride	C^7H^{12}	37° – 41°	
Hexylene	C^8H^{12}	65° – 66°	3.9 "
Hexane	C^6H^{14}	67.5° – 68°	2.8 "
Benzene	C^6H^6	80° – 81°	3.1 "
Heptylene	C^8H^{14}	93° – 94°	4.7 "
Heptane	C^7H^{16}	97.8°	7.6 "
Toluene	C^7H^8	110° – 111°	6.9 "
Octylene	C^9H^{16}	121° – 122°	12.5 "
Octane	C^8H^{18}	128° – 129°	
Xylene	C^8H^{10}	140° – 144°	13.3 "
Nonylene	C^9H^{18}	153°	7.8 "
Decylene	$C^{10}H^{20}$	165° – 174°	23.5 "
Isocumene	C^9H^{12}		
Undecylene	$C^{11}H^{22}$	193° – 196°	10.2 "
Duodecylene	$C^{12}H^{24}$	208° – 213°	3.1 "

MENYANTHIN. Kromayer (*Arch. Pharm.* [2] cxxiv. 37; *Jahresb.* 1865, p. 610) recommends certain modifications of the process originally given for the preparation of this compound from *Menyanthes trifoliata*; he now assigns to it the formula $C^{10}H^{14}O^{11}$, with variable amount of water. The sugar formed in the decomposition of menyanthin by acids is dextroglucose, $C^6H^{12}O^6 \cdot 6H^2O$. The volatile product of the reaction, menyanthol, is represented by the formula $C^8H^{10}O$ (which, however, does not agree well with the analysis), and the decomposition is represented by the equation

By exposure to the air, and by fusion with potash, menyanthol is converted into a crystalline sublimable acid.

MERCURACETYL OXIDE. See ACETYLENE (p. 36).

MERCURAMMONIUMS (Weyl, *Pogg. Ann.* cxxi. 601; cxxxi. 524; *Zeitschr. f. Chem.* [2] iv. 129; *Jahresb.* 1864, p. 282; 1867, p. 306).—Hydrated dimercurammonium oxide, $(NH_4^2)^2O \cdot 3H^2O$, is obtained by passing dry ammonia gas over amorphous mercuric oxide, or more quickly by the action of ammonia on mercuric oxide under pressure in the apparatus described under SODAMMONIUM (v. 328), one arm of the tube containing silver chloride saturated with ammonia, the other mercuric oxide; also by treating the oxide with an alcoholic solution of ammonia for several hours, and drying the product at ordinary temperatures. The product obtained by either of these processes has, if formed in the dark, the same yellow colour as precipitated mercuric oxide; if it has been exposed to light during its formation, it has a lighter colour, and leaves mercurous chloride when dissolved in hydrochloric acid; by prolonged exposure to the light, it suffers further decomposition and yields metallic mercury. It is decomposed by water or dilute sulphuric acid, giving up ammonia, and being converted into a white insoluble substance. In warm hydrochloric or nitric acid it dissolves, with formation of the corresponding mercury and ammonium compounds. Heated in a flame on platinum foil, it detonates with great violence. When heated in a stream of dry ammonia gas, it gives off 2 mol. water at 80° , leaving a light brown monohydrate, and at 100° , the remaining molecule, leaving the dark brown anhydrous oxide $(NH_4^2)^2O$. This anhydrous oxide detonates by heat, percussion, or friction. In contact with water it assumes a lighter colour, but the water at the same time takes up ammonia. The trihydrate may also be converted into the anhydrous oxide by treating it with ammonia under such a pressure that the compound may be surrounded for a long time with liquid ammonia.

The corresponding haloid compounds cannot be prepared by treating the oxide with aqueous acids, and only in an impure state by the use of alcoholic solutions of the acids. When mercuric chloride or iodide is subjected to the action of liquefied ammonia, in the apparatus above mentioned, a monomercuro-diammonium compound is first produced, which afterwards dissolves in ammonia, and on evaporation of the excess of ammonia, yields a crystalline mass, which, according to the observed increase of weight, may be regarded either as a monomercuro-diammonium compound, or as a dimercurammonium compound mixed with ammonium salt, its formation being represented by the equation

These compounds do not, however, admit of purification. Better results are obtained by the use of mercuric oxychloride or oxyiodide. The oxychloride (obtained by heating a mixture of 3 mol. mercuric oxide with 1 mol. of the chloride to above 100°) yields *dimercurammonium chloride* in the form of a yellow body insoluble in excess of liquid ammonia:

This chloride, heated to 300° , is resolved into mercurous chloride, metallic mercury, and nitrogen; it is not attacked by water, either cold or boiling; is dissolved by cold hydrochloric acid after prolonged contact; decomposed by cold potash-ley with formation of potassium chloride and yellow explosive dimercurammonium oxide, and by boiling potash-ley or potassium chloride with evolution of ammonia and formation of mercuric oxychloride or chloride.

Mercuric oxyiodide, $3HgO \cdot HgI^2$, similarly treated yields a brown non-explosive product, which when freed from excess of ammonia by heating to 100° in a stream of dry air, has the composition of *dimercurammonium iodide*, and resembles the chloride in its properties. The corresponding *bromide* and *cyanide* have also been obtained; the cyanide is highly explosive. Mercuric oxychloride or oxyiodide heated in a

stream of ammonia gas is converted into *amidated oxychlorid*, $\text{NH}^2\text{Hg}^2\text{ClO} = \text{NH}^2\text{HgCl} \cdot \text{HgO}$, or *oxyiodide*, $\text{NH}^2\text{HgI} \cdot \text{HgO}$, which again are converted by the action of liquid ammonia in a sealed tube into dimercurammonium compounds; e.g.,

MERCURIALINE. This name is given by Reichardt (*J. pr. Chem.* civ. 301; *Zeitschr. f. Chem.* [2] iv. 734) to a volatile base having the composition of methylamine, which is obtained, together with ammonia, by distilling the seeds or other parts of *Mecurialis annua* or *M. perennis* with lime or potash and water. It is described as liquid at ordinary temperatures, and strongly alkaline, and its sulphate and oxalate are said to differ from those of methylamine; but it is probably nothing but impure methylamine.

MERCURY. The boiling point of mercury under a pressure of 760 mm. is 357.25° (Regnault, *Relation des Expériences*, &c.). Its specific gravity at 4° , reduced to a vacuum and compared with that of water at 4° , is 13.594 (Balfour Stewart, *Proc. Roy. Soc.* xv. 10); this determination agrees with those of Regnault and Kopp (iii. 584).

Its heat-conducting power in the liquid state is 53.5 according to Calvert a. Johnson (*Jahresb.* 1864, p. 169); 35.4 according to Gripon (*Phil. Mag.* [4] xxxii. 547); that of silver being = 1000. Its coefficient of cubical expansion is 0.0001812 (Matthiessen, *Proc. Roy. Soc.* xiv. 551). (See HEAT, p. 671.) Regnault's experiments gave 0.00018153.

Amalgams. According to Cailletet (*Bull. Soc. Chim.* [2] viii. 299) the amalgamation of metals (including the zinc cylinders of galvanic batteries) may be easily effected by dipping them into sodium-amalgam containing 0.5 p. c. sodium.

Calvert a. Johnson (*loc. cit.*) have found the following values for the heat-conducting powers of solid amalgams (silver = 1000):

HgSn^2	. . . 272.1	HgZn^2	. . . 304.1	HgBi^4	. . . 67.4
HgSn^3	. . . 296.3	HgZn^3	. . . 315.0	HgBi^6	. . . 81.5
HgSn^4	. . . 302.5	HgZn^4	. . . 378.7	HgBi^8	. . . 79.9
HgSn^5	. . . 332.3	HgZn^5	. . . 409.1	HgBi^{10}	. . . 73.7

Liquid amalgams containing excess of mercury were found to differ but little in heat-conducting power from pure mercury, although the percentage of tin varied from 10.5 to 22.95, that of zinc from 6.09 to 13.97, that of bismuth from 17.55 to 34.73.

Magnesium-amalgam is formed, according to Wanklyn a. Chapman (*Chem. Soc. J.* [2] iv. 141), by contact of mercury with magnesium free from oxide, slowly in the cold, quickly and with violence when the two metals are heated to the boiling point of mercury. In this amalgam the affinities of the magnesium are exalted, contrary to what takes place in the case of sodium-amalgam. Magnesium-amalgam containing 0.5 p. c. magnesium swells up instantly in contact with the air, and loses its lustre, decomposes water with violence, and more rapidly than sodium-amalgam containing twice that percentage of sodium.

Phipson (*Bull. Soc. Chim.* [2] v. 243) observed that when 207 pts. lead, 118 tin, 284 bismuth, and 1617 mercury were mixed together, the temperature of the amalgam fell from $+17^\circ$ to -10° .

Sodium-Amalgam.—This compound easily reduces mercuric chloride, auric chloride, and the haloid compounds of silver when laid in a thin slice on the pulverised substance placed in a test-tube together with a little water. Ferric chloride is partly reduced to ferrous chloride, partly to metallic iron, and with a sufficient quantity of the amalgam, completely to metal, which remains as iron-amalgam. Chromic chloride suspended in very dilute hydrochloric acid is reduced in like manner to liquid, easily decomposable chromium-amalgam, the liquid turning green before complete reduction takes place. Sodium-amalgam is well adapted for the reduction of chloride, iodide, and bromide of silver. It acts but slowly on an ethereal solution of ferric chloride, and not at all on silver chloride under rock-oil (Bunge, *Chem. Centr.* 1865, p. 257).

Bromiodide. HgIBr .—Produced by heating mercuric bromide dissolved in acetone with an alcoholic iodide; also by crystallising mercuric bromide and iodide together from solution in ether or acetone; and by adding iodine to a solution of the bromide in acetone. Forms beautiful yellow crystals melting at 229° , subliming without decomposition, and separating in scales from solution in ether, without alteration of colour (Oppenheim, *Deut. chem. Ges. Ber.* 1869, 571; *Zeitschr. f. Chem.* [2] v. 165).

Chlorides. For the preparation of *mercuric chloride* on the large scale, Wagner (*Dingl. pol. J.* cxxxvi. 135) recommends: (a) Decomposition of basic mercuric sulphate (*mineral turpithum*) by heating it with hydrochloric acid, whereupon mercuric chloride separates and sulphuric acid passes into solution (the acid liquid yields by evaporation a sulphuric acid containing mercuric oxide, and adapted for dissolving mercury).—(b) Digestion of the yellow mercuric oxide precipitated by caustic soda from the nitrate with magnesium chloride (the mother-liquor of the working of carnallite), the reaction being represented by the equation: $\text{HgO} + \text{MgCl}_2 = \text{HgCl}_2 + \text{MgO}$. If the presence of potassium chloride in the mercuric chloride is not objectionable, the solution of the carnallite may be directly saturated with mercuric oxide. After the separation of the precipitated magnesia, the liquid yields by evaporation the salt $\text{KCl} \cdot \text{HgCl}_2 + \text{H}_2\text{O}$. Wagner observes that this salt may be used just as well as pure mercuric oxide for the preparation of rosaniline salts.

Mercuric chloride prepared by sublimation in an atmosphere of hydrochloric acid gas is quite free from calomel. It may be obtained by dissolving 10 pounds of mercury in 12.5 pounds of sulphuric acid of 66° Bm., carefully evaporating the liquid, and subliming the residual mass of neutral and acid mercuric sulphate with 9 pounds of sodium chloride (H. Fleck, *Bull. Soc. Chim.* [2] viii. 39).

According to Bonnewyn (*ibid.* iv. 201), the presence of an extremely small proportion of corrosive sublimate in calomel may be detected by immersing a clean knife-blade in the calomel moistened with alcohol or ether. If only $\frac{5}{100,000}$ part of corrosive sublimate is present, a black spot will be formed on the steel, very difficult to remove by friction, whereas if the calomel is pure no such spot will be formed.

Debray (*Compt. rend.* lxi. 1339) finds that gold-leaf heated in vapour of calomel to 410° retains its lustre and malleability, whereas when heated in vapour of mercuric iodide to the temperature at which that compound suffers dissociation it becomes white and friable. Hence Debray concludes that mercurous chloride at 440° (the temperature at which Deville a. Troost determined its vapour-density) is not resolved into metallic mercury and mercuric chloride, and that therefore its abnormal vapour-density (for the formula Hg_2Cl_2) does not result from dissociation. On the other hand, Erlenmeyer and Odling find that gold-leaf immersed in calomel vapour heated to about the boiling point of mercury becomes amalgamated, showing that the mercurous chloride is at least partly decomposed, with separation of mercury. Erlenmeyer observes, however, that this decomposition cannot decide the question as to the molecular weight of mercurous chloride, inasmuch as it may take place either in the manner represented by the equation $\text{Hg}_2\text{Cl}_2 = \text{HgCl}_2 + \text{Hg}$, or $\text{HgCl} + \text{HgCl} = \text{HgCl}_2 + \text{Hg}$ (*Jahresh.* 1864, p. 280).

Iodide. According to Oppenheim (*Zeitschr. f. Chem.* [2] vi. 156), mercuric iodide passes from the red to the yellow modification at a temperature between 148° and 154°, probably nearer to the former.

Oxides. Mercuric oxide added to melting potassium hydrate dissolves without evolution of gas; and if the addition be continued not quite to saturation, the mass then slowly cooled and lixiviated with water, a heavy violet crystalline powder is obtained, consisting of $\text{K}_2\text{O} \cdot \text{HgO}$, and a lighter grey-green powder of variable composition, containing from 2 to 5 p. c. potash. Similar results are obtained with sodium hydrate (St. Meunier, *Compt. rend.* ix. 557, 1232; *Jahresh.* 1865, p. 277).

Fouberg (*Ann. Ch. Phys.* [4] i. 300) finds, contrary to the statement of H. Rose (iii. 909), that alkalis and alkaline earths are separated by mercuric and by mercurous oxide, when the saturated solutions of their haloid salts in large excess are agitated or boiled with the oxide; the decomposition is facilitated by passing carbon dioxide through the solution. The oxygen-salts of these bases are also decomposed in this manner, but with much greater difficulty. These reactions appear also to have been observed by Melsens in 1819 (*Ann. Ch. Phys.* [3] xxvi. 220), who likewise found that a neutral or slightly acid solution of potassium iodide becomes alkaline by agitation with air and metallic mercury together.

Sulphides. When a mercuric double salt, e.g. $(2\text{KCyS} \cdot \text{HgCyS}^2 + 2\text{NaCl} \cdot \text{HgCl}_2)$, is heated with an equivalent quantity of sodium hyposulphite, black mercuric sulphide is precipitated as soon as the liquid becomes acid; if the hyposulphite is used in excess, the mercuric sulphide separates in the form of cinnabar as long as the liquid remains neutral; but on heating it above 60°, the black sulphide makes its appearance as soon as the liquid acquires an acid reaction. The reaction in the acid solution (a), and in the neutral solution (b), may be represented by the following equations:

The formation of cinnabar under the conditions above mentioned does not take place in presence of strontium, calcium, or magnesium salts, but is accelerated by copper or zinc salts. When 1 mol. mercuric chloride is mixed with 4 mol. sodium hyposulphite and 4 mol. zinc sulphate in very dilute solution, and the mixture is heated to 45° or 50° for about sixty hours, three-fourths of the mercury is separated from the neutral liquid as dark red crystalline cinnabar, the rest at a higher temperature as black amorphous sulphide. If barium chloride be used instead of zinc sulphate, barium sulphate separates together with the cinnabar. In the ordinary mode of preparing cinnabar in the wet way, the transformation of the amorphous sulphide depends upon its successive solution in the alkaline sulphide, from which it separates in the crystalline form. The presence of sodium hyposulphite does not facilitate, but rather hinders this transformation (H. Fleck, *J. pr. Chem.* xcix. 247).

The solubility of mercuric sulphide in the sulphides of the alkali-metals and alkaline-earth metals may be made available for the extraction of the sulphide from its gangue, and especially for the valuation of poor cinnabar ores (containing 2 to 3 p. c. cinnabar). The best solvent for the purpose is a solution of barium sulphide, containing about 50 grms. of barium in a litre, obtained by dissolving crude barium sulphide in water, and crystallising out the greater part of the barium hydrate. The mercuric sulphide is precipitated from the solution of hydrochloric acid (whereby barium chloride is obtained as a secondary product), and decomposed in the ordinary way. For the assay of poor bituminous ores, the bituminous matter must first be extracted by benzol, the ore then well dried and exhausted with barium sulphide, and the precipitate thrown down by hydrochloric acid freed from admixed sulphur by digestion with carbon bisulphide (Wagner, *J. pr. Chem.* xcviii. 23; *Jahresb.* 1866, p. 834).

Cinnabar digested for a day with excess of a solution of iodine in potassium iodide is converted into potassio-mercuric iodide: $\text{HgS} + 2\text{KI} + \text{I}_2 = 2\text{KI} \cdot \text{HgI}_2 + \text{S}$. The diminution of the free iodine affords a measure of the quantity of mercury dissolved (Wagner, *loc. cit.*).

The black precipitate formed in mercurous salts by hydrogen sulphide, or colourless ammonium sulphide, is not a definite compound, but a mixture of mercury and mercuric sulphide, from which nitric acid extracts the metallic mercury, forming either a mercurous or a mercuric salt, and in the latter case the white double compound $\text{Hg}(\text{NO}_3)_2 \cdot 2\text{HgS}$. This double compound is nearly insoluble in nitric acid, and forms with hydrochloric acid the yellow compound $\text{HgCl}_2 \cdot 2\text{HgS}$, which decomposes when heated in the liquid, with formation of sulphuric acid and separation of sulphur; sulphuric acid of medium strength converts it into the white salt, $\text{HgSO}_4 \cdot 2\text{HgS}$. Mercuric sulphide, which under ordinary circumstances is insoluble in nitric acid, is likewise converted by prolonged heating with that acid into the white compound $\text{Hg}(\text{NO}_3)_2 \cdot 2\text{HgS}$. Mercuric sulphide is insoluble in sodium sulphhydrate, and consequently its solution in sodium sulphide is precipitated by hydrogen sulphide or ammonium sulphhydrate. It appears from the preceding that the separation of mercury as sulphide from other sulphides of the same group by nitric acid is exact only when the mercury is present as mercuric sulphide (Barfoed, *Bull. Soc. Chim.* [2] iii. 183).

MERCURY-RADICLES, ORGANIC. *Mercuric ethide* is rapidly decomposed at temperatures near its boiling point by carbon oxysulphide, metallic mercury being separated, and a liquid having a strong alliaceous odour being formed, probably ethyl thiopropionate (Than, *Zeitschr. f. Chem.* [2] iv. 56).

Mercuric acetoxymethide, $\text{C}^2\text{H}^6\text{O}^2\text{Hg} = \text{Hg} \left\{ \begin{smallmatrix} \text{C}^2\text{H}^5\text{O}^2 \\ \text{CH}^3 \end{smallmatrix} \right.$, is produced by heating mercuric methide with acetic acid to 120°–130° in a sealed tube. It crystallises from hot glacial acetic acid in shining, white, thin, rhombic tables, melting at 142°–143°, having an offensive and very persistent odour, nearly insoluble in boiling water and cold acetic acid, more soluble in hot acetic acid and in alcohol. It volatilises with vapour of water, and reacts with hydrochloric acid, ammonium sulphide, and iodine, like the corresponding compounds of the aromatic series described below. *Mercuric acetoxethide* resembles the methyl-compound, and melts at 178° (Otto, *Zeitschr. f. Chem.* [2] vi. 25).

Mercuric Naphthylide. $\text{Hg}(\text{C}^{10}\text{H}^7)^2$ (Otto a. Möries, *Ann. Ch. Pharm.* cxlvii. 164; *Zeitschr. f. Chem.* [2] iii. 377; iv. 162; *Jahresb.* 1867, p. 715).—This compound is easily and abundantly formed by the action of sodium-amalgam on monobromonaphthalene:

A solution of bromonaphthalene in several times its volume of coal-tar naphtha boiling between 120° and 140° is boiled for about nineteen hours with pasty sodium-amalgam, in a flask having an upright condenser, and the liquid is filtered hot, whereupon the mercuric naphthide crystallises out almost completely. After recrystallisation from benzol or carbon bisulphide, it forms small white crystals, appearing under the microscope as rhombic prisms terminated by four-sided pyramids. It is inodorous, unaffected by air and light, insoluble in water, slightly soluble in boiling alcohol, cold benzol, or ether, more easily in hot carbon bisulphide, chloroform, and benzol. It melts at 243° and decomposes at a higher temperature, depositing small quantities of charcoal and mercury, and yielding an oily crystallising distillate. By ignition with soda-lime it yields naphthalene, together with another hydrocarbon crystallising in canary-yellow laminae, and melting at 133° . Heated with concentrated hydriodic, hydrobromic, or hydrochloric acid, it is resolved into naphthalene and mercuric iodide, bromide, or chloride. With iodine it unites directly, forming naphtho-mercuric di-iodide, $(C^{10}H^7)_2HgI_2$, which on further addition of iodine is resolved into mercuric iodide and idonaphthalene, $C^{10}HI$.

trivalent), is prepared by mixing the solutions of 1 mol. mercuric naphthylide and 1 mol. iodine in carbon bisulphide, distilling off the latter, and recrystallising the residue from hot alcohol. It forms soft satiny needles or dendritic groups, not altered by light, insoluble in water, slightly soluble in hot alcohol, chloroform, benzol, and carbon bisulphide, melting at 185° , and resolved by ignition with lime into naphthalene, iodine, and mercuric oxide.

Bromine acts on mercuric naphthylide in the same manner as iodine, forming in the first instance a crystallisable dibromide, which is decomposed by more bromine into bromonaphthalene and mercuric bromide.

Mercuric Acetoxynaphthylide, $C^{12}H^{10}HgO_2 = Hg \left\{ \begin{array}{c} C^{10}H^7 \\ OC^{12}H^{10}O \end{array} \right\}$, is produced, together with naphthalene, by heating mercuric naphthylide with excess of glacial acetic acid:

On mixing the solution with a large quantity of hot water, and crystallising the resulting white precipitate from hot alcohol, naphthalene separates out, while mercuric acetoxynaphthylide remains in solution, and may be obtained by evaporation, prolonged heating, and recrystallisation. It is insoluble in water, easily soluble in hot glacial acetic acid, alcohol, carbon bisulphide, benzol, and chloroform, less soluble in ether; crystallises in small needles appearing under the microscope as flat rhombic prisms or tables; melts at 154° , and decomposes at a higher temperature, depositing charcoal, and yielding an oily distillate which quickly solidifies. With hydrochloric, hydriodic acid, &c., it reacts like mercuric naphthylide. It is not decomposed by heating with water to 140° , with ethyl iodide to 160° , or by sodium-amalgam, zinc, copper, or tin at ordinary temperatures; neither does it unite with mercuric chloride.

Mercuric Phenylide. $Hg(C^6H^5)_2$ (Dreher u. Otto, *Zeitschr. f. Chem.* [2] iv. 685; vi. 9).—This compound is prepared, like the naphthylide, by heating a mixture of monobromobenzene and anhydrous benzol (B. P. 100° – 120° – 140°) with pasty sodium-amalgam; the reaction may, however, be considerably facilitated by addition of a little acetic ether ($\frac{1}{10}$ of the weight of the bromobenzene).

Mercuric phenylide crystallises from a hot-saturated benzol-solution in small, white, vitreous, asbestos-like needles; from a dilute solution in white rhombic prisms often united in tufts. It is insoluble in water, easily soluble in chloroform, carbon bisulphide, and benzol, less easily in ether and boiling alcohol, slightly in cold alcohol. Melts at 120° ; sublimes without decomposition when cautiously heated in small quantities; boils when heated above 300° , and distils, with formation of benzene and diphenyl, and separation of mercury and charcoal; probably thus:

and

It is quickly decomposed by dry hydrochloric acid gas, or by heating with the concentrated aqueous acid, into benzene and mercuric chloride:

and reacts in a similar manner with hydriodic, hydrobromic, nitric, sulphuric acid, &c.

Heated with 2 at. *sulphur* above the melting point of the latter, it yields mercuric sulphide and phenyl sulphide, together with a small quantity of phenyl sulphhydrate:

A solution of mercuric phenylide in alcohol or carbon bisulphide acted upon by 2 at. *iodine* yields phenyl iodide and mercuric iodophenylide:

With 4 at. *iodine* the products are phenyl iodide and mercuric iodide:

Mercuric Iodophenylide crystallised from boiling benzol, or a mixture of benzol and absolute alcohol, forms white satiny rhombic tables, not altered by light, melting at 265° – 266° , insoluble in water, nearly insoluble in cold alcohol, ether, and benzol, more easily in hot benzol or chloroform, still more in carbon bisulphide. Heated above its melting point, it partly sublimes unaltered, and is partly decomposed, with separation of mercuric iodide.

Mercuric Bromophenylide, $\text{Hg}\left\{\text{C}^6\text{H}^5\right\}_{\text{Br}}$, obtained in like manner, resembles the iodine-compound in the form and lustre of its crystals, and in its relations to solvents; melts at 291° ; and is converted by excess of bromine into mercuric bromide and phenyl bromide.

Mercuric Chlorophenylide is obtained by slowly passing chlorine, not in excess, over mercuric phenylide, or into a solution of that compound in carbon bisulphide; more easily, however, by heating mercuric phenylide with mercuric chloride to 110° in sealed tubes: $\text{Hg}(\text{C}^6\text{H}^5)^2 + \text{HgCl}^2 = 2\text{Hg}\left\{\text{C}^6\text{H}^5\right\}_{\text{Cl}}$. The iodine and bromine derivatives may be obtained in a similar manner. Mercuric chlorophenylide resembles the two preceding compounds, and is likewise decomposed in a similar manner, though less readily, by excess of chlorine. Hypochlorous acid acts upon mercuric phenylide in the same manner as free chlorine.

Nascent hydrogen, evolved by sodium-amalgam in alcoholic solution, converts mercuric iodophenylide into mercuric phenylide; thus:

In contact with anhydrous benzol, *sodium-amalgam* acts upon mercuric iodophenylide in the same manner as nascent hydrogen:

but *free sodium* unites with the mercury of the phenyl-compound, producing sodium-amalgam, sodium-iodide being also formed, together with a brown organic product which does not dissolve in the ordinary solvents.

Mercuric bromophenylide, boiled for some time with alcoholic solution of *potassium sulphide*, is decomposed in the manner shown by the equation:

Mercuric Acetoxyphenylide, $\text{Hg}\left\{\text{C}^6\text{H}^5\right\}_{\text{C}^2\text{H}^3\text{O}_2}$, is formed, like the corresponding naphthyl-compound, by boiling mercuric phenylide with several times its volume of strong acetic acid:

The product separated from the solution by water and crystallised from hot water, forms small, white, inodorous, vitreous, rhombic prisms, mostly in radiate groups; melting at 140° , slightly soluble in cold water, more easily in hot water, strong acetic acid, benzol, and alcohol. Similar compounds are formed with *acetic* and *propionic acids*.

Mercuric acetoxyphenylide is decomposed by distillation, yielding benzene, acetic anhydride, acetic acid, and diphenyl, together with free carbon and mercury. Boiled with aqueous *hydrochloric acid*, it yields mercuric chloride, benzene, and acetic acid:

Hydriodic, sulphuric, and other acids act in a similar manner. With *nascent hydrogen*, generated by sodium-amalgam in the alcoholic solution, it yields mercury, benzene, and acetic acid:

In aqueous solution it is decomposed by *iodine*, yielding mercuric iodide, phenyl iodide, acetic acid, and iodic acid. Perhaps Schützenberger's acetate of iodine, $(C^2H^3O)IO$ (p. 25), is first formed:

and then decomposed by the water, in the manner shown by the equation:

An alcoholic solution of mercuric acetoxyphenylide is decomposed by *hydrogen sulphide* into mercuric sulphide, benzene, and acetic acid:

in like manner, but more quickly, by heating in a sealed tube with *ammonium sulphide*.

Mercuric Tolylide. $Hg(C^2H^3)^2$ or $\begin{matrix} C^2H^3 & \diagup & CH^3 \\ & Hg & \\ C^2H^3 & \diagdown & CH^3 \end{matrix}$ (Dreher u. Otto, *loc. cit.*).—

Obtained, similarly to the phenyl-compound, by the action of sodium-amalgam on bromotoluene. Beautiful white rhombic tablets, having a nacreous to adamantine lustre, insoluble in water, slightly soluble in cold alcohol, more freely in hot benzol, chloroform, and carbon bisulphide. Melting point 235° . It appears to be analogous in all its reactions to the phenyl-compound. By boiling with *hydrochloric acid* it is resolved into mercuric chloride and toluene, $Hg(C^2H^3)^2 + 2HCl = HgCl^2 + 2C^2H^6$. When carefully heated, it distills almost without decomposition; but on passing its vapour through a red-hot tube filled with pumice, it is resolved into mercury, carbon, toluene, and an oily body, probably ditolyl. Treated with 2 at. *iodine*, *bromine*, or *chlorine*, it is converted into mercuric iodotolylide, $\begin{matrix} C^2H^3 & \diagup & CH^3 \\ & Hg & \\ & \diagdown & Cl \end{matrix} \rightarrow Hg, \&c.;$ by 4 at. iodine, &c., into mercuric iodide and iodotoluene, &c.

Mercuric Iodotolylide forms white rhombic tables having a satiny lustre, insoluble in water, slightly soluble in boiling alcohol, more freely in hot benzol; melting at 120° , and subliming without decomposition when cautiously heated.

Mercuric Acetoxytolylide, $Hg(C^2H^3)(C^2H^3O^2)$, prepared like the phenyl-compound, forms small, white, shining, rhombic prisms, melting at 153° , nearly insoluble in cold water, sparingly soluble in boiling water, more easily in alcohol, carbon bisulphide, and benzol. With acids, hydrogen sulphide, and iodine, it reacts like the phenyl-compound.

Mercuric Benzylide, isomeric with mercuric tolylide, and represented by the formula $\begin{matrix} C^2H^3 \cdot CH^2 & \diagup & Hg \\ & & \\ C^2H^3 \cdot CH^2 & \diagdown & \end{matrix}$, is not produced by the action of sodium-amalgam either on benzyl bromide or on benzyl chloride. A compound, $Hg(C^2H^3)^2$, called by this name, was described in 1865 by Campisi (*Compt. rend.* lxi. 86) as crystallising in white needles, melting above 200° , soluble in ether, and slightly soluble in alcohol; but its mode of formation is not given.

MESACONIC ACID. $C^2H^3O^4$ (iii. 928).—This acid repeatedly heated to 160° with very strong hydrochloric acid is converted into mesamono-chloropyro-tartaric acid, $C^2H^3ClO^4$. The latter separates in small shining crystals, much more soluble than mesaconic acid, melting at 129° – 130° , and decomposed by boiling with water into hydrochloric and mesaconic acids; by bases with formation of crotonic acid (Swarts, *Jahresb.* 1866, p. 407).

MESIDIC ACID. $C^2H^3O^4 = C^2H^3(CO^2H)^2 = C^2H^3(CH^3)(CO^2H)^2$ (Fittig u. von Furtenbach, *Zeitschr. f. Chem.* [2] iv. 1).—An acid intermediate in composition between mesitylenic acid, $C^2H^3O^2$, and trimelic acid, $C^2H^3O^4$. It is produced by oxidising mesitylenic acid with chromic acid mixture; perhaps also, together with mesitylenic acid, in the preparation of the latter by the action of dilute nitric acid on mesitylene. It is nearly insoluble in cold water, very slightly soluble in hot water, more easily in alcohol and ether. From boiling water it crystallises in colourless slender needles, from alcohol in indistinct groups of very small crystals. It melts at 287° – 288° , and solidifies again at 286° .

Mesidic acid is bibasic. Its *potassium salt*, $C^2H^3O^4K^2$, crystallises from alcohol in shining laminae very soluble in water. The *silver salt*, $C^2H^3O^4Ag^2$, is nearly insoluble in cold water, and crystallises from boiling water in colourless dendritic groups. The

* The equation given in the original memoir for the action of water on acetate of iodine is incorrect.

barium salt, $C^9H^6O^4Ba + H^2O$, is a white cauliflower-like crystalline mass, easily soluble in water. The *calcium salt*, $C^9H^6O^4Ca + H^2O$, forms small, colourless, silvery crystals, less soluble than the barium salt. The neutral solution of the ammonium salt forms with cupric sulphate, lead nitrate, ferric chloride, and zinc sulphate, bulky precipitates slightly soluble in cold water; no precipitate with nickel salts. *Ethyl mesidate*, $C^9H^6O^4 \cdot (C^2H^5)^2$, is a colourless radio-crystalline mass, insoluble in water, soluble in all proportions in alcohol, melting at 35° , and having a great tendency to remain liquid.

Mesidic acid is identical with uvitic acid produced by the action of baryta-water on pyroracemic acid (v. 971). The same acid is formed by heating the potassium salt of chlorotoluene-sulphuric acid with potassium cyanide, whereby toluylene cyanide, $C^7H^5(CN)^2$, is obtained, and distilling this compound with potash: $C^7H^5(CN)^2 + 3H^2O = 2NH^3 + C^7H^5(CO^2H)^2$ (Ireland, *Zeitschr. f. Chem.* [2] v. 612). Heated with soda-lime it yields toluene: $C^9H^6O^4 = 2CO^2 + C^7H^8$ (Baeyer, *ibid.* iv. 119). By prolonged oxidation with chromic acid it is converted into trimesic acid.

The relations of this acid to mesitylenic and trimesic acids are indicated by the following formulae:

MESIDINE or AMIDOMESITYLENE. See MESITYLENE, under BENZENE, HOMOLOGUES OF (p. 300).

MESITIC COMPOUNDS (Baeyer, *Ann. Ch. Pharm.* cxl. 297; *Jahresb.* 1866, p. 308).—When acetone saturated with hydrochloric acid gas is left to itself for 8 to 14 days, and then mixed with a large quantity of water, a heavy brownish oil separates consisting chiefly of hydrochlorides of mesityl oxide and phorone. On decomposing this oil with alcoholic potash in a cooled vessel, and subjecting the non-chlorinated oil precipitated by water to fractional distillation, the portion which boils at 140° yields, after washing with water, drying with calcium chloride, and rectification, pure mesityl oxide, $C^9H^{10}O$ (iii. 929), as a colourless liquid smelling strongly of peppermint and boiling at 130° . On carefully mixing it with phosphorus pentachloride till the latter is dissolved, and then pouring the gently warmed liquid into a large quantity of water, the chloride C^9H^9Cl separates as a heavy oil not volatile without decomposition. This chloride smells strongly like turpentine oil, resinises on exposure to the air, and is decomposed by alcoholic potash-solution, with formation of various products. By distillation over potash, baryta, or lime, it yields the chloride C^9H^9Cl as a mobile colourless liquid having an odour of turpentine, and boiling at 130° .

Nitric acid acts violently on mesityl oxide, forming a yellow resin and an oil smelling like nitrous ether. When mesityl oxide diluted with several times its volume of alcohol is treated with sodium-amalgam, the odour of peppermint disappears, and water then separates from the liquid a colourless oil which smells like camphor and decomposes at about 150° , yielding, together with water, a liquid smelling like camphor, boiling at about 206° , and having the composition of mesitic ether, $C^9H^{12}O = (C^9H^{11})^2O$.* The oil produced from mesityl oxide by the action of sodium-amalgam, is regarded by Baeyer as mesitic alcohol, $C^9H^{12}O$ or $C^9H^{11}OH$, which is converted by distillation into the ether: $2C^9H^{12}O = C^9H^{12}O + H^2O$. By simple distillation, or more easily by distillation with lime, mesitic ether is decomposed, with formation of higher condensation-products; by distillation with zinc chloride, hydrocarbons are obtained which have not yet been examined.

MESITYLENE. C^9H^{12} .—See BENZENE, HOMOLOGUES OF (p. 298).

MESITYLENE-SULPHURIC or SULPHOMESITYLIC ACID (p. 300).

MESITYLENIC ACID. $C^9H^6O^4 = C^9H^5 \begin{Bmatrix} CH^3 \\ CH^3 \\ COOH \end{Bmatrix}$ (Fittig, *Ann. Ch. Pharm.* cxli.

129; *Jahresb.* 1866, p. 610. Fittig a. Brückner, *Zeitschr. f. Chem.* [2] iv. 493; *Jahresb.* 1867, p. 705. Fittig a. Hoogewerff, *Zeitschr. f. Chem.* [2] v. 169).—An acid isomeric with xylic acid, and related to mesitylene in the same manner as benzoic acid to toluene. It is produced by boiling mesitylene with dilute nitric acid (1 vol. nitric acid of sp. gr. 1.4 and 2 vol. water) for 16 to 20 hours, and passes over with the watery

* Formerly called mesitic camphor by Baeyer (*Zeitschr. f. Chem.* [2] i. 313). Altogether there is great confusion in the names of these compounds.

vapours. After complete oxidation, the liquid diluted with a large quantity of water is repeatedly distilled as long as crystals collect in the condensing tube and the acid suspended in the distillate is collected on a filter. The portion which still remains dissolved is obtained by neutralising the filtrate with sodium carbonate, evaporating, and decomposing with hydrochloric acid. For complete purification, the product is boiled with a small quantity of tin and strong hydrochloric acid (to decompose a nitro-compound); and the portion which remains undissolved on cooling is dissolved in sodium carbonate, precipitated at the boiling heat by hydrochloric acid, and crystallised from alcohol. The formation of mesitylenic acid is represented by the equation: $C^6H^{12} + O^8 = C^6H^{10}O^2 + H^2O$.

Mesitylenic acid dissolves very sparingly in water, very easily in alcohol, and crystallises from the latter in large well-defined monoclinic crystals. When the hot dilute alcoholic solution is mixed with boiling water till permanent turbidity is produced, the acid crystallises in broad laminae and needles, very much like benzoic acid. It melts at 166° , and sublimes without decomposition even below its melting point. By boiling with chromic acid mixture it is oxidised to trimelic acid:

Heated with quick lime it is resolved into carbon dioxide and isoxylene:

Mesitylenic acid is monobasic. All its salts are more or less soluble in water. The *sodium salt*, $C^6H^9O^2Na$, is easily soluble in water and alcohol, and remains on evaporation as a white non-crystalline mass, or as a gradually crystallising syrup. The *silver salt*, $C^6H^9O^2Ag$, is formed in a somewhat concentrated solution, as a precipitate consisting of small needles which may be recrystallised from hot water. The *calcium salt*, $2(C^6H^9O^2)^2Ca + H^2O$, forms crystalline crusts not more soluble in hot than in cold water. The *barium salt*, $(C^6H^9O^2)^2Ba$, forms silky prisms more soluble than the calcium salt. The *magnesium salt*, $(C^6H^9O^2)^2Mg + 5H^2O$, crystallises in groups of monoclinic prisms not much more soluble in hot than in cold water, easily soluble in alcohol, insoluble in ether. The *zinc salt*, $(C^6H^9O^2)^2Zn$, crystallises in laminae or small needles sparingly soluble in water; the *nickel salt*, $(C^6H^9O^2)^2Ni$, in light green sparingly soluble crusts; the *manganese salt*, $(C^6H^9O^2)^2Mn$, in flesh-coloured scales. The *ethylic ether*, $C^6H^9O^2 \cdot C^2H^5$, is a colourless liquid heavier than water, insoluble therein, easily soluble in alcohol, smelling like oil of roses; it boils at 241° , and solidifies in the crystalline form when cooled below 0° .

Chloromesitylenic acid, $C^6H^8ClO^2$, produced by boiling chloromesitylene with dilute nitric acid, is but slightly soluble in water even at the boiling heat, easily soluble in alcohol. Heated above 200° , it turns brown without melting, and may be sublimed without decomposition. The *barium salt*, $(C^6H^8ClO^2)^2Ba + 4H^2O$, crystallises in hemispherical groups of slender colourless needles slightly soluble in cold water. The *calcium salt*, $(C^6H^8ClO^2)Ca + 5H^2O$, forms tufts or fan-shaped groups of flattened needles moderately soluble in hot water (Fittig u. Hoogewerff).

Nitromesitylenic acid, $C^6H^8(NO^2)O^2$, is formed by dissolving mesitylenic acid in fuming nitric acid, and occurs as a secondary product in the distillation-residue of the preparation of mesitylenic acid; it may be purified by precipitation from the sodium or barium salt with hydrochloric acid, and recrystallisation from alcohol. It is very sparingly soluble even in hot water, but dissolves easily in alcohol, and separates from the latter in large crystals, mostly having the aspect of rhombohedral tables; from a solution diluted with hot water, in broad laminae. It melts at 218° , and sublimes even below that temperature in long needles.

Sodium Nitromesitylenate, $C^6H^8(NO^2)O^2Na$, is deliquescent, and crystallises from alcohol in indistinct prisms. The *silver salt*, $C^6H^8(NO^2)O^2Ag$, is a flocculent precipitate slightly soluble in boiling water, and separates therefrom in needles. The *barium salt*, $[C^6H^8(NO^2)O^2]^2Ba$, crystallises by slow evaporation from the cold solution in large hard needles containing 3 mol. water; from hot-saturated solution, as a yellow crystalline powder containing 1 mol. water. The *calcium salt*, $[C^6H^8(NO^2)O^2]^2Ca$, is also sparingly soluble, and resembles the mesitylenate in nearly all its properties. The *magnesium salt*, $[C^6H^8(NO^2)O^2]^2Mg + 11H^2O$, forms indistinct prisms insoluble in ether, very soluble in alcohol, moderately soluble in water. The *ethylic ether*, $C^6H^8(NO^2)O^2 \cdot C^2H^5$, is insoluble in water, and crystallises from alcohol in short prisms melting at 72° .

Amidomesitylenic acid, $C^6H^8(NH^2)O^2$, produced by heating nitromesitylenic acid with tin and concentrated hydrochloric acid, is sparingly soluble in water, easily in hot alcohol, also in acids and in alkalis; crystallises in long needles, melts at 225° ,

and decomposes at a higher temperature. It unites with hydrochloric acid, forming the compound $C^9H^9(NH^2)O^2 \cdot HCl$, which crystallises from excess of hydrochloric acid in long needles, and is decomposed by heating its aqueous solution, with separation of free amidomesitylenic acid.

Mesitylenamide, $C^9H^9O \cdot NH^2$, is obtained by gently heating 1 mol. mesitylenic acid with rather more than 1 mol. phosphorus pentachloride, adding the product to strong aqueous ammonia, washing the resulting crystalline pulp with dilute ammonia, and recrystallising from boiling water. It crystallises in long needles; melts at 133° ; sublimes without decomposition; dissolves sparingly in cold, more easily in boiling water, also in alcohol and ether; and is decomposed by alkalis into ammonia and mesitylenate.

Oxymesitylenic acid, $C^9H^{10}O^3 = C^9H^2 \cdot \begin{Bmatrix} OH \\ (CH^3)^2 \\ CO^2H \end{Bmatrix}$, is produced by heating the dry potassium salt of mesitylene-sulphuric acid with three times its weight of potassium hydrate to 240° – 250° :

Part of the oxymesitylenate is at the same time converted into the potassium-compound of isoxylylic phenol, $C^9H^4(CH^3)^2O$, which is moreover the chief product obtained when the temperature is raised to 280° :

On dissolving the cooled mass in water, acidulating with sulphuric acid, and distilling, a small quantity of isoxylylic phenol passes over at first with the vapour of water; and if the distillation be continued as long as suddenly solidifying oil-drops appear in the condensing tube, the residual liquid repeatedly agitated with ether, and the ether evaporated, oxymesitylenic acid is obtained as a dark-coloured crystalline mass. It may be purified by repeated solution in sodium carbonate, precipitation with hydrochloric acid, conversion into barium salt, repeated crystallisation of this salt from water, separation of the acid therefrom by hydrochloric acid, repeated crystallisation from alcohol, and final sublimation.

Oxymesitylenic acid melts at 176° ; sublimes without decomposition in broad dazzling white needles nearly an inch long, insoluble in cold, slightly soluble in hot water, very soluble in alcohol and ether; and crystallises from dilute alcohol in long silky needles. The aqueous solution of the acid or its salts acquires, on addition of a drop of ferric chloride, a very deep blue colour with a faint tinge of violet, changing to dirty yellow at the boiling heat. Free acids and alkalis interfere with this reaction. *Barium oxymesitylenate*, $(C^9H^{10}O^3)^2Ba + 5H^2O$, forms compact groups of hard shining laminae; very soluble in hot, moderately soluble in cold water, turning brown at 110° and black at 130° . The *calcium salt*, $(C^9H^{10}O^3)^2Ca + 5H^2O$, crystallises in dense tufts of colourless needles easily soluble in water, especially at the boiling heat, somewhat more permanent than the barium salt (Fittig a. Hoogewerff).

MESOSIDERITE. This name is applied by G. Rose to meteorites consisting of nearly equal portions of metal and silicates (*Beschreibung und Eintheilung der Meteoriten*, Berlin, 1864; *Jahresb.* 1863, p. 909; 1865, p. 945).

MESOXALIC ACID. $C^9H^2O^3$.—This acid, originally obtained, together with urea, by boiling alloxan or alloxanic acid with alkalis (iii. 932), is also produced by oxidation of amidomalonic acid, e.g. by treating that acid with iodine and water (iv. 115):

On the preparation of mesoxalic acid from alloxan, see Deichsel (*Berl. Akad. Ber.* 1864, p. 587; *Jahresb.* 1864, p. 640). It crystallises from a syrupy solution evaporated at 40° – 50° , and finally over sulphuric acid, in prismatic crystals, $C^9H^2O^3 \cdot H^2O$, very deliquescent, easily soluble in alcohol, melting without loss of water at 115° , and resolidifying at 55° . It has a strong acid taste and reaction; decomposes in concentrated aqueous solution at 70° – 80° ; forms with barium and lead acetate, flocculent precipitates which gradually become crystalline; and after neutralisation with ammonia, is precipitated by barium and calcium salts, also by silver

nitrate and mercurous nitrate. The following mesoxalates have been examined by Deichsel:

Ammonium salt	. $\text{C}^3\text{O}^3(\text{NH}^1)^2$,	granular crystals, turning red in the air.
Sodium salt	. $\text{C}^3\text{O}^3\text{Na}^2 + \text{H}^2\text{O}$,	thin laminae easily soluble in water.
Silver salt	. $\text{C}^3\text{O}^3\text{Ag}^2 + \text{H}^2\text{O}$,	amorphous yellowish precipitate composed of microscopic needles.
Barium salt	. $2\text{C}^3\text{O}^3\text{Ba} + 3\text{H}^2\text{O}$,	microscopic crystals, nearly insoluble in cold, slightly soluble in hot water, becoming anhydrous at $170^\circ\text{--}180^\circ$.
Lead salt	. $\text{C}^3\text{O}^3\text{Pb}.\text{PbH}^2\text{O}^2$,	nearly insoluble in water.

Ethylie Mesoxalate, $\text{C}^3\text{O}^3.(\text{C}^2\text{H}^3)^2 + \text{H}^2\text{O} (?)$, is formed by treating the silver salt with ethyl iodide and alcohol, as a yellowish non-volatile oil, dissolving easily in water, with formation of mesoxalic acid. With ammonia it forms a crystallisable amide which turns red on exposure to the air.

Mesoxalic acid in dilute aqueous solution treated with *sodium-amalgam*, finally at $80^\circ\text{--}90^\circ$ is converted into tartronic acid, $\text{C}^2\text{H}^4\text{O}^3$. The silver salt boiled with water is resolved into carbonic acid, oxalic acid, and metallic silver, a reaction which may serve for the detection of mesoxalic acid (Deichsel).

On the relations of mesoxalic acid to uric acid and its derivatives, see *Uric Acid* (v. 958).

METABRUSHITE. A calcic orthophosphate, $\text{PO}^4\text{CaH} + \frac{3}{2}\text{H}^2\text{O}$, occurring in monoclinic crystals in the guano of Sombbrero (Julien, *Sill. Am. J.* [2] xl. 367; *Jahresh.* 1865, 909).

METACOPAIVIC ACID. See COPAIRA (p. 490).

METAHEMOGLOBIN. A compound of an albuminous substance with a brown colouring matter, produced by the decomposition of hemoglobin when a concentrated solution of that substance is left to itself at ordinary temperatures, or evaporated to dryness at a temperature above 100° . The brown colouring matter resembles hæmatin in its optical characters, but differs from it in its solubility in water and in dilute acids. The albuminous substance resembles serum albumin (Hoppe-Seyler, *Zeitschr. f. Chem.* 1865, 218; *Jahresh.* 1865, 668).

METAPETIC ACID. This acid, prepared from mangold-wurzel, is described by C. Scheibler (*Zeitschr. f. Chem.* [2] iv. 433).

METASILICIC ACID. See SILICA.

METHACRYLIC ACID. $\text{C}^4\text{H}^4\text{O}^2$ (Frankland & Duppa, *Chem. Soc. J.* [2] iii. 133).—An acid isomeric with crotonic acid, obtained in the form of an ethylic ether by the action of phosphorus trichloride on ethylic dimethoxalate: $\text{C}^4\text{H}^4\text{O}^3 + \text{H}^2\text{O} = \text{C}^4\text{H}^4\text{O}^2$. (See ACIDS, ORGANIC, p. 41; also iv. 273.) By boiling the ether thus produced with alcoholic potash, and distilling the resulting potassium salt with sulphuric acid, methacrylic acid is obtained as a colourless oil, not solidifying at 0° , having a faint odour of pyrogallie acid, and a strong acid reaction. Its salts exhibit the same tendency as those of the other acids of the acrylic series to give up their acid on evaporation. The silver salt is a white precipitate not much affected by light. The barium salt is gummy, very easily soluble; the copper salt moderately soluble in water.

Methacrylic acid heated with potash to the temperature of boiling oil is resolved into propionic and formic acids:

differing therein from crotonic acid, which yields only acetic acid.

METHANE. CH^4 . *Marsh Gas. Methyl Hydride.*—This gas is decomposed by the continued passage of electric sparks, partly into hydrogen and carbon, partly into hydrogen and acetylene: $2\text{CH}^4 = \text{C}^2\text{H}^2 + 3\text{H}^2$. The volume of gas obtained is, however, less than the calculated quantity, because part of the acetylene is converted into liquid polymerides (Berthelot, *Compt. rend.* lxvii. 1188; *Zeitschr. f. Chem.* [2] v. 160).

Dimethyl-dichloromethane. $\text{C}^2\text{H}^4\text{Cl}^2 = \text{C} \begin{Bmatrix} \text{CH}^3 \\ \text{Cl}^1 \\ \text{CH}^3 \end{Bmatrix}$.—This compound, isomeric

with propylene chloride, and likewise called *methyl-chloroacetol* (iii. 1003), is produced by the action of phosphorus pentachloride on acetone (iii. 1003):

Friedel a. Ladenburg (*Ann. Ch. Pharm.* cxlii. 310) prepare it by dropping acetone upon phosphorus pentachloride, cooling the mixture at first, and afterwards distilling it, till the liquid which passes over dissolves in water without leaving any oily residue. The distillate washed with water and dried yields by repeated rectification chloropropylene, C^3H^5Cl , between 25° and 35° , and dimethyl-dichloromethane between 66° and 78° .

Dimethyl-diethyl-methane or **Carbodimethyl-diethyl**. $C^3H^6 = C \left\{ \begin{smallmatrix} (C^2H^3)^2 \\ (C^2H^5)^2 \end{smallmatrix} \right.$ —This hydrocarbon, isomeric with heptane or septane, is produced by gently heating dimethyl-dichloromethane with zinc-ethyl. The two bodies do not act on one another in the cold, and if they are heated together in sealed tubes, explosion takes place; but if the dimethyl-dichloromethane be added by drops to zinc-methyl contained in a flask with an upright condenser, the mixture gently heated for some time, and then distilled, dimethyl-diethyl-methane will be found in the portion boiling below 110° . This distillate must be mixed with water, added by drops in a cooled flask, to decompose unaltered zinc-ethyl, the resulting zinc oxide dissolved in hydrochloric acid, and the residual oil submitted after drying to fractional distillation. The portion which then distils between 85° and 90° yields, after being heated for several days with sodium (to remove chlorine), pure dimethyl-diethyl-methane, boiling between 86° and 87° , having a vapour-density = 3.46 (obs. 3.62), and a sp. gr. of 0.7111 at 0° ; 0.6958 at 20.5° .

Dimethyl-chloriodomethane or **Methyl-iodochloroacetol**, $C \left\{ \begin{smallmatrix} CH^3 \\ CHI \\ CHI^3 \end{smallmatrix} \right.$, is produced by heating chloropropylene, C^3H^5Cl , with concentrated hydriodic acid. It is a liquid boiling between 110° and 130° . Treated with silver benzoate it is converted into **dimethyl-dioxybenzomethane** or **methyl-benzacetol**, $C \left\{ \begin{smallmatrix} (C^2H^3)^2 \\ (C^2H^5O^2)^2 \end{smallmatrix} \right.$, isomeric with propylene dibenzoate. This compound crystallises from ether in oblique rectangular octohedrons, and is decomposed by water into benzoic acid and a liquid smelling like acetone (Oppenheim, *Bull. Soc. Chim.* x. 128).

METHENYL. CH'' .—The triatomic radicle derived from methane by abstraction of 3 at. hydrogen; it may be supposed to exist in chloroform, $CHCl^3$, iodoform, CHI^3 , &c.

METHENYL-SULPHUROUS ACID. $CH^3S^2O^2 = (CH)''.(SO^2H)^2$. *Methintrisulphonic acid* (Theilkuhl, *Ann. Ch. Pharm.* cxlvii. 134; *Chem. Soc. J.* [2] vi. 192).—This acid, the third term of the series of which methyl-sulphurous acid, $CH^3.SO^2H$, and methylene-sulphurous acid, $CH^2.(SO^2H)^2$, are the two preceding terms, is produced as a calcium salt by heating well-dried calcium methylsulphate on the water-bath for a day, with six times its weight of strongly fuming sulphuric acid containing about 10 p. c. of the anhydride. The product may be purified by boiling with water to decompose unaltered methyl-sulphuric acid, neutralising with lime, precipitating the excess of lime from the filtrate by carbonic acid, and recrystallising. The *calcium salt*, $(CHS^2O^2)^2Ca^2 + 12H^2O$, thus obtained separates in very fine crystals from a moderately concentrated aqueous solution covered with a layer of alcohol and left to itself for several days. It gives off 10 mol. water at 120° , the remaining 2 mols. at 180° , and is not easily decomposed by high temperature or by oxidising agents. The *barium salt*, $(CHS^2O^2)^2Ba^2 + 9H^2O$, separates in shining laminae on mixing the calcium salt with barium chloride, and crystallises from boiling water or boiling dilute sulphuric acid in beautiful needles or laminae; gives off 6 mol. water at 100° and the rest at 200° . A *basic lead salt*, $(CHS^2O^2)^2Pb^2.2PbO$, is precipitated by lead acetate from a warm solution of the calcium salt containing a little alcohol, in stellate groups of needles sparingly soluble in water. The *potassium salt*, $CHS^2O^2K^2 + H^2O$, obtained by exactly precipitating a boiling solution of the calcium salt with potassium bicarbonate, is easily soluble in water, and crystallises in small shining prisms, which give off their water at 100° . The *free acid*, or *hydrogen salt*, obtained by decomposing the lead salt with hydrogen sulphide, and carefully evaporating in a vacuum over sulphuric acid, forms long, very deliquescent needles, having a strong acid reaction, easily soluble in absolute alcohol, and separating therefrom in needles.

METHINTRISULPHONIC ACID. See the last article.

METHYL. $(CH)^2$.—See ETHANE.

METHYL-ACETONE. Syn. with METHYL-ETHYL KETONE (p. 766).

METHYL ALCOHOL and **ETHERS**. Methyl alcohol, CH_3OH , may be prepared from hydrocyanic acid by converting that compound into methylamine by Mendius's process (iv. 58), and boiling the slightly acid aqueous solution of the nitrite of that base, whereby it is resolved into methyl alcohol, water, and nitrogen:

The methyl alcohol thus obtained boils at $66^\circ\text{--}66.5^\circ$ (corr. 67.1°), and has a sp. gr. of 0.8574 at 21° (Linnemann, *Zeitschr. f. Chem.* [2] iv. 284).

Methyl Bromide is produced by boiling amyl bromide with methyl alcohol: $\text{C}_5\text{H}_{11}\text{Br} + \text{CH}_3\text{OH} = \text{C}_5\text{H}_{11}\text{OH} + \text{CH}_3\text{Br}$ (Hofmann u. Girard, *Zeitschr. f. Chem.* [2] v. 653).

Methyl Chloride, exposed to the action of chlorine in direct sunshine is converted mainly into dichlorinated methyl chloride or methylene dichloride, CH_2Cl_2 . By washing the gaseous product with water, passing it into glacial acetic acid, which absorbs it, then slowly heating the saturated acetic acid to $100^\circ\text{--}105^\circ$, and mixing the distillate with water, an oil is obtained which begins to boil at 30° , the temperature, however, quickly rising to 40° , and about half of the product passing over between 40° and 50° . This distillate after two rectifications yielded a liquid boiling at $40^\circ\text{--}42^\circ$, and having the composition CH_2Cl_2 . The products of higher boiling point consisted of chloroform and carbon tetrachloride (Perkin, *Chem. Soc. J.* [2] vii. 260).

Methyl Sulphoxide. $(\text{CH}_3)_2\text{SO}$ (Saytzeff, *Ann. Ch. Pharm.* cxliv. 148; *Jahresh.* 1867, p. 540).—Methyl sulphide added by drops to cooled fuming nitric acid dissolves to a homogeneous liquid which when evaporated leaves the *nitrate of methyl sulphoxide*, $(\text{CH}_3)_2\text{SO} \cdot \text{HNO}_3$, which after pressure, standing over lime, and recrystallisation from water, forms colourless deliquescent needles dissolving very easily in water, with acid reaction, less easily in alcohol and ether, melting at 100° , and decomposing with slight explosion at a higher temperature. When its aqueous solution is treated with barium carbonate, and the evaporated residue is digested with absolute alcohol, methyl sulphoxide, $(\text{CH}_3)_2\text{SO}$, dissolves, and remains, after evaporation of the alcohol, as a colourless, inodorous, syrupy liquid, which solidifies to a crystalline mass on cooling. It is not volatile without decomposition, dissolves easily in water, alcohol, and ether, and is reduced by zinc and sulphuric acid to methyl sulphide.

When methyl sulphoxide is heated to 100° for five or six hours with concentrated sulphuric acid, a solution is formed, which on evaporation leaves methylsulphone, $(\text{CH}_3)_2\text{SO}_2$, as a viscid mass which crystallises on cooling. This compound dissolves easily in water, alcohol, and fuming nitric acid, crystallises therefrom in prisms, sublimates at 100° , boils without decomposition at 238° , melts at 109° , and solidifies again at 99° . By zinc and dilute sulphuric acid it is also reduced to methyl sulphide.

Methyl Bisulphoxide, $(\text{CH}_3)_2\text{S}_2\text{O}_2$, is produced by treating the bisulphide, $(\text{CH}_3)_2\text{S}_2$, with nitric acid of sp. gr. 1.2 diluted with an equal volume of water. After washing with water and drying with calcium chloride, it forms a colourless oil heavier than water. It is converted into methyl-sulphuric acid by strong nitric acid, and reduced to methyl bisulphide by zinc and dilute sulphuric acid (Saytzeff, *Zeitschr. f. Chem.* [2] iv. 641).

The trimethyl-sulphurous compounds produced by combination of methyl sulphide, $(\text{CH}_3)_2\text{S}$, with ethyl iodide, bromide, &c., are described in vol. v. p. 886.

METHYL-ALLYL. $\text{CH}_3 \cdot \text{C}_3\text{H}_5$.—This hydrocarbon, identical or isomeric with butylene, is produced by heating a mixture of zinc-methyl and allyl iodide with sodium to 120° , or by heating a mixture of methyl and allyl iodides with sodium to 100° (p. 375).

METHYLAMINE. $\text{CH}_3 \cdot \text{H}_2\text{N}$.—When an aqueous solution of this base is set on fire, the hydrogen chiefly burns, and hydrocyanic acid is found in the remaining liquid: $\text{CH}_3\text{N} + \text{O} = \text{HCN} + 2\text{H}_2\text{O}$ (Tollens, *Zeitschr. f. Chem.* [2] ii. 516). Methylamine heated with saturated hydriodic acid yields ammonia and methane: $\text{CH}_3\text{N} + 2\text{HI} = \text{CH}_4 + \text{NH}_3 + \text{I}_2$ (Berthelot).

Trimethylamine is said to occur in *Arnica montana* (Hesse, *Jahresh.* 1864, p. 459), in the seeds of the beech (Brandt u. Rakowiecki, *ibid.* 607), and in *Cotyledon umbellatus*. According to E. Ludwig (*Zeitschr. f. Chem.* iv. 96), it occurs in small quantity in several Austrian and Hungarian wines.

Trimethyl-oxethylammonium hydrate. See CHOLINE (p. 448).

METHYL-AMYL-ACETONE. Syn. with methyl-hexyl ketone, $\text{CO} \begin{Bmatrix} \text{CH}_3 \\ \text{CH}_5 \end{Bmatrix}$ = $\text{CO} \begin{Bmatrix} \text{CH}_3 \\ \text{CH}_2(\text{C}_4\text{H}_9) \end{Bmatrix}$. (See KETONES, p. 766.)

METHYL-BENZACETOL. See page 826.

METHYL-BENZENES. Several methylic derivatives of benzene have already been described, viz. monomethyl-benzene or toluene, $C^6H^5.CH^3$ (p. 279), dimethyl-benzene, $C^6H^4(CH^3)^2$, and trimethyl-benzene, $C^6H^3(CH^3)^3$, the last two occurring in several modifications (pp. 293, 296, 298).

Tetramethyl-benzene or **Durene**, $C^{10}H^{14} = C^6H^2(CH^3)^4$, isomeric with cymene (p. 302), has lately been obtained by Jannasch and Fittig (*Zeitschr. f. Chem.* [2] vi. 161). It is prepared by the action of sodium and methyl-iodide on monobromo-pseudocumene in ethereal solution:

After six days' digestion, the liquid was distilled and the product fractionated. After the first distillation, the whole of the liquid collected between 170° and 200° solidified in the crystalline form on cooling, the last portion completely. After two or three distillations, the greater portion passed over between 185° and 195° , and solidified completely on cooling. It was purified by repeated pressure between paper, drying over sulphuric acid, and rectification.

Durene is the only known hydrocarbon of the benzene series which is solid at ordinary temperatures. It dissolves easily in alcohol, ether, and benzene; crystallises from alcohol in compact crystals belonging either to the monoclinic or to the triclinic system; has but a faint benzolic odour; melts between 79° and 80° ; and boils constantly at 189° - 191° . It floats on water, volatilises with aqueous vapour, and burns with a very bright flame.

Dibromodurene, $C^{10}H^{12}Br^2 = C^6Br^2(CH^3)^4$, is formed, with violent reaction, when durene is dissolved at ordinary temperatures in excess of bromine; the product may be purified by washing with soda-ley and with water. It is nearly insoluble in cold alcohol, but slightly soluble in boiling alcohol, and crystallises therefrom in thin silky brittle needles; melts at 199° , and sublimes undecomposed at higher temperatures.

Dinitrodurene, $C^{10}H^{12}(NO^2)^2 = C^6(NO^2)^2(CH^3)^4$, separates as a white precipitate, when durene is added to cold very strong nitric acid, and the resulting solution is poured into water; it crystallises from alcohol in colourless shining rhombic prisms, from benzene in compact crystals. It is easily soluble in ether, somewhat less in benzene, still less in hot alcohol, very slightly in cold alcohol. It melts at 199° , and sublimes without decomposition at a higher temperature in splendid shining needles.

Oxidation-products of Durene (Jannasch, *Zeitschr. f. Chem.* [2] vi. 449; vii. 33).—By oxidising durene with dilute nitric acid, two acids are obtained, one of which volatilises with the aqueous vapour, while the other remains behind.

Cumylic acid, $C^{10}H^{12}O^2 = C^6H^2(CH^3)^4.CO^2H$, the more volatile of these two acids, is the third homologue of benzoic acid. It is nearly insoluble in cold water, very slightly soluble in boiling water, very easily soluble in alcohol and ether, somewhat less soluble in benzene, from which it crystallises on cooling in irregular arborescent groups of hard, limpid, highly lustrous needles. It volatilises with vapour of water, sublimes in long delicate needles, and melts at 140° - 150° . It is monobasic. The **barium salt**, $(C^{10}H^{11}O^2)^2Ba + 7H^2O$, crystallises in transparent tabular prisms efflorescing over sulphuric acid. The **calcium salt**, $(C^{10}H^{11}O^2)^2Ca + 2H^2O$, forms smaller crystals arranged in nodular groups.

Cumidic acid, $C^{10}H^{10}O^4 = C^6H^2(CH^3)^4.(CO^2H)^2$, the less volatile acid above mentioned, is bibasic and homologous with phthalic, uvicic, and xylic acids. It is nearly insoluble in water, very slightly soluble in ether and in benzene, more readily in boiling alcohol. On adding benzene to the alcoholic solution, the acid slowly crystallises in long transparent needles. At a very high temperature it sublimes, without previous fusion, and condenses in small shining transparent plates. The **barium salt**, $C^{10}H^8O^4Ba + 2H^2O$, forms rhombic plates having a fine pearly lustre. The **calcium salt**, $C^{10}H^8O^4Ca + 2H^2O$, crystallises in small, very shining, transparent, very compact prisms.

METHYL-CHLORACETOL. Syn. with DIMETHYL-DICHLOROMETHANE (p. 825).

METHYL-CROTONIC ACID. $C^8H^8O^2$ (Frankland and Duppa, *Chem. Soc. J.* [2] iii. 133).—Isomeric with angelic acid. Its ethylic ether, $C^8H^8O^2.C^2H^5$, produced by the action of phosphorus trichloride on ethylic ethomethoxalate (iv. 275), is a mobile liquid having an intolerable odour of decayed fungi, and a burning taste; boiling at 156° ; insoluble in water, but miscible in all proportions with alcohol and ether. By alcoholic potash, it is resolved into alcohol and methyl-crotonic acid, which melts at 62° , and crystallises on cooling in shining needles, much more soluble in water than ethyl-crotonic acid (p. 600). Its **barium salt**, $(C^8H^7O^2)^2Ba$, is easily

soluble and difficult to crystallise; the *silver salt*, $C^3H^3O^2Ag$, is a white crystalline powder, slightly soluble in water. Methyl-crotonic acid heated with potassium hydrate, is resolved, like angelic acid, into propionic and acetic acid:

METHYL-DIACETIC ACID. $C^3H^3O^4$ (R. Brandes, *Jenaische Zeitschr.* iii. 25; *Jahresb.* 1866, p. 305). *Formate of Acetylated Ethyl* (p. 590).—Produced by the action of sodium on methyl acetate, in the same manner as ethyl-diacetic acid from ethyl acetate (p. 601). The sodium salt, which is the direct product of the reaction, may be purified by treatment with anhydrous ether. It is slightly soluble in pure ether, easily in alcoholic ether, and is decomposed gradually by contact with the air, more quickly by boiling its aqueous solution, in the manner represented by the following equation:

Methyl-diacetic acid separated from the sodium salt by acetic acid, and purified by agitation with ether and fractional distillation of the ethereal extract, is a colourless liquid having a fruity odour, a sp. gr. of 1.037, and boiling at 169° to 179° . With ferric chloride it produces a characteristic dark cherry-red colour, rose-red in very dilute solutions. It distils with aqueous vapour in oily drops, and is decomposed by heating with strong acids and bases, in the same manner as the sodium salt by boiling with water. The *copper salt*, $(C^3H^3O^3)_2Cu + 2H^2O$, separates on adding cupric acetate to the acid neutralised with baryta-water, in pale green crystals insoluble in alcohol. When heated with water it is decomposed like the ethyl-diacetate. The *methylic ether*, $C^3H^3O^3.C^2H^3$, obtained by heating the sodium salt with methyl iodide, is a colourless liquid boiling at 177.4° ; having a sp. gr. of 1.020 at 9° ; smelling like mint when diluted, and producing a violet-red coloration with ferric chloride. The *ethylic ether*, $C^3H^3O^3.C^2H^5$, prepared in like manner, boils at 189.7° (corr.) and has a sp. gr. of 0.995 at 14° . It is distinguished from the isomeric compound, methyle ethyl-diacetate, by its somewhat lower boiling point, and by producing a splendid violet-red colour with ferric chloride. By prolonged contact with strong aqueous ammonia, it forms an oil, $C^3H^3NO^2$, which may be either the amide of ethyl-methyl-diacetic acid, or the ethylamide of methyl-diacetic acid, and a solution which on evaporation yields the amide of methyl-diacetic acid, $C^2H^3NO^2$, in concentric groups of silky needles melting at 82° – 83° .

In the rectification of methyl-diacetic acid there remains, together with colouring matter, a crystallisable substance which volatilises with vapour of water and exhibits the composition and properties of dehydracetic acid, $C^3H^3O^4$ (p. 543). The same acid is also formed by heating sodium methyl-diacetate to 170° in dry carbonic acid gas, methyl-diacetic acid then distilling, whilst dehydracetate and carbonate of sodium remain behind, together with a resinous body.

METHYL-DIETHYL-CARBINOL. $C^5H^{11}O = CH^3(C^2H^5)_2.CO.H$.—See HEXYL ALCOHOLS (p. 698).

METHYLENE-COMPOUNDS. The *chloride*, CH^2Cl^2 , is produced: 1. By the action of chlorine on methylene iodide (iii. 1005); to remove the last traces of iodine, prolonged treatment with chlorine at ordinary temperatures is required (Buttlerow, *Zeitschr. f. Chem.* [2] v. 276).—2. By the action of chlorine on methyl chloride in sunshine (Perkin, p. 827).—3. Together with marsh gas, by agitating an alcoholic solution of chloroform with excess of zinc-powder and a small quantity of ammonia. The methylene-chloride thus produced is separated from unaltered chloroform by fractional distillation (Perkin, *Chem. News*, xviii. 106). It is a colourless mobile liquid, smelling like chloroform and having a burning taste; slightly soluble in water, especially at high temperatures. Sp. gr. 1.3604 at 0° ; coefficient of expansion for 1° between 0° and $+20^\circ = 0.00137$. Boiling point 40° (Buttlerow); 40° – 42° (Perkin). The idea formerly entertained of the existence of two isomeric compounds having the composition CH^2Cl^2 is no longer admissible.

Methylene Iodide, CH^2I^2 , is produced by heating chloroform with hydriodic acid to 125° in sealed tubes; probably thus: $CHCl^3 + 3HI = 3HCl + CHI^3$; and $CHI^3 + HI = I^2 + CH^2I^2$ (Lieben, p. 438).

Hexamethylenamine, $C^6H^{12}N^4 = (C^2H^3)^2N^4$.—A base produced by the action of dry ammonia gas on pulverised oxymethylene (dioxymethylene, iii. 1007):

or by heating a mixture of vapour of oxymethylene and ammonia gas to 160° – 170° .

It crystallises from alcohol in colourless shining rhombohedrons or short prisms; is inodorous in the cold, but has a very disagreeable odour when heated; sublimes slowly at 100° in small highly lustrous crystals; dissolves easily in water and in boiling alcohol, less easily in cold alcohol, scarcely at all in ether; has a distinct alkaline reaction. The *hydrochloride*, $C^6H^{12}N^4$. HCl, is easily soluble in water, slightly soluble in alcohol; crystallises in long white needles; melts and decomposes completely when heated. Its solution forms with *platinic chloride* a pale orange-coloured precipitate, often exhibiting octohedrons and tetrahedrons, insoluble in cold water, decomposed by boiling water (Buttlerow, *Ann. Ch. Pharm.* cxv. 322; *Zeitschr. f. Chem.* [2] v. 278).

METHYL-HEXYL. CH^1 . C^6H^{12} .—See HEPTANE (p. 696).

METHYL-HYDANTOIN. See HYDANTOIN (p. 703).

METHYLIC ALDEHYDE. See FORMIC ALDEHYDE (p. 622).

METHYL-IODOCHLORACETOL. Syn. with DIMETHYL-CHLORIODOMETHANE (p. 826).

METHYLURAMINE, $C^2H^4N^3$, may be regarded as carbomethyltri-amine, $\left\{ \begin{array}{l} C^1 \\ N^2 \end{array} \right\} CH^3$ (Hofmann, *Ann. Ch. Pharm.* cxxxix. 107).

MIASCITE. Analyses of this rock from Ditro in Transylvania have been made by Fellner (*Jahresb.* 1867, p. 1026).

MILK-ANALYSIS. According to Wanklyn, whose researches on milk are published in the *Milk Journal*, almost the only sophistications to which milk is actually subjected are the more or less complete removal of the cream, and dilution with water. Out of some hundreds of samples of milk bought in London in the present year (1871), so large a proportion as about $\frac{9}{10}$ were found to have been either skimmed or watered, or both skimmed and watered, no other kind of adulteration being recognised. The method of examination consisted in taking the solid residue dried at 100° and measuring the yield of cream, or else estimating the fat by means of ether.

Contrary to what has been often stated, Wanklyn finds that a milk residue may be easily and conveniently dried until its weight is quite constant at 100° C. For this purpose, about 5 grams of milk are evaporated in the water-bath, in a thin platinum dish, and maintained at 100° for the space of three hours, when the weight of the solid residue will be found to have become constant, being incapable of sensible diminution by prolonging the drying for three hours longer. The following examples may be cited (see *Milk Journal*, vol. i. p. 109). A specimen of genuine country-fed milk furnished in four experiments:

Milk.		Solids dry at 100° .	Percentage of solids.
I.	4.969 grams gave	0.616 grams	12.40
II.	5.0105 " "	0.6255 "	12.48
III.	5.007 " "	0.623 "	12.44
IV.	5.0145 " "	0.626 "	12.48
Mean percentage of solids		.	12.45

A specimen of very rich town-fed milk gave in four experiments:

Milk.		Solids.	Percentage.
I.	5.000 grams gave	0.7035 grams	14.07
II.	5.004 " "	0.705 "	14.09
III.	5.000 " "	0.7025 "	14.05
IV.	5.006 " "	0.705 "	14.08
Mean percentage of solids		.	14.07

The complete analyses of the two kinds of milk furnished the following results:

	Country milk.	Town milk.
Water	87.55	85.93
Fat	3.07	4.00
Casein	4.04	5.02
Milk-sugar . .	4.63	4.31
Ash	0.71	0.74
	100.00	100.00

100 vols. of the country milk yielded 9·8 vols. of cream, whilst 100 vols. of the town milk yielded 13 vols. From the results obtained by Alex. Müller and Eisenstuck, who conducted an investigation for the Royal Agricultural Academy of Sweden, it would appear that the milk of well-fed cows never becomes very poor at any season of the year, and that the milk-solids seldom fall so low as 12 per cent., and never so low as 11·5 per cent.

In the *Milk Journal*, vol. i. p. 160, a method of estimating the casein in milk by means of Wanklyn, Chapman, and Smith's ammonia-process is described. The milk is first diluted with a known quantity of water, so that 1 cubic centimetre of the diluted milk contains 10 milligrams of milk. About 5 c. c. of this diluted milk is a convenient quantity for experiment, and is boiled with alkaline permanganate so long as it evolves ammonia, the latter being estimated by the Nessler test. From the amount of ammonia furnished by oxidation of the specimen of milk, the amount of casein present in the milk may be deduced, since it has been ascertained experimentally that 6·5 parts of ammonia are furnished by 100 parts of casein. J. A. W.

MIZZONITE. A variety of scapolite from Somma, formerly confounded with mejonite (iii. 1027). According to an analysis by G. vom Rath (*Pogg. Ann.* cxix. 254; *Jahresb.* 1863, p. 812), it contains 54·70 p. c. SiO_2 , 23·80 Al_2O_3 , 8·77 CaO , 0·22 MgO , 2·14 K_2O , 9·83 Na_2O , and 0·13 loss by ignition = (99·59), whence the oxygen-ratio $\text{MO} : \text{M}'\text{O}^s : \text{SiO}_2 = 1 : 2 : 5$.

MOHITLI. *Sericographis Mohitli*, an acanthaceous plant indigenous in Mexico, and used by the natives as a remedy for dysentery, contains, according to Thomas (*J. Pharm.* [4] iii. 251), a blue colouring matter which reacts with acids and bases like litmus. By exhausting the fresh leaves with water, boiling the decanted liquid, evaporating the filtrate, and redissolving the residue, this colouring matter is obtained as an amorphous dark blue mass easily soluble in water. By exhausting the leaves with de-aerated water in a close vessel, a greenish solution is obtained, which becomes bluish-violet on agitation with air, is decolorised by stannous chloride, and then deposits a dark green flocculent precipitate. Thomas designates the original colourless principle of the plant as *mohitlin*, the green oxidation-product as *mohitlin*, and the blue substance, which is an acid and forms salts, as *mohitlic acid*. None of these bodies have, however, been obtained in the pure state.

MOLYBDENUM. J. E. Loughlin (*Sill. Am. J.* [2] xlv. 131) obtains metallic molybdenum by exposing a mixture of the trioxide with $\frac{1}{2}$ pt. potassium cyanide to a white heat for a quarter of an hour (in a luted porcelain crucible enclosed in a larger crucible filled with charcoal). The silver-white metal thus produced (containing 1·3 p. c. carbon and silica) has a specific gravity of 8·56.

Debray (*Bull. Soc. Chim.* [2] x. 451) has determined the atomic weight of molybdenum: 1. By reducing the trioxide with hydrogen at a very high temperature.—2. By evaporating the ammoniacal solution of a weighed quantity of the trioxide with excess of silver nitrate in the dark, lixiviating the dry crystallised silver molybdate, and determining the excess of silver nitrate remaining. The first method gave numbers varying from 95·68 to 96·06; the second from 95·96 to 96·00. The mean of all these determinations, 95·94, confirms the number 96 obtained by Dumas (iii. 1032).

Molybdic Chloride, obtained by gently heating molybdenum in a stream of chlorine, and purified by rectification in a stream of carbon dioxide, has a dark green colour, melts at 194° and boils at 268° , forming a deep red vapour, which condenses to crystals having a green reflex. It alters quickly in moist air, dissolves in water with great rise of temperature, and exhibits all the essential properties of the tetrachloride, MoCl_4 , described by Berzelius (iii. 1031). Its analysis, however, gives 35 to 35·2 p. c. molybdenum, leading to the formula MoCl_3 or Mo^sCl_3 , requiring 35·1 p. c., whereas MoCl_4 requires 40·3 p. c. The vapour-density at 350° was found = 9·53 to 9·40; the formula MoCl_3 , calculated for a condensation to 2 volumes, gives 9·47 (Debray, *loc. cit.*).

Oxides. Rammelsberg (*Pogg. Ann.* cxxvii. 381) finds that the oxide formed by the action of zinc or copper on a hydrochloric acid solution of the trioxide or a molybdate, is not the monoxide, as stated by Berzelius (iii. 1034), but the sesquioxide. The trioxide heated to full redness for three hours in a stream of hydrogen is completely reduced to metal. A hydrochloric acid solution of the trioxide heated with metallic molybdenum yields a dark red liquid, similar to that obtained with zinc or copper, but nevertheless containing the dioxide MoO_2 , mixed with trioxide less in proportion as the action is more complete. Ammonia produces in this solution an easily alterable precipitate (intermediate between MoO_2 and Mo^sO_3), having the

aspect of ferric hydrate, whilst only very small quantities of trioxide remain in solution: hence the dioxide cannot be regarded as a molybdate of the sesquioxide, $\text{Mo}^2\text{O}^3 \cdot \text{MoO}^3$. *Blue oxide of molybdenum* is obtained by mixing the brown solution of the dioxide with a solution of the trioxide in hydrochloric acid, and washing the precipitate with a mixture of alcohol and sal-ammoniac. After drying over sulphuric acid it has the composition $\text{Mo}^2\text{O}^3 + 3\text{H}^2\text{O}$. By strong bases it is decomposed, like the other blue oxides of molybdenum, into dioxide and trioxide. When a mixture of molybdic chloride and ammonium molybdate is left to itself for some time, crystals form in the blue precipitate, which may be purified by washing with alcohol. They are very small, prismatic, brown by transmitted light, and dissolve in water, forming a yellow solution, with separation of dioxide; silver salts added to this solution throw down a yellow precipitate easily soluble in nitric acid. Heated out of contact with the air, they give off water and ammonia, and leave a blue oxide containing Mo^3O^3 . Their composition may be represented by the formula $2(\text{MoO}^2 \cdot \text{MoO}^3) \cdot (\text{NH}^4)^2\text{O} \cdot 2\text{MoO}^3 + 9\text{H}^2\text{O}$.

The *dioxide*, MoO^2 , is obtained in the crystalline form by fusing sodium molybdate in a porcelain crucible with a third of its weight of zinc added by small portions, the heat being continued till the crystalline growth which spreads out from the zinc fills the entire liquid. The cooled mass digested alternately with caustic potash and hydrochloric acid, and washed with water, leaves the dioxide in dark blue-violet prisms, having a strong metallic lustre, and appearing light violet-red by transmitted light. They conduct electricity well (quickly becoming covered with copper when immersed in solution of cupric sulphate in contact with zinc); are not attacked by hydrochloric acid or potash-ley even at the boiling heat; but are converted into trioxide by heating with nitric acid. Sodium molybdate is not reduced by tin (Ullik, *Jahresb.* 1867, p. 237).

Trioxide or Molybdic Anhydride.—On the preparation of this oxide from native lead molybdate, see Ullik (*Zeitschr. f. Chem.* [2] iv. 690). The soluble (colloidal) modification (iii. 1036) may be prepared by decomposing precipitated barium molybdate with an exactly equivalent quantity of sulphuric acid. The solution evaporated over sulphuric acid leaves soluble molybdic acid in the form of a transparent blue or blue-green mass, easily soluble in water, but gradually becoming less soluble by keeping, and converted at higher temperatures, *with loss of water*, into ordinary molybdic anhydride (Ullik). According to Graham, the colloidal solution evaporated at 100° leaves *soluble* molybdic anhydride.

Amorphous soluble molybdic acid retains at different temperatures constant quantities of water, corresponding to definite hydrates, $\text{H}^2\text{O} \cdot 2\text{MoO}^3$ being formed at 100° , $\text{H}^2\text{O} \cdot 4\text{MoO}^3$ at 120° , and $\text{H}^2\text{O} \cdot 8\text{MoO}^3$ at 160° – 170° . The hydrate $\text{H}^2\text{O} \cdot 2\text{MoO}^3$ is also formed when molybdic acid is left for several months over oil of vitriol. The hydrate $\text{H}^2\text{O} \cdot 5\text{MoO}^3$ is produced: 1. By evaporating a solution of amorphous molybdic acid over the water-bath.—2. By boiling a solution of the magnesium salt, $\text{MgO} \cdot \text{MoO}^3 + 7\text{H}^2\text{O}$, with a large excess of nitric acid.—3. By boiling the aqueous solution of amorphous molybdic acid with sulphuric acid. This hydrate separates as a fine white powder which is nearly insoluble in water, and when suspended therein forms a milky liquid which runs through the filter; it may however be washed by decantation with water containing nitric acid. It does not lose weight over oil of vitriol or at 100° . The hydrate, $\text{H}^2\text{O} \cdot \text{MoO}^3$, was once obtained accidentally when a solution of the salt $\text{MgO} \cdot \text{MoO}^3 + 7\text{H}^2\text{O}$ was mixed with a quantity of nitric acid nearly equivalent to the magnesium and left to itself. It formed crystalline crusts composed of very small needles, nearly insoluble in cold, very slightly soluble in hot water, and not losing weight at 100° (Ullik, *Ann. Ch. Pharm.* cliii. 368).

A weak solution of molybdenum trioxide in nitric acid yields with potassium xanthate, even in very dilute solutions, a light yellow to flesh-coloured precipitate, which in a few minutes, especially on agitation, assumes a splendid violet colour. More concentrated solutions immediately yield a nearly black coagulating precipitate, which, after drying in a vacuum, has the composition $(\text{C}^3\text{H}^3\text{O}^3\text{S}^3)^2\text{Mo} + \text{H}^2\text{O}$ (Siewert, *Jahresb.* 1864, p. 707).

The dark red coloration produced by boiling an ammoniacal solution of molybdic acid for a short time with a moderate excess of yellow *ammonium sulphide*, appears reddish-yellow in more dilute solutions, and after a while brick-red, depositing salmon-coloured flocks; this reaction is perceptible in a solution containing only 0·8 milligr. molybdic anhydride in a litre. On adding to the reddish-yellow solution potassium sulphocyanate and ether (which produce no alteration), then a strongly acid solution of stannous chloride, and agitating, the ether takes up molybdenum sulphocyanate, and acquires an orange-red colour, changing to carmine-red on exposure to the air.

The brown liquid produced by adding the acid solution of stannous chloride to ammonium molybdate exhibits with potassium sulphocyanate and ether the same reaction, which depends on the formation of molybdenum trichloride and trisulphocyanate, and oxidation of the latter to carmine-coloured tetrasulphocyanate:

By means of this reaction a trace of molybdenum has been detected in the vanadiferous brown hematite of Haverloh (C. D. Braun, *Zeitschr. anal. Chem.* vi. 86; *Jahresb.* 1867, p. 852).

Molybdates (Delafontaine, *Bull. Soc. Chim.* [2] iv. 257; *Jahresb.* 1865, p. 215. Ullik, *Ann. Ch. Pharm.* cxliv. 204, 320; cliii. 368; *Zeitschr. f. Chem.* [2] iv. 690; vi. 434; *Chem. Centr.* 1867, 977; 1870, 117. *Crystalline forms*: Zopharovich, *Wien. Akad. Ber.* lviii. [2] 111; *Jahresb.* 1868, 221).—Several new classes of these salts have lately been discovered, which, together with those previously known, may be formulated as follows, the symbol R standing for 2 atoms of a monatomic or 1 atom of a diatomic metal:

Monomolybdates . . .	RO. MoO ³	=	$\left. \begin{array}{c} \text{MoO}^2 \\ \text{R} \end{array} \right\} \text{O}^3$
Dimolybdates . . .	RO. 2MoO ³	=	$\left. \begin{array}{c} 2\text{MoO}^2 \\ \text{R} \end{array} \right\} \text{O}^3$
$\frac{2}{3}$ Molybdates . . .	3RO. 7MoO ³	=	$\left. \begin{array}{c} 7\text{MoO}^2 \\ \text{R}^3 \end{array} \right\} \text{O}^{10}$
Trimolybdates . . .	RO. 3MoO ³	=	$\left. \begin{array}{c} 3\text{MoO}^2 \\ \text{R} \end{array} \right\} \text{O}^4$
Tetramolybdates . . .	RO. 4MoO ³	=	$\left. \begin{array}{c} 4\text{MoO}^2 \\ \text{R} \end{array} \right\} \text{O}^4$
Octomolybdates . . .	RO. 8MoO ³	=	$\left. \begin{array}{c} 8\text{MoO}^2 \\ \text{R} \end{array} \right\} \text{O}^8$
Decamolybdates . . .	RO. 10MoO ³	=	$\left. \begin{array}{c} 10\text{MoO}^2 \\ \text{R} \end{array} \right\} \text{O}^{11}$
Hexdecamolybdates . . .	RO. 16MoO ³	=	$\left. \begin{array}{c} 16\text{MoO}^2 \\ \text{R} \end{array} \right\} \text{O}^{17}$

Monomolybdates or Neutral Molybdates. RO. MoO³ + nH²O.—The solutions of these salts are not coloured by potassium ferrocyanide. The *potassium salt*, first obtained by Svanberg a. Struve (i. 1140), may be prepared by fusing equivalent quantities of potassium carbonate and molybdic anhydride, dissolving the fused mass in hot water, and evaporating the filtered solution over sulphuric acid; it crystallises in anhydrous microscopic prisms (Ullik). Delafontaine, by leaving the solution to evaporate spontaneously, obtained a pentahydrated salt, K²O. MoO³ + 5H²O, in transparent hexagonal prisms combined with the end-face and a subordinate hexagonal pyramid. The crystals give off their water at 100°, and melt without decomposition at a red heat. The *sodium salt*, Na²O. MoO³ + 2H²O, forms nacreeous laminae or monoclinic tables apparently isomorphous with the corresponding tungstate. A *sodio-potassic salt*, K²O. 2Na²O. 3MoO³ + 14H²O, is obtained by saturating potassium trimolybdate with sodium carbonate, and leaving the solution to evaporate; it crystallises in hexagonal prisms like those of the pentahydrated potassium salt, easily soluble in hot water, and forming an alkaline solution (Ullik). A *lithium salt*, 5(Li²O. MoO³) + 2H²O, is obtained, by heating molybdic anhydride with lithium carbonate and water and evaporating, in nodular groups of easily soluble crystals (Rammelsberg, *Jahresb.* 1866, p. 234. Delafontaine). Another salt, containing 3(Li²O. MoO³) + 8H²O, was once obtained by saturating an insoluble acid lithium molybdate with lithium carbonate (Delafontaine). The *thallium salt*, Tl²O. MoO³, is obtained as a crystalline powder, by boiling aqueous thallous oxide with molybdic anhydride, or as a white curdy precipitate by mixing the hot aqueous solutions of thallous sulphate and sodium molybdate. It is slightly soluble in water, melts at a red heat, and gives off black-brown vapours when fused with sodium carbonate (Delafontaine). The *magnesium salt*, MgO. MoO³ + 7H²O, remains, on evaporating the solution formed by boiling magnesia with water and molybdic anhydride, in groups of thin, vitreous, efflorescent prisms, which give off their water without fusion at a red heat (Ullik). By cooling a solution evaporated by heat, Delafontaine obtained monoclinic prisms containing MgO. MoO³ + 5H²O. The *potassio-magnesian salt*, K²O. MgO. 2MoO³ + 2H²O, crystallises from a solution of equivalent quantities of the component salts in groups of small vitreous

Shp.

3 H

prisms, which give off their water at a moderate heat, and melt without decomposition at a dull red heat; easily soluble in water. The *ammonio-magnesian salt*, $(\text{NH}_4)_2\text{O} \cdot \text{MgO} \cdot \text{MoO}_3 + 2\text{H}_2\text{O}$, obtained in like manner, forms larger crystals isomorphous with the preceding.

Dimolybdates. $\text{RO} \cdot 2\text{MoO}_3$.—The *sodium salt*, containing 1 mol. water according to Struve, anhydrous according to Ullik, is produced by adding 1 mol. molybdic anhydride to 1 mol. fused sodium nitrate, and remains in silky needles when the undecomposed half of the nitrate is dissolved out by water. Potassium nitrate is likewise only half decomposed by molybdic anhydride, but the resulting potassium bimolybdate is very easily decomposable and cannot be obtained pure (Ullik).

Seven-thirds Molybdates. $3\text{RO} \cdot 7\text{MoO}_3 + n\text{H}_2\text{O}$.—The *potassium salt*, $3\text{K}_2\text{O} \cdot 7\text{MoO}_3 + 4\text{H}_2\text{O}$ (described by Svanberg & Struve as a compound of the bi- and tri-molybdate), is always formed when molybdic acid is evaporated to dryness with potassium carbonate even in excess, the pulverulent residue dissolved in the smallest possible quantity of water, and the solution left to evaporate. It forms small, deeply striated monoclinic prisms, which melt without decomposition at a red heat, and give off their water at a lower temperature. They are decomposed by water, depositing trimolybdate:

(Delafontaine). The *sodium salt*, $3\text{Na}_2\text{O} \cdot 7\text{MoO}_3 + 22\text{H}_2\text{O}$, crystallises on cooling from a hot solution of molybdic acid in sodium carbonate mixed with nitric acid, in transparent well-defined prisms; by slow evaporation, in larger opaque rectangular tables, which effloresce rather quickly in dry air, give off 21 mol. water at 100° , the last molecule at 200° , and may also be fused without decomposition (Delafontaine). According to Ullik it separates from a solution of 1 mol. sodium trimolybdate mixed with 1 mol. sodium carbonate, in large transparent crystals which lose 8 mol. water by efflorescence, 21 mol. at 100° , and the last between 120° and 130° . When treated with different quantities of sodium carbonate, a corresponding portion of it is converted into the monomolybdate, the rest remaining undecomposed. The *ammonium salt*, $3(\text{NH}_4)_2\text{O} \cdot 7\text{MoO}_3 + 4\text{H}_2\text{O}$, is the salt formerly described (iii. 1037) as a bimolybdate (Delafontaine; Ullik). A *sodio-ammonic salt*, $2\frac{1}{2}(\text{NH}_4)_2\text{O} \cdot \frac{3}{2}\text{Na}_2\text{O} \cdot 7\text{MoO}_3 + 6\text{H}_2\text{O}$, obtained by adding nitric acid to a mixed solution of sodium and ammonium molybdates, crystallises in small striated rhombic or monoclinic prisms (Delafontaine).

The *magnesium salt*, $3\text{MgO} \cdot 7\text{MoO}_3 + 20\text{H}_2\text{O}$, crystallises by spontaneous evaporation from a solution of 7 mol. magnesium monomolybdate mixed with 4 mol. nitric acid, in radiate groups of transparent, vitreous, tabular, oblique prisms. It is permanent in the air, gives off all its water without decomposition at a red heat, and is moderately soluble even in cold water (Ullik).

Trimolybdates, $\text{RO} \cdot 3\text{MoO}_3 + \text{H}_2\text{O}$, are obtained by boiling the carbonates of the several bases with water and excess of molybdic anhydride (4 mol. MoO_3 to 1 mol. base), whereby quadromolybdates are formed in the first instance, and decompose when the solutions are slowly evaporated; also by mixing the solution of a less acid molybdate with any acid in not too large a quantity (the precipitates formed in solutions of molybdates by acids always consist, according to Ullik, of acid salts, never of pure molybdic anhydride). The solutions of the trimolybdates are coloured light red by potassium ferrocyanide. They crystallise by slow evaporation in cauliflower-like aggregates of nodular crystalline groups, and dissolve freely in hot, very slightly in cold water. By more rapid evaporation, especially of small quantities, amorphous salts are obtained with different quantities of water. The following trimolybdates have been obtained by Ullik:

The *rubidium salt*, $\text{Rb}_2\text{O} \cdot 3\text{MoO}_3 + 2\text{H}_2\text{O}$, obtained by fusing rubidium carbonate with excess of molybdic anhydride, and dissolving the fused mass in boiling water,

crystallises on cooling in small shining six-sided prisms, easily soluble in hot, sparingly in cold water (Delafontaine).

Tetramolybdates, $\text{RO} \cdot 4\text{MoO}_3 + n\text{H}_2\text{O}$, are contained, according to Ullik, in the solutions which yield the trimolybdates by spontaneous evaporation. When these solutions (which are coloured dark red by potassium ferrocyanide), in the concentrated state, are quickly evaporated on a glass plate, they leave amorphous, transparent, easily soluble masses, which have the composition of quadromolybdates, are permanent in close vessels, but become opaque and are converted into trimolybdates in contact with the air. In the crystalline form they appear to separate only from solutions likewise containing other salts, sodium chloride for example. Ullik has obtained an **amorphous sodium salt**, $\text{Na}_2\text{O} \cdot 4\text{MoO}_3 + 5\frac{1}{2}\text{H}_2\text{O}$, usually of slight greenish or bluish colour; a **crystallised sodium salt**, $\text{Na}_2\text{O} \cdot 4\text{MoO}_3 + 6\text{H}_2\text{O}$, by adding 3 mol. hydrochloric acid to a solution of 4 mol. of the neutral salt; a **calcium salt**, $\text{CaO} \cdot 4\text{MoO}_3 + 9\text{H}_2\text{O}$, in brownish amorphous masses, fusing with decomposition at a red heat; and a **bluish-green zinc salt**, $\text{ZnO} \cdot 4\text{MoO}_3 + 8\text{H}_2\text{O}$, behaving like the calcium salt when heated.

Octomolybdates, $\text{RO} \cdot 8\text{MoO}_3 + n\text{H}_2\text{O}$, are formed by treating any of the preceding salts with a sufficient quantity of one of the stronger acids (7 mol. acid to 1 mol. of a neutral molybdate). They all crystallise, and apparently in perfectly similar forms (oblique rhombic prisms with basal end-face), are extremely soluble in water, and their solutions form a red-brown precipitate with potassium ferrocyanide. The **sodium salt**, $\text{Na}_2\text{O} \cdot 8\text{MoO}_3 + 17\frac{1}{2}\text{H}_2\text{O}$, gives off $14\frac{1}{2}\text{H}_2\text{O}$ at 100° , the rest between 160° and 180° , melts below a red heat, and decomposes at a higher temperature. The **potassium salt**, $\text{K}_2\text{O} \cdot 8\text{MoO}_3 + 13\frac{1}{2}\text{H}_2\text{O}$, separates from a hot solution on cooling, in small shining crystals, converted by drying with water into a white sparingly soluble powder. The **magnesium salt**, $\text{MgO} \cdot 8\text{MoO}_3 + 20\frac{1}{2}\text{H}_2\text{O}$, forms efflorescent prisms, melting with partial decomposition at a red heat. The **barium salt**, $\text{BaO} \cdot \text{MoO}_3 + 18\text{H}_2\text{O}$, separates from the acid solution in vitreous prisms insoluble in cold water, and decomposed by hot water. The **calcium salt**, $\text{CaO} \cdot 8\text{MoO}_3 + 18\text{H}_2\text{O}$, crystallises in very small prisms, easily soluble in hot, nearly insoluble in cold water. Both these salts decompose like the magnesium salt when heated (Ullik).

Decamolybdates.—The **sodium salt**, $\text{Na}_2\text{O} \cdot 10\text{MoO}_3 + 21\frac{1}{2}\text{H}_2\text{O}$, is produced by dissolving the heptahydrated trimolybdate or sodium carbonate in the corresponding quantity of soluble molybdic acid, and leaving the solution to evaporate; it resembles the octomolybdate with $17\frac{1}{2}\text{H}_2\text{O}$, and is very soluble in water. $\text{Na}_2\text{O} \cdot 10\text{MoO}_3 + 12\text{H}_2\text{O}$ separates as a white crystalline, sparingly soluble powder, when a solution of the salt $\text{Na}_2\text{O} \cdot \text{MoO}_3 + 2\text{H}_2\text{O}$ is heated on the water-bath with a quantity of hydrochloric acid equivalent to the sodium present.

Hexadecamolybdates.—The **sodium salt**, $\text{Na}_2\text{O} \cdot 16\text{MoO}_3 + 9\text{H}_2\text{O}$, separates as a fine white insoluble powder when a solution of the normal sodium salt in a small quantity of water is heated to boiling with a large excess of strong nitric acid. When a solution of 1 mol. sodium carbonate is poured upon 1 mol. of this salt, carbon dioxide is given off, and there remains a white pulverulent sparingly soluble octomolybdate, $\text{Na}_2\text{O} \cdot 8\text{MoO}_3 + 4\text{H}_2\text{O}$. The latter salt is also formed when 2 mol. sodium carbonate are used; but in this case a soluble molybdate is likewise produced, and on evaporating the solution, the salt $\text{Na}_2\text{O} \cdot 3\text{MoO}_3 + 7\frac{1}{2}\text{H}_2\text{O}$ crystallises out.

Ullik has also obtained double molybdates in which part of the molybdenum is replaced by sulphur or chromium. A mixed solution of ammonium sulphate and magnesium molybdate, or of magnesium sulphate and ammonium molybdate, yields well-defined crystals having the composition of the double sulphate $\text{Mg}(\text{NH}_4)_2(\text{SO}_4)_2 + 6\text{H}_2\text{O}$, in which variable quantities of sulphur are replaced by molybdenum, without essential alteration of the crystalline form. When hot strong solutions are used and the mixture is left to crystallise by cooling, or when a considerable excess of ammonium molybdate is added, the crystals are rich in molybdic acid; but by spontaneous evaporation of dilute solutions, crystals are formed containing a smaller proportion of molybdic acid. The latter are permanent, whereas the former give off water and ammonia on exposure to the air. In six such salts, the proportion of SO_3 was found to vary from 16.46 to 41.79 p. c., and that of MoO_3 from 38.56 to 3.43 p. c. All the crystals were isomorphous with the known double salts of the magnesium group. A solution of equivalent quantities of neutral magnesium molybdate and neutral potassium chromate yielded by slow evaporation

small light yellow crystals of the salt $\left\{ \begin{array}{l} \text{K}_2\text{O} \\ \text{MgO} \end{array} \right\} \cdot \left\{ \begin{array}{l} \text{MoO}_3 \\ \text{CrO}_3 \end{array} \right\} + 2\text{H}_2\text{O}$, easily soluble in water, and resembling potassio-magnesian molybdate in their form and their behaviour at high temperatures.

Fluomolybdates. These salts are formed by dissolving the neutral and acid molybdates in hydrofluoric acid. They are mostly easily soluble, crystallise well, and are isomorphous with the corresponding compounds of tin, titanium, and zirconium. The *neutral potassium salt*, $K^2MoF^4O^2 + H^2O$, crystallises from a solution of potassium molybdate slightly supersaturated with hydrofluoric acid, in very thin octagonal tables, which, according to Marignac's determinations, belong to the triclinic system and agree nearly in their angles with the crystals of fluotungstate of potassium, although the latter, according to Marignac, is monoclinic. It is not altered by exposure to the air, gives off its water below 100° , melts at a red heat, and is converted by prolonged fusion in moist air into neutral potassium molybdate, with evolution of hydrofluoric acid. The *acid potassium salt*, $K^2Mo^2F^6O^4 + 2H^2O$, obtained by dissolving the neutral salt in hydrofluoric acid, or by treating acid potassium molybdate with hydrofluoric acid and evaporating, crystallises on cooling in transparent silky needles, which after gentle heating in contact with the air, leave a residue of potassium bimolybdate, but when quickly heated give off molybdic fluoride. The *neutral sodium salt*, $2Na^2MoF^4O^2 + H^2O$, separates from the acid solution in crystalline grains, behaving like the potassium salt when heated, but more soluble. The *acid rubidium salt*, $Rb^2Mo^2F^6O^4 + 2H^2O$, crystallises on cooling from the warm solution of rubidium trimolybdate in hydrofluoric acid, in scaly groups of slender needles, having when dry the aspect of potassium tantalofluoride. It is easily soluble in water, and behaves like the preceding when heated. The *neutral ammonium salt*, $(NH^4)^2MoF^4O^2 + H^2O$, obtained by supersaturating the solution of ordinary ammonia molybdate with ammonia, slightly acidulating with hydrofluoric acid, and evaporating, crystallises in six- or eight-sided tables, isomorphous with the neutral potassium salt. When heated in an open dish, it melts to a pasty mass, gives off vapours of water, hydrofluoric acid, and molybdic fluoride, and when heated to low redness, leaves a residue of molybdic anhydride. The *acid salt*, $(NH^4)^2Mo^2F^6O^4 + 2H^2O$, crystallises in rhombic prisms isomorphous with acid ammonium fluotungstate. The *neutral thallium salt*, $Tl^2MoF^4O^2 + H^2O$, is formed on mixing the neutral potassium salt with thallious sulphate, as a curdy precipitate, which dissolves when warmed and separates again as a crystalline powder on cooling. From a warm solution of neutral thallious molybdate in hydrofluoric acid, it crystallises on cooling in shining straw-yellow rhombic prisms, $\infty P \cdot \infty P \cdot \infty P$. The crystals melt below a red heat, and when roasted leave the neutral molybdate. The *neutral fluomolybdates of zinc, cadmium, cobalt, and nickel* are obtained by dissolving equivalent quantities of the corresponding oxides or carbonates in hydrofluoric acid, and evaporating the solutions, in well-defined crystals of the hexagonal system (six-sided prisms with an acuter or obtuser rhombohedron). The composition of all these salts is represented by the formula $R^2MoF^4O^2 + 6H^2O$. They are isomorphous with the corresponding titanofluorides, zirconofluorides, and fluoniobates. The zinc and cadmium salts are colourless; the cobalt salt is dark red; the nickel salt light green. They are permanent in dry air (the cadmium salt inclined to effloresce), leave nearly pure molybdic oxide when quickly heated, and neutral molybdates when carefully roasted (Ullik, *loc. cit.*).

Phosphomolybdic Acids. Debray (*Bull. Soc. Chim.* [2] x. 369) has obtained two of these compounds, viz. $P^2O^5 \cdot 20MoO^3$ and $P^2O^5 \cdot 6MoO^3$. The former is produced when the precipitate formed by ammonium molybdate in the acidulated solution of a phosphate is boiled with nitromuriatic acid, and the liquid is left to evaporate. It crystallises from this solution in yellow oblique rhombic prisms containing $13 \cdot 3$ p. c. water, which nearly agrees with the formula $P^2O^5 \cdot 20MoO^3 + 26H^2O$. The aqueous solution of these crystals yields by spontaneous evaporation a second hydrate, $P^2O^5 \cdot 20MoO^3 + 52H^2O$, containing $23 \cdot 4$ p. c. water, and crystallising in large regular octohedrons; a third, $P^2O^5 \cdot 20MoO^3 + 40H^2O$, containing $19 \cdot 4$ p. c. water, separates from highly concentrated solutions mixed with a large quantity of nitric acid in less developed and more easily alterable rhombic prisms. Phosphomolybdic acid separates potash, rubidia, caesia, thallia, ammonia, and the organic bases, but not soda and lithia, from their strongly acidulated solutions, in the form of yellow precipitates. The potassium, ammonium, and thallium salts have the composition $3R^2O \cdot P^2O^5 \cdot 20MoO^3$ or $R^2PO^4 \cdot 10MoO^3$, the two former containing 3 mol. (or $3\frac{1}{2}$ mol.) water. The potassium and thallium salts melt at a dull red heat to oily liquids which solidify in the crystalline form on cooling. The ammonium salt is obtained in small yellow highly lustrous crystals when solutions of sodium pyrophosphate and acid ammonium molybdate are mixed together, the precipitates then forming slowly as the pyrophosphate in the liquid becomes converted into orthophosphate. Neutral solutions of silver nitrate give with phosphomolybdic acid a precipitate

which gradually changes into microscopic crystals consisting of $2\text{Ag}^2\text{O} \cdot \text{P}^2\text{O}^5 \cdot 20\text{MoO}^3 + 7\text{H}^2\text{O}$. In acid solutions the salts of the heavy metals give no precipitates; hence phosphomolybdic acid crystallises unaltered from a strongly acidulated solution of bismuth. This acid, however, as well as its salts, is stable only in acid solutions. With alkalis it forms molybdates and salts of the second phosphomolybdic acid, $\text{P}^2\text{O}^5 \cdot 5\text{MoO}^3$, according to the equation:

The salts of this second phosphomolybdic acid are colourless or slightly coloured, crystallise well, have a mother-of-pearl aspect, and are easily soluble. By excess of acid they are reconverted, with separation of phosphoric acid, into yellow phosphomolybdates:

Treated with a small quantity of acid, they yield salts having the composition $5\text{R}^2\text{O} \cdot 2\text{P}^2\text{O}^5 \cdot 10\text{MoO}^3 + \text{H}^2\text{O}$. The anhydride $\text{P}^2\text{O}^5 \cdot 5\text{MoO}^3$ cannot be isolated, on account of its instability. Of its salts the following have been prepared:

Ammonium salt, $3(\text{NH}^2\text{O}) \cdot \text{P}^2\text{O}^5 \cdot 5\text{MoO}^3 + 7\text{H}^2\text{O}$.

Potassium salt, $3\text{K}^2\text{O} \cdot \text{P}^2\text{O}^5 \cdot 5\text{MoO}^3 + 7\text{H}^2\text{O}$.

Sodium salt, $3\text{Na}^2\text{O} \cdot \text{P}^2\text{O}^5 \cdot 5\text{MoO}^3 + 11\text{H}^2\text{O}$.

Silver salt, $3\text{Ag}^2\text{O} \cdot \text{P}^2\text{O}^5 \cdot 5\text{MoO}^3 + 7\text{H}^2\text{O}$.

The existence of the above-described compounds, and the frequently occurring of molybdates, together with vanadates, lead to the supposition that the constitution of molybdic anhydride is analogous to that of vanadic anhydride, and represented by the formula Mo^2O^3 ($\text{Mo}^2 = 80$). The phosphomolybdic anhydrides would then have the simpler formulae $\text{P}^2\text{O}^5 \cdot 12\text{Mo}^2\text{O}^3$ and $\text{P}^2\text{O}^5 \cdot 3\text{Mo}^2\text{O}^3$. But the vapour-density of molybdic chloride does not agree with this hypothesis.

MORESNETITE. A zinc-aluminic silicate from the Altenberg, near Aachen; mostly dark green to leek-green and opaque, sometimes light emerald-green and translucent. Fracture, small conchoidal. Hardness = 2.5. Streak, white.

	SiO^2	Al^2O^3	ZnO	FeO	NiO	CaO	MgO	H^2O	
Light green	30.31	13.68	43.41	0.27	1.14	traces	11.37	=	100.18
Dark green	29.36	13.02	37.98	5.61	0.24	0.76	0.54	11.34	= 98.85

Hence the formula $9(2\text{ZnO} \cdot \text{SiO}^2) + 2(2\text{Al}^2\text{O}^3 \cdot 3\text{SiO}^2) + 20\text{H}^2\text{O}$ (H. Rissé, *Jahresh.* 1866, p. 940).

MORIN (Hlasiwetz a. Pfaundler, *J. pr. Chem.* xciv. 65).—The colouring matter of old fustic (iii. 1047). When completely dehydrated by prolonged drying at 100° in a stream of dry air, or by heating to 200° – 250° , it has the composition $\text{C}^{12}\text{H}^2\text{O}^3$; *morin hydrate* or *morie acid* is $\text{C}^{12}\text{H}^2\text{O}^4$ or $\text{C}^{12}\text{H}^2\text{O}^3 \cdot \text{H}^2\text{O}$. *Potassium morate*, $\text{C}^{12}\text{H}^2\text{O}^3\text{K}$, crystallises from a warm solution in concentrated aqueous potassium carbonate, in soft yellow needles, greenish-brown after drying, and recrystallisable only from solution of potassium carbonate. The *sodium-compound* exhibits similar characters. *Calcium morate*, $(\text{C}^{12}\text{H}^2\text{O}^3)_2\text{Ca}$, is formed as a yellow precipitate on mixing potassium morate with calcium chloride. *Zinc morate*, $(\text{C}^{12}\text{H}^2\text{O}^3)_2\text{Zn}$, is formed by boiling an alcoholic solution of morin with a little sulphuric acid and zinc, in lemon-yellow needles insoluble in water, but soluble in alkalis. In dry ammonia gas, morin assumes a deep yellow colour, and increases in weight by 12.3 p.c. *Bromo-moric acid*, $\text{C}^{12}\text{H}^2\text{BrO}^3$, formed by triturating moric acid with bromine, crystallises from alcohol in microscopic needles mostly grouped in tufts.

When an alkaline solution of moric acid is treated with sodium-amalgam, the liquid first becomes indigo-blue, then green, finally yellow, and at the end of the reaction contains phloroglucin, formed according to the equation: $\text{C}^{12}\text{H}^2\text{O}^4 + \text{H}^2 = 2\text{C}^6\text{H}^2\text{O}^2$. When an alcoholic solution of morin acidulated with hydrochloric acid is treated with sodium-amalgam, it turns purple-red, and finally also yields phloroglucin; if, however, before the reaction is complete, the deep purple solution decanted from the sodium-amalgam be evaporated over the water-bath, it deposits purple-red prisms of a body having the same composition as morin, and therefore designated as *isomorin*. This substance heated either alone or in alcoholic solution, or more quickly by treatment with alkalis, is reconverted into ordinary morin, even when the air is completely excluded. Its solution mixed with alum exhibits a characteristic dichroism. Morin fused with potash yields phloroglucin, together with a little oxalic acid.

Morin in alcoholic solution is not fluorescent, but exhibits a beautiful green fluorescence, like that of uranium glass, on addition of an aluminium salt. Zinc salts produce a faint yellow fluorescence, which becomes very deep on addition of alum. Many metallic salts produce no fluorescence in a solution of morin, and prevent the development of that produced by aluminium salts. Acetic, hydrochloric, nitric, sulphuric, phosphoric, and arsenious acids neither produce fluorescence nor prevent that developed by aluminium salts. Boric acid produces a yellow, silicofluoric acid a dark green fluorescence. A morin solution rendered fluorescent by aluminium acetate deposits on boiling a yellow compound of morin and alumina, and the solution then no longer exhibits fluorescence. Morin is oxidised by chromic acid, and the oxidised product no longer gives rise to fluorescence. Silver nitrate oxidises it, with separation of silver, but the filtered liquid, if it has not been heated, exhibits a beautiful yellow fluorescence. Auric chloride acts in the same manner. The alcoholic solution of the aqueous extract of Kuba wood (the best kind of fustic, *Morus tinctoria*) is dark garnet-red by transmitted light, and fluorescent with dark green colour by reflected light. Alum or any aluminium salt added to this solution much diluted with alcohol, produces the green fluorescence above mentioned, which must be due to the morin contained in the extract, inasmuch as solutions of maclurin do not produce it (Goppelsröder, *J. pr. Chem.* ci. 406; civ. 10; *Zeitschr. f. Chem.* [2] iv. 154, 607).

MORINDIN or MORINDONE. According to W. Stein (*J. pr. Chem.* xcvii. 234; *Jahresb.* 1866, p. 645), morindin is not identical with ruberythric acid, as supposed by Rochleder (iii. 1048), being distinguished from the latter by its insolubility in ether, the violet colour of its barium-compound, and its reaction with potash. It melts at 245° , but yields even below that temperature a crystalline sublimate of morindone. This latter substance is regarded by Stein as different from alizarin, on account of its giving somewhat different coloured reactions with sulphuric acid and with ferric chloride. He assigns to morindone the formula $C^{14}H^8O^3$. From the experiments of Stenhouse, however, morindone appears to be identical with alizarin (iii. 1048).

MOROXOLITE. A potassio-ferric sulphate, $K^2O(Na^2O)SO^3 + 4(Fe^2O^3.SO^3)$, from an American locality (Shepard, *Jahresb.* 1866, p. 952).

MORPHINE. $C^{17}H^{19}NO^3$.—This alkaloid, in contact with a solution of molybdic acid in strong sulphuric acid, assumes a violet colour, changing to blue and dingy green. With solid nitrates, especially those of potassium, sodium, and mercury, the sulphuric acid solution of morphine forms after a while a blood-red zone, and with the dissolved salts a violet liquid, changing to brown or brownish-yellow (Fröhde, *Zeitschr. anal. Chem.* v. 214).

On the characters of sublimed morphine, see ALKALOIDS (p. 87).

An aqueous solution of a morphine salt mixed with excess of iodine, deposits a crystalline precipitate of a tetriodide, $C^{17}H^{19}NO^3HI^4$, which may be recrystallised from a strong solution of potassium iodide, but not from alcohol (Jørgensen, *Zeitschr. f. Chem.* [2] v. 673).

A compound of morphine and zinc chloride, $C^{17}H^{19}NO^3.ZnCl^2 + 2H^2O$, is obtained in vitreous granules by mixing the alcoholic solutions of the two bodies, carefully dissolving out the separated zinc oxide by hydrochloric acid, and cooling the hot filtrate. The salt is also said to crystallise with 7 mol. water (Gräffinghoff, *Jahresb.* 1866, p. 446).

Estimation of Morphine in Opium.—1. Two grams of chopped opium are macerated with 8 c. c. of a solution of ammonium oxalate (to decompose the calcium meconate), triturated after some hours, then thrown on a filter, and washed with 5 c. c. water. The filtrate mixed with an equal volume of 80 p. c. alcohol, and then with ammonia to alkaline reaction, is left for 24 hours in a closed flask and frequently agitated, and the flask is washed out with a small quantity of 40 p. c. alcohol. The dried filter with its contents is returned to the uncleansed flask, and after addition of a few drops of the alcoholic tincture of St. Martha wood, is treated with a slight excess of an exactly measured titrated solution of oxalic acid, containing 4.42 crystallised acid in a litre, of which from 10 to 15 c. c. are sufficient (the acid liquid turns yellow), then diluted with 100 c. c. water, and the excess of acid is determined by means of a dilute titrated solution of soda. Each cub. cent. of the oxalic acid solution corresponds to 0.2 p. c. morphine (Fleury, *J. Pharm.* [4] vi. 99).

2. Guilliermond (*ibid.* vi. 102) gives the following modifications of his former process (iii. 1053). Fifteen grams of opium are triturated to complete comminution

with 120 c. c. of 70 p. c. alcohol; the mixture is introduced into a glass vessel and repeatedly agitated, after the weight has been made up, if necessary, to 125 grams; the liquid is filtered after a while; and 80 c. c. of the filtrate (containing 10 grm. opium) are introduced into a wide stoppered glass. Two grams of the ammoniacal liquid are then transferred by means of a drawn-out pipette to the bottom of the vessel, and the stopper is introduced without allowing the two liquids to mix. After 36 hours the morphine is found separated in thick reddish crystals, the narcotine in slender white needles; the two alkaloids are separated by levigation, and the morphine is washed with boiling water. Stronger or weaker spirit is not so well adapted for the separation. As, however, a considerable quantity of morphine remains dissolved in the 70 p. c. alcohol ($\frac{1}{3}$ of the whole amount, according to Guilliermond), the results obtained by this process are not absolute, but only comparable under similar conditions.

3. Schachtrupp (*Zeitschr. anal. Chem.* vii. 284, 509) describes a method founded on the solubility of narcotine and the insolubility of morphine in benzol, and the easy solubility of morphine in amylie alcohol. A weighed quantity of opium is treated with a solution of sodium carbonate till the opium is completely comminuted; the still alkaline mixture is evaporated over the water-bath; the dry dusty residue is digested several times with hot benzene; the filter through which the liquid has passed is added to the residue; the remainder of the benzene is evaporated off; and the residue is exhausted with boiling amylie alcohol. The greater part of the morphine then crystallises from the united extracts on cooling. The amylie alcohol is decanted and the greater part of it distilled off; the brown residue is agitated while still hot with water containing hydrochloric acid; the crystals previously obtained are dissolved in the same liquid; and the solution is evaporated to twice the weight of the opium used, then filtered, and precipitated with ammonia. The morphine thus separated, which is still coloured, but otherwise pure, is collected after 24 hours, washed, dried, and weighed. Two samples of Smyrna opium thus treated yielded 8.30 and 8.29 p. c. morphine; the same samples treated by Merck's process gave respectively 7.96 and 8.01 p. c.

For the preparation of morphine also, Schachtrupp recommends the treatment of opium with sodium carbonate, and preliminary exhaustion of the dried mass with hot benzene. The residue again dried is drenched with water; strong acetic acid is added; the mixture warmed for some time and strained; and the undissolved portion is treated several times in the same manner. The united extracts evaporated down to twice the weight of the opium used are mixed with a slight excess of ammonia, and the morphine which separates after some time is redissolved in acetic acid and precipitated by ammonia. For final purification it is dissolved in boiling amylie alcohol, from which it separates in colourless crystals without the use of animal charcoal.

Derivatives of Morphine.

Apomorphine or Apomorpha. $C^{17}H^{19}NO^2$ (Matthiessen a. Wright, *Proc. Roy. Soc.* xvii. 455, 460).—An organic base differing from morphine by containing H^2O less, and produced: 1. By heating morphine in a sealed tube to 140° – 150° for two or three hours with a large excess of hydrochloric acid:

2. From codeine (which has the composition of methyl-morphine) by similar treatment:

The methyl chloride formed in the second case collects on cooling on the top of the tarry contents of the tube, and escapes as gas when the tube is opened. The residue in this or in the first process contains the hydrochloride of apomorphine, and when dissolved in water, and precipitated by sodium carbonate, yields, on extraction with ether and agitation with hydrochloric acid, crystalline hydrochloride of apomorphine, from which the base may be precipitated by sodium bicarbonate, as a snow-white crystalline mass, which quickly turns green on exposure to the air. The green mass is partly soluble in water, communicating to it a fine emerald colour, in alcohol with green, in ether and benzene with splendid rose-purple, and in chloroform with violet colour.

Hydrochloride of apomorphine may also be prepared by digesting morphine with

excess of hydrochloric acid under paraffin on the water-bath for some days. It is anhydrous. When exposed to the air in the moist state, or heated in the dry state, it turns green, like the free base, probably from oxidation, as it exhibits an increase of weight.

Apomorphine differs greatly from morphine in its relations to solvents and reagents. It is soluble in alcohol, ether, and chloroform, whereas morphine is almost insoluble in the last two liquids, and but sparingly soluble in cold alcohol. In water apomorphine is slightly soluble, especially in presence of carbonic acid, whereas morphine is nearly insoluble.

The following comparative reactions are exhibited by solutions containing each 1 per cent. of the hydrochloride of the base:

Reagents	Morphine	Apomorphine
Caustic potash	No pp. Stronger solutions give a white pp. easily soluble in excess, without decomposition	White pp. soluble in excess, speedily blackening
Ammonia	No pp. Stronger solutions give a crystalline white pp. insoluble in excess	White pp. soluble in excess, very speedily blackening
Lime-water	No pp. Morphia dissolves readily in lime-water	White pp. soluble in excess, slowly darkening
Sodium bicarbonate	No pp. Stronger solutions yield a white unalterable pp. slightly soluble in excess	White pp. slightly soluble in excess, turning green
Strong nitric acid	Yellow-orange colour, almost bleached on warming	Blood-red colour, becoming paler on warming
Neutral ferric chloride	Greenish-blue colour. Morphine alone gives a pure blue colour	Dark amethyst colour
Potassium dichromate	—	Dense yellow-orange pp., soon decomposing
Potassium dichromate and strong sulphuric acid	—	Dark red coloration
Silver nitrate	Very slowly reduced	Quickly reduced, even in the cold
Potassium iodide	— No pp. with concentrated solution	White non-crystalline pp. speedily becoming green
Platinic chloride	— Yellow crystalline pp. in stronger solutions	Yellow pp.; decomposes on warming
Mercuric chloride, sodium phosphate, ammonium oxalate	The morphine precipitates with these reagents are much more soluble than the corresponding precipitates of apomorphine	

The physiological action of apomorphine is also very different from that of morphine; a very small dose of the former speedily produces vomiting and considerable depression, but this soon passes off, leaving no ill effects. The hydrochloride is a non-irritant emetic and powerful antistimulant; $\frac{1}{10}$ of a grain of this salt subcutaneously injected, or $\frac{1}{4}$ gr. taken by the mouth, produces vomiting in from four to ten minutes.

Oxymorphine. $C^{17}H^{19}NO^4$ (Schützenberger, *Bull. Soc. Chim.* [2] iv. 176).—When a solution of morphine hydrochloride is heated to 60° with an equivalent weight of silver nitrite, nitrogen dioxide is evolved free from carbon dioxide, the liquid becoming yellow and slightly alkaline. At the end of the reaction the precipitated silver chloride contains the greater part of the morphine in the form of oxymorphine, which may be separated from the silver chloride by solution in water containing hydrochloric acid. The *hydrochloride*, $C^{17}H^{19}NO^4 \cdot HCl$, thus obtained, crystallises in microscopic needles easily soluble in hot water, insoluble in alcohol; it has a slightly bitter taste, and does not appear to be poisonous. Ammonia separates the *base* in the form of a powder which redissolves in a large excess of the precipitant, and separates in small needles on boiling. It is quite insoluble at the boiling heat in water, alcohol, and ether, has no taste, melts at about 245° . The *platinochloride*, $2(C^{17}H^{19}NO^4 \cdot HCl) \cdot PtCl_4$, is an amorphous yellow powder easily decomposed by heating with platinic chloride. The *sulphate*, $4C^{17}H^{19}NO^4 \cdot H^2SO^4$ (at 140°), is slightly soluble in cold water, and separates in small needles on mixing the hydrochloride with sulphuric acid.

By the prolonged action of silver nitrite on morphine hydrochloride, another base is produced closely allied to the preceding, namely oxymorphine hydrate, $C^{17}H^{21}NO^4$. It dissolves more readily in cold ammonia, and separates therefrom at the boiling heat in crystalline grains (compare iv. 313).

MUCEDIN. This name is applied by Ritthausen to a constituent of wheat-gluten soluble in alcohol, and to a similar, if not identical compound, forming part of the proteïn-substance of rye. Wheat-mucedin was formerly called *mucin*. Respecting the preparation and properties of these substances, see Ritthausen (*J. pr. Chem.* xci. 296; xcix. 439; *Bull. Soc. Chim.* [2] viii. 132; *Jahresh.* 1864, p. 625; 1866, p. 716; *Gmelin's Handbook*, xviii. 443, 444). The gelatinous substance of the vineyard snail (*Helix pomatia*) is also called mucin by E. Eichwald, who has described its preparation and properties (*Ann. Ch. Pharm.* cxxiv. 177; *Bull. Soc. Chim.* [2] v. 308; *Jahresh.* 1868, p. 649; *Gmelin's Handbook*, xviii. 340-347).

MUCOBROMIC, MUCOCHLORIC, and MUCONIC ACIDS. See PYROMUCIC ACID, iv. 763; also v. 1093.

MURRAYIN. $C^{26}H^{40}O^{28}$ (Blas, *Zeitschr. f. Chem.* [2] v. 316).—A glucoside, prepared by de Vrij from *Murraya exotica*, an East Indian plant. It occurs in all parts of the plant, but chiefly in the petals. These are repeatedly exhausted with boiling water; the evaporated extract is treated with cold water to remove colouring matter, extractive matter, &c.; and from the undissolved residue, murrayin, and a product of its decomposition, murrayetin, are extracted by absolute alcohol. The latter is precipitated by an alcoholic solution of lead acetate; the remaining liquid, freed from lead by hydrogen sulphide, is evaporated to dryness; the residue is dissolved in the smallest possible quantity of absolute alcohol; and the solution, decolorised with animal charcoal, is left to crystallise.

Murrayin is a white light powder consisting of small needles, inodorous, slightly bitter, and not at all poisonous. It dissolves sparingly in cold, easily in boiling water and alcohol, but is insoluble in ether; the solutions have a neutral reaction, and leave the murrayin, when evaporated, in the form of an amorphous jelly. Murrayin crystallises from absolute alcohol. The air-dried crystals contain $C^{26}H^{40}O^{28} + H^2O$; they give off 1 mol. water (2.7 p. c.) at 115° , and the residue melts at 170° . Murrayin dissolves easily in alkalis and alkaline carbonates; the concentrated solutions quickly turn yellow, become brown when heated, and are decolorised by acids without precipitation. The alkaline solutions exhibit a yellow fluorescence by transmitted, greenish-blue by reflected light. The aqueous solution does not exhibit this fluorescence; but the addition of the smallest quantity of murrayetin develops it immediately. The aqueous solution is not precipitated by iron, copper, mercury, or lead-salts, excepting basic lead acetate. Murrayin reduces ammoniacal silver solution at a gentle heat, and Fehling's solution at 100° . Strong sulphuric acid dissolves it with deep yellow colour. By heating with dilute sulphuric or hydrochloric acid, it is resolved into murrayetin and glucose:

Murrayetin crystallises in needles aggregated into a white, light, silky mass;

sometimes also in ~~amorphous~~ *prisms*. The crystals contain $C^{24}H^{24}O^{10} \cdot H_2O$, and give ~~off their water~~ (36 p. c.) over sulphuric acid. Murrayetin heated in an air-bath between watch-glasses melts at 100° , and sublimes partially in shining crystals. It is tasteless and scentless, slightly soluble in cold, more freely in boiling water, easily in alcohol, less easily in ether. The concentrated solutions have a faint acid reaction, and all the solutions are fluorescent. Caustic alkalis and alkaline carbonates dissolve murrayetin with yellowish colour, and intensify the fluorescence. These solutions when heated acquire a deeper yellow colour, but lose their fluorescent property, which is moreover not restored by neutralisation. Ferric chloride produces in the aqueous solution a fine blue-green colour; lead acetate a yellow colour; and soon afterwards a yellow precipitate, which is decomposed by washing with water.

MYCO-INULIN. $C^{12}H^{22}O^{11} \cdot H_2O$.—A substance resembling inulin, occurring in a kind of truffle (*Elaphomyces granulatus*). Its aqueous solution is not altered by iodine-water, ferric chloride, ferrous sulphate, mercuric chloride, mercurous nitrate, basic lead acetate, baryta-water, lime-water, or ammonium oxalate. It is neutral, and prevents the precipitation of cupric oxide by caustic soda, but does not reduce it on boiling. Boiled with dilute sulphuric acid, it yields sugar (Ludwig, *Zeitschr. f. Chem.* [2] vi. 668).

MYELIN. Neubauer has shown that the peculiar forms designated by this name (iii. 1069) may be produced in various ways, without the presence of cholesterin or protagon, e.g. by adding a drop of ammonia to a drop of oleic acid on the object-glass of a microscope, or a drop of water to the white greasy mixture of oleic acid and ammonia: he therefore regards the production of these forms as a purely physical phenomenon (*Zeitschr. anal. Chem.* vi. 189; *Jahresb.* 1867, p. 781).

MYELOÏDIN and **MYELOÏDIC ACID.** These names are given by Köhler (*Chem. Centr.* 1867, pp. 406, 1022; *Jahresb.* 1867, p. 809) to two phosphoretted bodies which he has extracted from brain. The first is described as neutral and yielding with lead-acetate a precipitate containing $C^{46}H^{70}PbNPO^{10}$; the second is said to yield a lead salt containing $C^{74}H^{113}PbNPO^{25}$.

MYOCTONIC ACID. An oily narcotic acid substance obtained by distilling the acidulated juice of *Palicourea Marcgravi* (Peckolt, *Arch. Pharm.* [2] cxxvii. 93).

MYOSIN. See MUSCULAR TISSUE (iii. 1065).

MYRRH. According to Brückner (*N. Rep. Pharm.* xvi. 76), this gum-resin contains in 100 pts.:

Substances soluble in water (vegetable mucilage and arabin).	67.76
Resin insoluble in ether	4.81
Resin soluble in ether	12.57
Resin soluble in carbon bisulphide	14.06
Substances soluble in alcohol and water	0.43
Insoluble (sand, bark, &c.)	0.38

According to Hlasiwetz a. Barth, myrrh is oxidised slowly and partially by potash, yielding protocatechuic acid and a small quantity of pyrocatechin (*Jahresb.* 1866, p. 630).

N

NAPHTHALENE. $C^{10}H^8$.—On the constitution of this hydrocarbon, see AROMATIC SERIES (p. 212). It is produced, together with others, by the decomposition of several of the aromatic hydrocarbons, when their vapours are passed through a red-hot tube :

Also when a mixture of the vapour of benzene, cinnamene, anthracene, or chrysene with ethylene gas is passed through a red-hot tube :

(Berthelot, *Bull. Soc. Chim.* [2] vi. 272, 279; *Jahresb.* 1866, p. 542-545). It occurs in Rangoon petroleum, separating at the temperature of a mixture of ice and salt from the portion which boils between 208° and 209° (corr.) (Warren a. Storer, *Mem. Amer. Acad.* ix. 208).

H. Vohl (*J. pr. Chem.* cii. 29) describes the preparation of naphthalene on the large scale. He finds that when purified by treatment with acids and alkalis and repeated rectification, it has a sp. gr. of 1.15173 at 15° , melts at 79.25° , and boils at $217.2-218^\circ$ (compare iv. 5). When formed into sticks like sulphur, it has the aspect of alabaster, cracks in the warm hand, and becomes negatively electric when rubbed with silk. Fused naphthalene absorbs a large quantity of air, which it gives off again with effervescence shortly before solidifying. Sulphur, phosphorus, and the sulphides of arsenic, antimony, and tin, are easily dissolved by boiling naphthalene, and separate for the most part in the crystalline form on cooling. Indigo is likewise dissolved by it, and remains in the form of slender copper-coloured needles when the cooled mass is treated with alcohol. Iodine, mercuric chloride and iodide, arsenious oxide, succinic, benzoic, and oxalic acids, dissolve with moderate facility in boiling naphthalene. When naphthalene is brought in contact with the strongest nitric acid, HNO^3 , a large quantity of water added, and the resulting precipitate, after washing with dilute alcohol, is mixed with a little hydrate and sulphide of potassium, and dried, the residue dissolves in alcohol with violet-red colour.

Decompositions.—1. According to Kletzensky (*Jahresb.* 1866, p. 561), naphthalene vapour passed through a red-hot tube is resolved into marsh gas and very finely divided carbon, available for making printers' ink, &c. According to Berthelot (*Bull. Soc. Chim.* [2] vi. 281), naphthalene undergoes no alteration at a red heat.—2. It is but slightly altered by heating with hydrogen; at a bright red heat, however, small quantities of benzene and acetylene are produced: $C^{10}H^8 + H^2 = C^6H^6 + 2C^2H^2$.—3. It acts rapidly at a red heat on acetylene, apparently forming anthracene: $C^{10}H^8 + 2C^2H^2 = C^{14}H^{10} + H^2$.—4. With benzene at a white heat it forms anthracene, $C^{10}H^8 + 3C^6H^6 = 2C^{11}H^{10} + 3H^2$ (Berthelot, *ibid.* vi. 280; vii. 292, 293).

5. Heated to 280° in a sealed tube with 20 pts. of saturated aqueous hydriodic acid, it yields a liquid chiefly consisting of naphthalene hydride, $C^{10}H^{10}$ (Berthelot, *Jahresb.* 1867, p. 709). If the heating be continued somewhat longer with 20 pts. of the acid, 3 mol. iodine are separated, and diethyl-benzene, $C^{10}H^{14}$, is produced, together with ethyl-benzene, C^8H^{10} , as the chief product, and a small quantity of benzene. When naphthalene is heated with 80 pts. of saturated hydriodic acid, 19 to 20 mol. iodine are separated to 1 mol. naphthalene, the chief product being decane, $C^{10}H^{22}$, with smaller quantities of octane, hexane, ethane, and free hydrogen. The same products are obtained with perchloronaphthalene, $C^{10}Cl^8$, the octane however predominating.

With 25 pts. acid to 1 pt. naphthalene, the reaction goes on in the same manner as in the last two cases, excepting that carbon is separated, and the more volatile products contain quintane or amyl hydride (Berthelot, *Jahresb.* 1867, p. 709).

6. By boiling with a solution of *potassium permanganate* it is oxidised to phthalic acid, $C^8H^6O^4$, and carbon dioxide. With *sulphuric acid* and *potassium dichromate* (or lead dioxide) it likewise yields phthalic acid, together with dinaphthyl and an acid having the composition $C^{20}H^{14}O^4$. With *sulphuric acid* and *manganese dioxide* the products are phthalic acid, dinaphthyl, and a red resin. The formation of dinaphthyl, $C^{20}H^{14}$, is represented by the equation: $2C^{10}H^8 + O = C^{20}H^{14} + H^2O$ (Lossen, *Ann. Ch. Pharm.* cxliv. 71).

7. Naphthalene heated with *silver oxide* (to 250°) or with *cupric oxide* (to 400°) yields several beautifully crystallising hydrocarbons, among which are C^8H^6 , C^8H^8 , and C^8H^{10} .

8. When *potassium chlorate* is added by small portions to a mixture of naphthalene and strong sulphuric acid, chlorous acid is evolved, and acts upon the naphthalene, partly by oxidation, forming phthalic acid and carbon dioxide, partly by direct addition, forming chloroxynaphthalic acid, $C^{10}H^7ClO^3$:

partly so as to form dichloronaphthalene, according to the equation:

Lastly, a chlorinated sulpho-acid, $C^{10}H^8ClSO^3$, is formed in considerable quantity (Th. Hermann, *Ann. Ch. Pharm.* cli. 1).

9. Naphthalene or bromonaphthalene, heated with *fuchsine*, yields a violet colouring matter, resembling Hofmann's violet, perhaps consisting of rosaniline with 1 at. hydrogen replaced by naphthyl, $C^{10}H^7$ (Bulló, *Dingl. pol. J.* cxcv. 82; *Zeitschr. f. Chem.* [2] vi. 283).

Compounds of Naphthalene.

Acenaphthene or *Acetyl-naphthalene*, $C^{12}H^{10} = C^2H^2 \cdot C^{10}H^8$, isomeric with diphenyl, has been already described (p. 3).

Respecting the *chlorides of naphthalene*, see CHLORONAPHTHALENES (p. 845).

Naphthalene Hydride, $C^{10}H^{10}$, is found amongst the heavy oils of coal-tar boiling between 200° and 220° . It is produced by heating naphthalene to 280° in a sealed tube for a short time with saturated aqueous hydriodic acid (20 pts.). It is a viscid liquid, having a strong disagreeable odour, and boiling between 200° and 210° . Heated to redness in a sealed tube, it is resolved into naphthalene and hydrogen. With cold nitric acid it forms, without evolution of gas, a solution from which water throws down a liquid smelling like naphthalene and nitrobenzene. It is dissolved by strong sulphuric acid with aid of heat; by the fuming acid at ordinary temperatures, forming a sulpho-acid which is soluble in water, and is attacked by bromine with evolution of hydrobromic acid.

Together with the hydride just described there is formed a small quantity of another hydrocarbon boiling at 190° , probably a second naphthalene hydride, $C^{10}H^{12}$ (Berthelot, *Jahresb.* 1867, p. 709).

Naphthalene-potassium, $C^{10}H^8K^2$, analogous to the hydride above described, is formed by fusing naphthalene in a glass tube with a small quantity of potassium, removing the black crust which covers the metal by pressure with a glass rod as fast as it forms, and boiling the black pulverulent product with benzol to remove unaltered naphthalene. With water it yields potassium hydrate, and, together with naphthalene, a hydrocarbon ($C^{10}H^{10}?$) more fusible than the latter (Berthelot, *Bull. Soc. Chim.* [2] vii. 110).

Substitution-derivatives of Naphthalene.

Bromonaphthalenes (Glaser, *Ann. Ch. Pharm.* cxxxv. 40).—*Monobromonaphthalene*, $C^{10}H^7Br$, is obtained by mixing a solution of naphthalene in carbon bisulphide with 6 at. bromine, and distilling the liquid which remains after the carbon bisulphide has been driven off. It is a colourless strongly refracting oil, having a sp. gr. of 1.555 and boiling at 285° . Dissolves easily in alcohol and ether; takes up naphthalene and iodine, but does not combine with the latter; is not decomposed by alcoholic potash, but is reconverted into naphthalene by sodium-amalgam. Wählfors (*Jahresb.* 1865, p. 564), by slowly adding bromine in rather more than the theoretical

quantity to naphthalene immersed in water, and repeatedly distilling the heavy oily layer, first with water, whereupon naphthalene passed over, then by itself, obtained monobromonaphthalene (with a residue of dibromonaphthalene) as a liquid having a sp. gr. of 1.503 at 12°, boiling at 277°, and forming with nitric acid a crystallisable nitro-compound.

Monobromonaphthalene heated with ethylic chlorocarbonate in presence of sodium-amalgam is converted into naphthoic acid, $C^{10}H^7 \cdot CO^2(C^2H^3)$ (Eghis, p. 851).

A *picrate of bromonaphthalene*, $C^{10}H^7Br \cdot C^6H^3(NO^2)^3O$, is produced by heating naphthalene-picric acid with 1 mol. bromine and carbon bisulphide to 100° in sealed tubes. When recrystallised from chloroform, it forms long shining yellow needles which melt at 133° (Wichelhaus, *Deut. chem. Ges. Ber.* 1869, p. 305).

Dibromonaphthalene, $C^{10}H^6Br^2$, is formed by mixing naphthalene with the required quantity of bromine, and may be purified by washing with a little alcohol and recrystallising from hot alcohol. It exists in two modifications, one of which crystallises by slow cooling in long silky needles melting at 81°, while the other, which is more soluble, separates from the mother-liquor in nodular crystals melting at 76° (Glaser).

Two other modifications of dibromonaphthalene are obtained as secondary products in the reaction of bromine on the aqueous solution of α -naphthylsulphurous acid (p. 860), the bromonaphthylsulphurous acid which is the first product of this reaction being partly converted into dibromonaphthalenes by the hydrobromic acid formed at the same time. The dibromonaphthalenes separate as an oil which solidifies to a crystalline cake; and on dissolving this cake in hot alcohol, one of them, which is but slightly soluble therein, quickly separates in microscopic needles melting at 126° to 127°. The mother-liquor afterwards deposits the other modification in beautiful, shining, colourless needles, melting at 76°–77°, and boiling without decomposition at a temperature above the boiling point of mercury. This modification agrees in melting point with one of those described by Glaser, but differs in crystalline form, and in being soluble only in hot alcohol (Darmsstädter a. Wichelhaus, *Ann. Ch. Pharm.* clii. 304).

Tri bromonaphthalene, $C^{10}H^5Br^3$, is gradually deposited from the oily secondary products obtained in the preparation of tetrabromonaphthalene dihydrobromide, and forms, after recrystallisation from alcohol, white needles melting at 75°, easily soluble in alcohol and ether, and not decomposed by alcoholic potash.

Tetrabromonaphthalene, $C^{10}H^4Br^4$, is produced by digesting dibromonaphthalene with an equal weight of bromine at 60°–70°, and washing the solidified product with ether. It crystallises from benzol in stellate groups of white slender needles nearly insoluble in alcohol, sparingly soluble in ether, distilling without decomposition, and not altered by alcoholic potash. *Tetrabromonaphthalene-dihydrobromide*, $C^{10}H^4Br^4 = C^{10}H^4Br^4 \cdot 2HBr$, is always formed when naphthalene is left in contact with excess of bromine at ordinary temperatures. When bromonaphthalene is treated with bromine in various proportions, according to Laurent's directions (iv. 11), oily secondary products are always formed, together with tri- and tetra-bromonaphthalene, the last in especially large proportion under the influence of heat and in sunshine. The oily bodies probably consist of the monohydrobromides of di-, tri-, and tetrabromonaphthalene; they are all converted by excess of bromine into the compound $C^{10}H^4Br^4$. This latter, when freed from the oily bodies by ether, crystallises from benzol or carbon bisulphide in colourless rhombic prisms with their acute edges truncated, and with two brachydiagonal domes. Axes $a : b : c = 0.612 : 1.4035 : 1$. It melts when heated, and is then resolved into tetrabromonaphthalene and hydrobromic acid. By strong nitric acid it is converted into a viscid resinous mass, a volatile body [probably dibromodinitroform, $CBr^2(NO^2)^2$], and dibromonaphthalic acid, $C^8H^4Br^2O^4$, which remains in solution (Glaser).

Pentabromonaphthalene, $C^{10}H^3Br^5$, formed by heating 2 pts. of tetrabromonaphthalene with 1 pt. of bromine to 150°, crystallises from benzol, after washing with ether, in white crystalline grains. It is insoluble in alcohol, scarcely soluble in ether, volatile without decomposition, does not unite with a further quantity of bromine, and is not decomposed by alcoholic potash. By prolonged treatment with strong nitric acid, it appears to be converted into bromonitronaphthalic acid, together with other bodies not yet examined (Glaser).

Chloronaphthalenes (Faust a. Saame, *Zeitschr. f. Chem.* [2] v. 705).—Pure dry chlorine was passed in a rapid stream into pure fused naphthalene till the mass assumed a buttery consistence on cooling. This mass was then mixed with *ligroin* (petroleum naphtha), the liquid filtered, the crystalline residue washed on a filter with *ligroin* and purified by repeated crystallization from chloroform: the product

thus obtained was naphthalene tetrachloride. The ligroin having been distilled off from the filtrate, the liquid residue was mixed with alcoholic potash and precipitated with water; and the oil thus separated, after being dried, was fractionated to constant boiling points. In this manner were obtained monochloronaphthalene and two isomeric dichloronaphthalenes. The distillates which could not be brought to constant boiling points were again treated with chlorine till they partly solidified, then mixed with ligroin, and the crystalline residue, consisting of dichloronaphthalene tetrachloride, was washed with ligroin and recrystallised from chloroform. The filtrate freed from ligroin by distillation yielded heptachlorodinaphthalene. In another experiment the passage of chlorine was continued at a gentle heat till the chlorinated naphthalenes formed on cooling a viscid oil which, when mixed with ligroin, deposited after a few days, hard crystals of monochloronaphthalene tetrachloride. Another portion of this thick oil was treated with chlorine at a higher temperature till the chlorine passed through unabsorbed, whereby a very viscid oil was produced, which, after washing with ligroin, was quickly converted into long yellow needles of β tetrachloronaphthalene. This body is the final product of the action of chlorine on heated chloronaphthalenes; it does not appear possible to introduce a larger proportion of chlorine, even with aid of iodine. (See, on the contrary, p. 847.)

ADDITIVE-PRODUCTS.—*Naphthalene Tetrachloride*, $C^{10}H^4Cl^4$, crystallises from chloroform in large rhombohedrons, melts at 182° , and is decomposed by boiling with alcoholic potash, yielding α dichloronaphthalene.

Monochloronaphthalene Tetrachloride, $C^{10}H^3Cl^4$, crystallises from chloroform in clinorhombic prisms melting at 128° – 130° ; with boiling alcoholic potash it yields trichloronaphthalene.

Dichloronaphthalene Tetrachloride, $C^{10}H^2Cl^4$, crystallises from chloroform in four-sided clinorhombic prisms melting at 172° ; converted by boiling alcoholic potash into α tetrachloronaphthalene, and by boiling with nitric acid into dichloronaphthalic acid.

It is remarkable that each of these three bodies contains four additive atoms of chlorine. They are nearly inodorous, dissolve sparingly in alcohol, somewhat more easily in ligroin and in ether, most easily in chloroform. The alcoholic solutions mixed with nitric acid and silver nitrate yield silver chloride on boiling.

SUBSTITUTION-PRODUCTS.—*Monochloronaphthalene*, $C^{10}H^7Cl$, is a colourless, rather mobile oil, boiling at 250° – 252° , having a strong odour of naphthalene, and not altered by light. *Monochlorodinitronaphthalene*, $C^{10}H^6Cl(NO_2)^2$, is produced by adding monochloronaphthalene to fuming nitric acid; it forms light yellow soft needles, which may be kneaded together in the hand, and melt at 104° – 106° .

Dichloronaphthalene, $C^{10}H^6Cl^2$, exhibits two modifications: α . Produced by boiling naphthalene tetrachloride with alcoholic potash. Boils at 280° – 282° , and solidifies on cooling to a crystalline mass which melts at 35° – 36° . Of the numerous modifications described by Laurent as produced by the process just mentioned (iv. 11), the authors were not able to obtain one: although they crystallised the α dichloronaphthalene in three fractions, all three were found to melt at the same temperature.

β *Dichloronaphthalene*.—The portion of the original chlorinated naphthalenes (see above) which boils between 280° and 285° is a mixture of α and β dichloronaphthalene, and partly solidifies in the crystalline form after long standing. When these crystals are freed by pressure between bibulous paper from the adhering α modification (which in the impure state is an oil), and frequently recrystallised from ether-alcohol, pure β dichloronaphthalene is obtained in colourless prisms boiling at 281° – 283° (i.e. at the same temperature as α) and melting at 68° . Th. Hermann (*Ann. Ch. Pharm.* cli. 63) has also obtained this β dichloronaphthalene, crystallising in needles and melting at 68° , as one of the products of the action of chlorous acid on naphthalene (p. 858); he also describes two other modifications formed at the same time, one (apparently identical with Laurent's modification c) crystallising in acuminate rhombic needles or rhombic laminae melting at 51° ; the other crystallising in strongly nacreous laminae melting at 92° .

The products formed by treating α and β dichloronaphthalene with fuming nitric acid are difficult to purify, and therefore not characteristic; but the bromine substitution-products differ somewhat in melting point. α *Tetrachlorotribromodinaphthalene*, $C^{10}H^4Cl^4Br^3$, or perhaps $C^{10}H^3Cl^4Br^3$, is obtained by dropping 4 at. bromine on 1 mol. of fused dichloronaphthalene, boiling the red solution, after 24 hours, with alcoholic potash, precipitating with water, and recrystallising from ether-alcohol. It forms long soft white needles melting at 74° – 76° . β *Tetrachlorotribromodinaphthalene*, $C^{10}H^3Cl^4Br^3$, obtained in the same manner is exactly like the α modification in external appearance, but melts at 71° – 73° .

Trichloronaphthalene, $C^{10}H^7Cl^3$, obtained by boiling chloronaphthalene tetrachloride with alcoholic potash, crystallises from ether-alcohol in brittle prisms melting at 81° . Its nitro-product is a soft, yellow, crystalline mass.

Heptachlorodinaphthalene, $C^{20}H^9Cl^7 = C^{10}H^4Cl^4 (?)$, crystallises from ether-alcohol in very long, yellowish, waxy needles melting at 106° . By prolonged boiling with alcoholic potash it is converted into a product which crystallises from ether-alcohol in colourless six-sided prisms melting at 101° – 102° . **Heptachlorodinitrodinaphthalene**, $C^{20}H^7Cl^7(NO^2)^2 (= C^{10}H^4Cl^4(NO^2)^2 \cdot C^{10}H^3Cl^3(NO^2)^2)$, crystallises from alcohol in soft yellowish needles melting at 104° – 106° .

Tetrachloronaphthalene, $C^{10}H^4Cl^4$, exists also in two isomeric forms: α . Produced by boiling dichloronaphthalene tetrachloride with alcoholic potash. Crystallises from ligroin and ether in soft white needles which melt at 130° . Its nitro-product forms yellow crystalline nodules.— β . Forms, as above mentioned, the ultimate product of the action of chlorine gas on heated chloronaphthalenes. It is originally obtained in long yellow needles, but after repeated crystallisation from alcohol, forms soft white needles which melt at 156° – 158° . The nitro-product is a soft yellow mass.

All the chloronaphthalenes are easily soluble in ether, ligroin, and chloroform, less easily in alcohol; they have an odour of naphthalene, weaker as their amount of chlorine is greater, and in the tetrachloronaphthalenes scarcely perceptible. Their nitro-derivatives are mostly soft yellow masses which are difficult to purify, and when heated with aqueous soda or ammonia, are partly converted into a brown-red colouring matter (Faust a. Sauer).

Pentachloronaphthalene, $C^{10}H^2Cl^5$, is produced by heating 1 mol. dichloronaphthoquinone with 2 mol. phosphorus pentachloride to 180° – 200° in a sealed tube till the yellow crystals disappear:

On washing the product with water and dilute soda-ley, and distilling, the pentachloronaphthalene passes over at a temperature above the boiling point of mercury, solidifies in the receiver, and may be obtained in colourless needles by recrystallisation from alcohol. It is insoluble in water, slightly soluble in cold, more freely in hot alcohol, easily soluble in ether. It melts at 108.5° , may be sublimed in needles by cautious heating, and distils unaltered at a higher temperature. It is not attacked by alkalis. It is much less easily oxidable than naphthalene, not being attacked by chromic acid mixture, or by boiling nitric acid of sp. gr. 1.35. By the action of fuming nitric acid, and more easily by heating it in sealed tubes to 180° – 200° with nitric acid of sp. gr. 1.15 to 1.2, it is converted into tetrachlorophthalic acid, $C^8H^2Cl^4O^4$ (Graebe, *Ann. Ch. Pharm.* clxix. 8).

Octochloro- or Perchloro-naphthalene, $C^{10}Cl^{10}$.—Berthelot a. Jungfleisch (*Ann. Ch. Phys.* [4] xv. 332) have prepared this compound—first obtained by Laurent (iv. 13)—by treating naphthalene with chlorine, ultimately with addition of antimonie chloride. The product, sublimed and recrystallised from carbon bisulphide, exhibits properties different from those assigned to it by Laurent. It forms splendid crystals belonging to the rhombic system, melts at 135° , and boils with slight decomposition at 403° ; 20 c. c. of its solution in carbon bisulphide saturated at 16° contained 5.86 grm. of the compound. Heated with potassium hydrate, it gives off violet vapours (according to Laurent it is not attacked). Heated with hydriodic acid it yields the same products as naphthalene. Its vapour passed, together with hydrogen, through a red-hot tube yields, together with naphthalene, chiefly resinous and coloured products similar to those produced under the same circumstances from naphthalene.

Cyanonaphthalenes. **Monocyano-naphthalene** or **Naphthyl Cyanide**, $C^{10}H^7CN$, is obtained in two modifications, α and β , by heating the potassium salts of the corresponding naphthyl-sulphurous acids with potassium cyanide:

The α cyanide distils over at about 300° , and after a few rectifications forms a colourless liquid having an agreeable odour somewhat like that of bitter almond oil, a sharp burning taste, and solidifying in a few days at ordinary temperatures, quickly and completely at 0° . It may be easily purified by crystallisation from ligroin, from which it separates in splendid groups of needles having a satiny lustre. It melts constantly at 37.5° , and distils at 297° – 298° (corr.).

The β cyanide likewise passes over in the first instance at about 300° , as a liquid, but solidifies very quickly at ordinary temperatures. When purified by repeated crystallisation from ligroin and rectification, it forms a beautiful white mass resembling stearin and melting at 66.5° (i.e. 29° higher than the α compound) to

a colourless or yellowish liquid which solidifies on cooling to a mass of crystalline nodules. It boils constantly at 304° – 305° (corr.). Has but a faint odour and a slowly developed burning aromatic taste. It is nearly insoluble in water, but dissolves easily in alcohol and ether, with moderate facility in hot ligroin, and separates in great part on cooling in groups of white but somewhat indistinct crystals. Better crystals are obtained by leaving solutions of the cyanide in ligroin or aqueous alcohol to evaporate spontaneously; it then forms thick colourless scales having the aspect of porcelain.

Both α and β naphthyl cyanides are converted by boiling with alcoholic potash into the corresponding naphthoic acids, $C^{10}H^7O^2$ (p. 851). Intermediate compounds are likewise formed having the composition $NH^2(C^{10}H^7O)$ (Merz a. Muhlhäuser, *Zeitschr. f. Chem.* [2] v. 70).

α Nitrocyanonaphthalene, $C^{10}H^6(NO^2)(CN)$, obtained by treating α cyanonaphthalene with fuming nitric acid, crystallises from alcohol in yellow needles melting at 81° and solidifying at 74° . It yields by reduction a liquid amido-base whose hydrochloride has the composition $C^{10}H^6(CN)NH^2.HCl$. The β nitro-compound crystallises from alcohol in yellowish-white laminae (Welkov, *Deut. chem. Ges. Ber.* 1869, p. 407).

Dicyanonaphthalene, $C^{10}H^4(CN)^2$, is obtained in three modifications by distilling potassium cyanide with the potassium salt: α . Of monobromonaphthyl-sulphurous acid: thin, long, faintly yellow needles, slightly soluble in alcohol and ether, insoluble in water, melting at 204° .— β . Of brominated α naphthyl-sulphurous acid: small yellowish needles, easily soluble in alcohol, melting at 236° .— γ . Of brominated β naphthyl-sulphurous acid: small needles, easily soluble in alcohol, melting at 170° .— δ . From naphthylene-sulphurous acid: yellowish, very slightly soluble in alcohol melting at 262° (Darmstädter a. Wichelhaus, *Zeitschr. f. Chem.* [2] v. 571).

Nitronaphthalenes (Lautemann a. d'Aguiar, *Zeitschr. f. Chem.* [2] i. 564).—Ordinary concentrated nitric acid converts naphthalene only into dinitronaphthalene even after prolonged treatment (Laurent, however, describes two modifications of trinitronaphthalene obtained in this manner, iv. 15). By digesting naphthalene for 12 to 14 days with fuming nitric acid at the boiling heat, a yellow crystalline mixture of di- and tri-nitronaphthalene is obtained; and on mixing the contents of the retort with water, washing the white substance thereby separated with water, drying, treating it with ether, and recrystallising from hot alcohol, trinitronaphthalene, $C^{10}H^4(NO^2)^3$, is obtained in monoclinic crystals agreeing perfectly in form with Laurent's β trinitronaphthalene.

Dinitronaphthalene, $C^{10}H^6(NO^2)^2$, which is always obtained in the preceding process as a secondary product, is likewise insoluble in water, but somewhat more soluble than trinitronaphthalene in hot ether or alcohol; it dissolves also in strong nitric acid, hot acetic acid, and turpentine oil, and crystallises therefrom in yellowish needles or in rhombic serrated tables, melting at about 210° . With alcoholic ammonia it forms a white crystalline precipitate, the liquid acquiring a faint rose colour. According to Hollemann (*Zeitschr. f. Chem.* [2] i. 555), yellow dinitronaphthalene may be rendered colourless by treatment with zinc and sulphuric acid at 200° , washing with hot water, and recrystallisation. Darmstädter a. Wichelhaus (*ibid.* v. 253), by exhausting the product of the action of fuming nitric acid on naphthalene with hot alcohol, obtain a dinitronaphthalene which crystallises on cooling in microscopic needles and tables, and when recrystallised from hot chloroform forms four- or six-sided rhombic tables, $\infty P. \infty P. \infty. \infty P$, with angles $\infty P = 137^{\circ}$ and 43° ; insoluble in water, dilute nitric acid, and benzol, easily soluble in hot ether and carbon bisulphide, soluble in hot alcohol and chloroform; melting at 170° and resolidifying at 157° – 156° . The compound detonates when distilled, dissolves in alcoholic potash with red colour, in sulphuric acid with yellow colour removable by ether. The residue of the treatment with alcohol consists of the modification of dinitronaphthalene previously described. The existence of the second modification of dinitronaphthalene is confirmed by Aguiar (*ibid.* 441), who finds that it possesses the properties described by Darmstädter a. Wichelhaus.

Trinitronaphthalene, $C^{10}H^4Cl^3$, is insoluble in water, only slightly soluble in alcohol and ether; precipitated in flocks from solution in fuming nitric acid. The crystals decrepitate when heated, melt at 214° with partial sublimation, and detonate at a higher temperature. In contact with phosphorus iodide and water it is converted into naphthensyltriammonium iodide, $(C^{10}H^5)^3 \cdot H^3N^3 \cdot H^3I^3$, which crystallises from the hot filtrate in needles (Lautemann a. Aguiar). The modification of dinitronaphthalene obtained by Darmstädter a. Wichelhaus yields when treated with fuming nitric acid, a more highly nitrated compound, different from the trinitronaphthalene just described.

Tetranitronaphthalene, $C^{10}H^4(NO_2)^4$, is produced by heating a solution of trinitronaphthalene in fuming nitric acid for four days in closed vessels, and crystallises from hot alcohol in long asbestos-like needles, which melt at 200° , detonate violently at a higher temperature, and are coloured deep red by alcoholic ammonia. By excess of phosphorus iodide and water it is converted into *naphthylxylene-tetrammonium iodide*, $(C^{10}H^4)^+H^+N^4 \cdot 4HI$, which crystallises in yellowish laminae easily soluble in alcohol (Lautemann a. d'Aguiar).

Diazonaphthalene, $C^{10}H^8N^2$.—The nitrate of this base, $C^{10}H^8N^2 \cdot HNO^3$, is formed by the action of nitrous acid on moistened nitrate of naphthylamine, and is obtained, on filtering the solution from a brown-red amorphous product, and leaving it to evaporate, in white, easily soluble, explosive needles. Its aqueous solution is decomposed at the boiling heat, with evolution of nitrogen and formation of naphthol (v. 856):

Diazonaphthalene perbromide, $C^{10}H^8N^2 \cdot HBr^3$, forms orange-red crystals; the *platinochloride*, $2(C^{10}H^8N^2 \cdot HCl) \cdot PtCl^4$, forms short, yellowish, nearly insoluble prisms. **Diazonaphthalimide**, $C^{10}H^6N^2 \cdot NH$, passes over as a yellowish oil, when the substance obtained by the action of ammonia on the perbromide is distilled with water (Griess, *Jahresb.* 1866, p. 459). All these reactions are analogous to those of diazobenzene (iv. 430).

Diazoamidonaphthalene, $C^{20}H^{15}N^3 = C^{10}H^8N^2 \cdot C^{10}H^7(NH^2)$, analogous to diazoamidobenzene (iv. 459), is formed by the action of nitrous acid on a well-cooled solution of naphthylamine:

or by precipitating diazonaphthalene hydrochloride with a solution of naphthylamine, or better by the action of a slightly alkaline solution of sodium nitrite on crystallised neutral naphthylamine hydrochloride. It separates from alcohol in yellow-brown laminae which melt at 100° , and decompose with explosion at higher temperatures. When heated, even with the weakest acids, it splits up into naphthylamine and naphthol; with concentrated mineral acids it acquires a transient violet colour (C. A. Martius, *Zeitschr. f. Chem.* [2] ii. 137).

Azodinaphthylidiamine, $\left. \begin{matrix} (C^{10}H^7)^2 \\ N'' \\ H \end{matrix} \right\} N^2$ (iv. 23), isomeric with the preceding, is

formed, together with naphthol, by the action of nitrous acid on warm alcoholic solutions of naphthylamine; also by treating that base with sodium stannate:

It forms tolerably stable salts, whose solutions are violet, and crystallises from alcohol in long reddish-yellow needles which melt at 136° , solidify at 125° , and distil almost without decomposition.

Azodinaphthylidiamine is also formed by the action of strong sulphuric acid and of other acids, except hydrochloric acid, on naphthylamine (Chapman, *Chem. Soc. J.* [2] iv. 329). On its formation by the action of nitrous acid on naphthylamine, see also Chapman (*ibid.* 135).

Ethyl-naphthalene, $C^{12}H^{12} = C^{10}H^7(C^2H^5)$, is produced, similarly to ethylbenzene (p. 292), by the action of sodium in excess on a cooled mixture of monobromonaphthalene and ethyl bromide in presence of ether. On distilling off the ether, and subjecting the liquid which passes over at a higher temperature to fractional distillation, it separates into naphthalene and ethyl-naphthalene. The latter is a colourless liquid having a faint odour, boiling at 250° , and of about the same specific gravity as water (Fittig a. Remsen, *Zeitschr. f. Chem.* [2] v. 37).

Methyl-naphthalene, $C^{11}H^{10} = C^{10}H^7(CH^3)$, is produced in like manner from bromonaphthalene and methyl iodide. The product is a colourless liquid, boiling constantly at 231° – 232° , having a sp. gr. of 1.027 at 11.5° , and remaining liquid at -18° (Fittig). Stacewicz (*ibid.* 182), by heating the lead salt of naphthyl-sulphurous acid with calcium acetate and quick lime, distilling, and crystallising from alcohol, obtained a small quantity of yellowish laminae, having nearly the composition of methyl-naphthalene. The reaction appears to be:

850 NAPHTHALENE ALCOHOL—NAPHTHOXYAMIC ACID.

NAPHTHALENE ALCOHOL. $C^{10}H^{12}O^4 = \left(\begin{smallmatrix} C^{10}H^9 \\ H^4 \end{smallmatrix} \right)^2 O^4$ (Neuhoff, *Ann. Ch. Pharm.* cxxxvi. 342).—A tetratomic alcohol produced from the corresponding chlorhydrin by decomposition with alkalis:

The chlorhydrin is obtained by treating finely pulverised naphthalene with excess of moderately concentrated hypochlorous acid, and agitating the liquid (filtered after 24 hours, freed from dissolved mercury by hydrogen sulphide, and saturated with common salt) with ether. On distilling off the ether, and drying the residue in rarefied air, *naphthalene chlorhydrin* remains as a light yellow body, crystallising in well-defined prisms, slightly soluble in water, easily soluble in alcohol, quickly turning brown in the air, melting at a gentle heat, and decomposing at a higher temperature.

To prepare the *alcohol*, the alcoholic or aqueous solution of the chlorhydrin is heated for a few hours with 3 or 4 mol. potassium hydrate, and the dilute solution, acidulated with hydrochloric acid and mixed with common salt, is agitated with ether. On evaporating the ether (and decolorising if necessary in alcoholic solution with animal charcoal) the naphthalene alcohol crystallises in prisms which rapidly turn brown. It melts at a gentle heat, decomposes when distilled, is slightly soluble in water, easily in alcohol and ether, and with brown colour in aqueous potash. The alcoholic solution mixed with a little ammonia, forms with salts of lead, silver, and other metals, precipitates which acquire a darker colour when exposed to light. The lead compound, $C^{10}H^9Pb^2O^4$, absorbs carbon dioxide from the air, and when decomposed by hydrochloric acid, yields the alcohol in its original state. The solution of the alcohol in strong sulphuric acid is brown, and contains an acid whose barium, calcium, and lead salts are easily soluble in water. The calcium salt, $(SO^2)^2$ $C^{10}H^9$ O^4 , crystallises in tufts of prisms. Glacial acetic acid decomposes the H^2Ca

alcohol, forming a black resin and a red body soluble in ether. The solution of the alcohol in warm very dilute nitric acid leaves on evaporation yellow prisms of naphthoxalic acid, $C^{10}H^9O^6$. The alcohol or the chlorhydrin heated for some time with concentrated hydriodic acid, forms a mobile liquid distillable with water, and probably consisting of cymene holding naphthalene in solution.

NAPHTHALENE-RED. See NAPHTHYLAMINE (p. 861).

NAPHTHENYL-AMMONIUMS. See page 848.

NAPHTHOXYAMIC ACID. $C^{12}H^{18}N^2O^9$ (Mühlhäuser, *Ann. Ch. Pharm.* cxli. 214).—Produced by the action of potassium cyanide on dinitro-naphthalene:

The potassium salt is prepared by agitating a mixture of 3 pts. pulverised dinitro-naphthalene in 38 pts. alcohol with a solution of 6 pts. potassium cyanide in 57 pts. water till a brown-red colour is produced, and then heating the liquid to the boiling point till it assumes a fine blue-green colour. The solution decanted while still hot gradually deposits the impure potassium salt, which may be purified by washing with cold water (till the water runs away blue), solution in hot water, repeated precipitation with concentrated potassium carbonate, and treatment with hot ether after drying over sulphuric acid. It contains $C^{12}H^{18}N^2O^9K + H^2O$, and forms a dark mass having a strong coppery lustre, especially after friction; insoluble in ether, but dissolving easily, and with fine blue colour, in hot water and in alcohol. When heated it detonates with a reddish light, giving off a peculiar aromatic odour, and leaving a bulky charcoal. The *ammonium salt*, formed by decomposing the potassium salt with strong solution of sal-ammoniac, is a crystalline precipitate soluble in hot water and in alcohol. The *barium salt*, $C^{12}H^{18}N^2O^9Ba$ (?), is a dark blue precipitate having a coppery lustre when dry, detonating when heated like the potassium salt. The *silver salt*, $C^{12}H^{18}N^2O^9Ag$, is insoluble in water, has a lustre of bronze, and detonates with great violence when heated. The blue solution of the potassium salt mixed with the smallest quantity of any free acid becomes greenish, and on further acidulation, greenish-yellow, depositing naphthoxyamic acid, $C^{12}H^{18}N^2O^9$, as a dark brown precipitate, forming when dry a black shining mass. It is insoluble in ether, nearly insoluble in water, more easily in alcohol, still more in amylie alcohol, forming a dark brown-red liquid. Its solution turns green or blue when mixed with a small quantity of a base.

NAPHTHOIC ACID. $C^{11}H^8O^2 = C^{10}H^7.CO^2H$. *Naphthalene-carboxylic Acid*, *Carbonaphthalic Acid*, *Menaphthoxylic Acid* (Hofmann, *Ann. Ch. Pharm.* cxlii. 121; *Zeitschr. f. Chem.* [2] iii. 164; *Deut. chem. Ges. Ber.* 1868, pp. 38, 100; *Zeitschr.* [2] iv. 291; v. 503. Merz, *ibid.* iv. 34. Merz a. Mühlhäuser, *ibid.* v. 70. Eghis, *Compt. rend.* lxxix. 360; *Zeitschr.* [2] v. 630).—This acid, related to naphthalene in the same manner as benzoic acid to benzene, is produced: 1. By distilling naphthylamine with oxalic acid, whereby naphthyl-formamide is produced, converting the latter into naphthyl cyanide by heating it with hydrochloric acid, and boiling this cyanide with caustic soda (Hofmann):

2. By distilling the potassium salt of naphthylsulphurous acid with an equal weight of potassium cyanide, whereby also naphthyl cyanide is produced:

and boiling the cyanide with alcoholic potash (Merz). The α and β naphthylsulphites yield corresponding modifications of naphthoic acid (Merz a. Mühlhäuser).

3. By heating a mixture of monobromonaphthalene and ethylic chlorocarbonate with sodium-amalgam to 105°–110° for several hours, whereby ethyl naphthoate is produced, together with mercuric naphthide as a secondary product:

On treating the product with ether, the ethyl naphthoate is dissolved, while the mercuric naphthide remains behind, and the ethereal solution leaves on evaporation a brown liquid, which, by saponification with alcoholic potash and addition of hydrochloric acid, yields a bulky precipitate of naphthoic acid (Eghis).

α Naphthoic acid, prepared from α naphthylsulphurous acid, or by Hofmann's process, crystallises in colourless needles melting at 160°, very slightly soluble in water, more freely in boiling alcohol. Its *silver salt*, $C^{11}H^7O^2Ag$, is a precipitate insoluble in water. The *barium salt*, $(C^{11}H^7O^2)^2Ba + 4H^2O$, forms sparingly soluble needles, becoming anhydrous at 110°. The *calcium salt*, $(C^{11}H^7O^2)^2Ca + 2H^2O$, resembles the barium salt, and likewise becomes anhydrous at 110°. The *cupric salt* is a green, the *lead salt* a white precipitate. The *ethylic ether*, $C^{11}H^7O^2.C^2H^5$, prepared from naphthoic chloride by the action of alcohol, is a liquid boiling at 309°.

β Naphthoic acid crystallises from hot water in long white needles; from carbon bisulphide in broader silky needles; it dissolves but sparingly in either of these liquids, easily in alcohol and ether. Like the α modification, it is inodorous and tasteless, but gives off cough-exciting vapours when heated, and sublimes in white shining needles. It melts at 182° (corr. 184°), and distils when heated above 300°. Heated with excess of barium hydrate, it is resolved (as also the α acid) into carbon dioxide and naphthalene.

The β naphthoates, excepting those of the alkali-metals, are but slightly soluble; less soluble than the α naphthoates. The *barium salt*, $(C^{11}H^7O^2)^2Ba + 4H^2O$, dissolves in 1400 pts. water at 15°, and crystallises from hot water in white needles. The *calcium salt*, $(C^{11}H^7O^2)^2Ca + 3H^2O$, crystallises from a large quantity of boiling water in tufts of long silky needles soluble in 1800 pts. of water at 15°; the α salt dissolves in 93 pts. (Merz a. Mühlhäuser).

α Naphthoic Chloride, $C^{10}H^7.OCl$ or $C^{10}H^7.COCl$, produced by mixing 4 pts. of the acid with 5 pts. phosphorus pentachloride, boils without decomposition at 297.6°, but is solid at lower temperatures. By water it is immediately resolved into hydrochloric and naphthoic acids (Hofmann).

Naphthoic Amide, $C^{10}H^7.CONH^2$, produced by treating the chloride with ammonia, or by dissolving naphthyl cyanide in alcoholic soda and precipitating with water, forms needles slightly soluble in alcohol, melting at 244°, and subliming at a higher temperature (Hofmann). Naphthoic anilide or naphthoic phenylamide, $C^{10}H^7.CONH(C^6H^5)$, produced by the action of aniline on the chloride, forms white silky crystals. Naphthoic naphthylamide, $C^{10}H^7.CONH(C^{10}H^7)$, obtained in like

manner with naphthylamine, is insoluble in water and benzol, slightly soluble in alcohol, and melts at 244° (Hofmann).

Naphthoic Anhydride, $(C^{10}H^7O)^2O$, obtained by distilling calcium naphthoate with naphthoic chloride, washing the distillate with water and alcohol, and crystallising from boiling benzol, forms prisms melting at 145° , insoluble in water, slightly soluble in alcohol, easily soluble in ether and in benzol (Hofmann).

Oxynaphthoic Acid, $C^{10}H^8O^3 = C^{10}H^7(OH).COOH$. *Carbonaphthoic Acid* (Eller, *Ann. Ch. Pharm.* clii. 277).—This acid, related to naphthol in the same manner as salicylic acid to phenol, is formed by passing dry carbon dioxide over an intimate mixture of 1 mol. naphthol and 2 at. sodium, the reaction being completed at the heat of the water-bath. The mass is then exposed to the air for a short time, to oxidise the remaining sodium, the sodium oxynaphthoate is dissolved in water, and the solution mixed with hydrochloric acid. The oxynaphthoic acid, which is almost insoluble in water, is then precipitated in yellowish flocks which may be recrystallised from alcohol and ether. It forms colourless needles easily soluble in alcohol and ether, and precipitated therefrom by water; it has an acid reaction, and melts at 186° to 188° , turning brown at the same time. The *potassium salt* forms slightly soluble needles. The *copper salt* is a green, the *lead salt* a white sparingly soluble precipitate; the *silver salt* a curdy precipitate. Ferric chloride produces with the acid a strong blue colour; ferrous sulphate, after a while, a blue-red colour. Barium chloride forms no precipitate.

The oxynaphthoic acid above described was prepared with a mixture of α and β naphthol. Schäffer, however (*Ann. Ch. Pharm.* clii. 291), has prepared α oxynaphthoic acid from pure α naphthol, and finds that it agrees in every respect with the acid obtained by Eller; melting point 185° – 186° . Hence it appears that a mixture of α and β naphthol treated with sodium and carbon dioxide yields only α oxynaphthoic acid. Schäffer finds indeed that β naphthol treated in the same manner is but very slowly attacked, yielding only small quantities of the corresponding oxynaphthoic acid. This β acid is very much like the α acid, and forms similar precipitates with lead, copper, and silver salts. With ferric chloride, however, it produces, not a blue, but an inky-violet colour. α Oxynaphthoic acid heated to 120° – 130° in sealed tubes with hydriodic acid, is reduced to α naphthol, just as salicylic acid is reduced to phenol (Schäffer).

Naphthyl-bicarboxylic, Bicarbonsaphthalic, or Naphthophthalic Acid, $C^{12}H^8O^4 = C^{10}H^6.(CO^2H)^2$, is easily produced by boiling dicyanonaphthalene with strong potash-ley, and precipitating the resulting potassium salt with hydrochloric acid:

It is very slightly soluble in hot water, and is precipitated from alcoholic solution by water in nearly colourless microscopic needles, which do not melt at 240° . Its neutral barium salt, $C^{10}H^6.(CO^2H)^2Ba + 2H^2O$, is very easily soluble, and its solution gives with ferric chloride a light yellow ferric salt nearly insoluble in hot water—also a copper salt separating in groups of green needles—and sparingly soluble lead and silver salts. The alcoholic solution of the acid poured into water, exhibits a fluorescence very much like that of quinine solutions (Darmstädter u. Wichelhaus, *Deut. chem. Ges. Ber.* 1869, p. 356).

NAPHTHOL. See NAPHTHYL ALCOHOL.

NAPHTHOQUINONE. $C^{10}H^6O^2$ (Graebe, *Ann. Ch. Pharm.* cxlix. 1; *Zeitschr. f. Chem.* [2] iv. 114; v. 563; *Jahresb.* 1868, p. 471. Th. Hermann, *Ann. Ch. Pharm.* cli. 63; *Jahresb.* 1868, p. 390).—This compound is derived from naphthalene by substitution of the diatomic group $(O=O)^{\cdot}$ for H^2 , being related to naphthalene in the same manner as ordinary quinone to benzene:

Naphthoquinone is obtained by subjecting the potassium salt of chloronaphthosulphoquinonic acid—one of the products of the action of potassium chlorate and sulphuric acid on naphthalene (p. 854)—to dry distillation. Sulphurous anhydride is then evolved, together with yellow-red vapours which quickly condense, and on treating this distillate, or the residual charcoal, with ether, golden-yellow solutions are obtained. These solutions, when left to evaporate, deposit yellow or red flocks, which when dried and heated between watch-glasses, yield naphthoquinone as a yellow sublimate consisting of soft laminae.

Naphthoquinone dissolves sparingly in alcohol and ether, forming golden-yellow solutions which exhibit a beautiful green fluorescence. The solutions mixed with ammonia reduce silver nitrate at the boiling heat. They are slowly decomposed by zinc and hydrochloric acid. With alcoholic potash, naphthoquinone forms a dark-coloured solution; in strong sulphuric acid, it dissolves with fine purple colour, and is precipitated apparently unaltered on dilution with water. By boiling with strong nitric acid in presence of silver, it is oxidised, the solution on cooling depositing shining rhombic lamine, which exhibit the characters of silver phthalate (Hermann).

The four oxychlorinated derivatives of naphthalene described by Laurent, two of which are acids, and the two others the corresponding chlorides (see OXYNAPHTHALIC ACID (iv. 313), may be regarded as derivatives of naphthoquinone; thus:

Chloroxynaphthyl Chloride = Dichloronaphthoquinone . . $C^{10}H^4Cl^2 \begin{Bmatrix} O \\ \diagup \end{Bmatrix}$

Perchloroxynaphthyl Chloride = Hexachloronaphthoquinone . . $C^{10}Cl^6 \begin{Bmatrix} O \\ \diagup \end{Bmatrix}$

Chloroxynaphthalic acid = Chloroxynaphthoquinone . . $C^{10}H^4Cl(OH) \begin{Bmatrix} O \\ \diagup \end{Bmatrix}$

Perchloroxynaphthalic acid = Pentachloroxynaphthoquinone $C^{10}Cl^5(OH) \begin{Bmatrix} O \\ \diagup \end{Bmatrix}$

To the last of these is related the acid $C^{10}H^4O^2$, discovered by Martius a. Griess (p. 857), which has the constitution of oxynaphthoquinone, $C^{10}H^4(OH) \begin{Bmatrix} O \\ \diagup \end{Bmatrix}$ (Graebe).

Dichloronaphthoquinone, $C^{10}H^4Cl^2(O^2)^-$, may be prepared by gradually adding a mixture of naphthalene-yellow (a commercial sodium or potassium salt of dinitronaphthol, p. 856) with 3 or 4 pts. of potassium chlorate to crude hydrochloric acid diluted with an equal volume of water. The mixture is warmed, and as soon as all the naphthalene-yellow has been introduced, more potassium chlorate is added by successive portions till the yellow-red oil at first produced is converted into yellow crystals. These washed on a filter with hot water, freed from oily mixtures by treatment with cold alcohol, and recrystallised from hot alcohol, yield dichloronaphthoquinone in golden-yellow needles, or more rarely in laminae. It is insoluble in water, slightly in cold alcohol or ether, moderately soluble in hot alcohol; is but slowly attacked by cold soda-ley, but dissolves at the boiling heat, with crimson colour, producing sodium chloroxynaphthalate. It melts at 189° , but begins to sublime below that temperature in long yellow needles, sometimes also in laminae. Heated in a sealed tube with phosphorus pentachloride, it is converted into pentachloronaphthalene:

Chloroxynaphthoquinone, $C^{10}H^4Cl(OH)(O^2)^-$, produced by the action of alkalis on dichloronaphthoquinone, is identical with the chloroxynaphthalic acid obtained in like manner by Laurent (iv. 14), and by P. and E. Depouilly (*Bull. Soc. Chim.* [2] iv. 10). On treating the dichloronaphthoquinone with a little alcohol, and adding caustic potash, the liquid solidifies to a mass of cherry-red needles, and by treating the product with hydrochloric acid, the chloroxynaphthalic acid is separated as a yellow precipitate melting at 200° , and subliming in needles. It is slightly soluble in cold water, more easily in boiling water, also in alcohol, ether, and benzol. It dissolves in strong sulphuric acid, and is precipitated therefrom by water. Its potassium salt forms cherry-red needles easily soluble in hot, slightly in cold water. The barium salt, obtained by precipitation, separates from hot-saturated aqueous solutions in yellow silky needles, $(C^{10}H^4ClO^2)^2Ba + H^2O$, which give up their water of crystallisation at 100° . The calcium salt, obtained in like manner, forms yellow needles, more soluble than the barium salt. The lead and silver salts are cherry-red precipitates.

Chloroxynaphthalic acid heated in sealed tubes with 3 mol. phosphorus pentachloride, yields pentachloronaphthalene, phosphorus oxychloride, and hydrochloric acid. Treated in aqueous or alcoholic solution with sodium-amalgam, it yields a number of reduction-products, which were observed some years ago by Strecker (*Ann. Ch. Pharm.* lxxv. 17), but have not been examined. Its potassium salt when heated yields phthalic anhydride, together with potassium chloride and carbon:

Sulpho-acids derived from Naphthoquinone.—Dichloronaphthoquinone dissolves at a gentle heat in acid potassium sulphite, and the solution on cooling deposits the potassium salt, $C^{10}H^4 \begin{Bmatrix} OH \\ O.80^{\circ}K + 2H^2O, \text{ in yellowish octohedrons, becoming pure } (80^{\circ}K)^2 \end{Bmatrix}$

and colourless by recrystallisation. This salt gives off 1 mol. water at 100°, dissolves very easily in water, but is insoluble in alcohol. Its formation is represented by the equation :

The sodium salt obtained in like manner contains $3\text{H}^2\text{O}$, is more soluble in water, and crystallises in hard ill-defined tables. Both salts decompose when heated above 100°.

The potassium salt is converted by potash-ley into *potassium oxynaphthosulphoquinonate* :

The yellow-red precipitate thus obtained is very soluble in water, and therefore difficult to separate from the excess of caustic potash and from the acid potassium sulphite. It is but slightly soluble in the strong alkaline liquid, insoluble in alcohol. By cooling the hot-saturated aqueous solution, it is obtained in yellow-red, microscopic, sickle-shaped needles. Barium chloride forms in the solution a yellow precipitate slightly soluble in water. The calcium precipitate is somewhat more soluble. Lead acetate forms a yellow precipitate insoluble in water. With tin and hydrochloric acid a colourless hydro-compound is obtained (Graebe).

Chloronaphthosulphoquinonic acid, $\text{C}^{10}\text{H}^4\text{ClSO}^3$, is formed as a potassium salt amongst the products of the reaction of potassium chlorate and sulphuric acid on naphthalene (pp. 844, 858). When the dark brown liquid remaining after repeatedly exhausting this product with ether, and containing sulphuric acid and acid potassium sulphate, is left to stand in the concentrated state, it gradually deposits potassium chloronaphthosulphoquinonate in brown crystalline crusts. These are washed, dried on bibulous paper, and freed from acid potassium sulphate by means of water or dilute alcohol. If the residue be then dissolved by boiling with water, and the solution filtered and evaporated, brown indistinctly crystalline masses are obtained,

consisting of potassium chloronaphthosulphoquinonate, $\text{C}^{10}\text{H}^4\text{KClSO}^3 = \text{C}^{10}\text{H}^4 \left\{ \begin{array}{l} \text{Cl} \\ (\text{O}^2)^2 \\ \text{SO}^3\text{K} \end{array} \right.$.

This salt is sparingly soluble in water and alcohol, insoluble in ether. The aqueous solution has an acid reaction, a deep red-brown colour, and is easily decolorised by zinc and hydrochloric acid. A fragment of the salt held in a flame swells up with vermicular excrescences. The solution dyes silk a fine reddish colour, is not precipitated by metallic salts, but reduces silver after addition of ammonia (Hermann).

When the action of potassium chlorate and sulphuric acid on naphthalene is completed, not by heating, but by leaving the mixture for a considerable time and frequently agitating, the liquid retains its yellow-red colour, and becomes dark brown only after dilution with water. In this case the potassium salt of the sulpho-acid, though obtained in a perfectly analogous way, has the composition $\text{C}^{20}\text{H}^8\text{K}^2\text{ClS}^2\text{O}^{12}$. It resembles the former sulpho-salt, but yields a lighter-coloured powder, and is somewhat more soluble in alcohol and ether (Hermann).

The first sulpho-acid is perhaps formed as follows: By the action of chlorous anhydride on naphthalene, dichloroxynaphthol is first produced :

this by further oxidation is converted into dichloronaphthoquinone, with simultaneous formation of dichloronaphthalene :

and the dichloronaphthoquinone reacts with the acid potassium sulphate, in such a manner as to form the potassium salt of the first of the above-described sulpho-acids :

The formation of the second sulpho-acid may be represented by the equation :

The following compounds belonging to the naphthoquinone group have recently been obtained by Graebe & a. Ludwig (*Ann. Ch. Pharm.* June 1870):

NAPHTHOXALIC ACID. $\text{C}^{10}\text{H}^6\text{O}^4$.—This acid, isomeric if not identical with dioxynaphthalic acid (p. 850), remains, on evaporating a solution of naphthalene alcohol (p. 850) in warm very dilute nitric acid, in yellowish prisms easily soluble in water and in alcohol. It sublimes when heated above 100° in monoclinic prisms, and forms easily soluble crystallisable salts with baryta and ammonia. The *silver salt*, $\text{C}^{10}\text{H}^6\text{Ag}^2\text{O}^4$, and the lead salt, are amorphous light yellow precipitates (Neuhoff, *Ann. Ch. Pharm.* cxxvi. 342).

NAPHTHYL or *Dinaphthyl*. $\text{C}^{20}\text{H}^{14} = \text{C}^{10}\text{H}^7 \cdot \text{C}^{10}\text{H}^7$ (Lossen, *Ann. Ch. Pharm.* cxliv. 71; *Jahresb.* 1867, p. 711).—This hydrocarbon is obtained, together with other products, by heating naphthalene with a mixture of manganese dioxide and sulphuric acid diluted with twice its weight of water. Carbon dioxide is then evolved; the acid liquid deposits phthalic acid together with manganous sulphate; and the viscid undissolved mass contains dinaphthyl together with a red resin:

On repeatedly exhausting the brown-red mass with hot alcohol, and leaving the united reddish-yellow extracts to cool, the red resin first separates, and then the dinaphthyl, in yellow nodules. After repeated crystallisation from alcohol, with addition of animal charcoal, it forms faintly yellow nacreous scales, which become colourless by sublimation. From ether, in which it is much more soluble, it crystallises in moss-like aggregates; from ether-alcohol in perfectly developed octohedrons. It dissolves very easily in carbon bisulphide, and crystallises from benzol in the same form as from alcohol. It melts at 154° , and boils at a temperature above the boiling point of mercury.

Dibromodinaphthyl, $\text{C}^{20}\text{H}^{12}\text{Br}^2$, is most easily prepared by allowing the vapour of a weighed quantity of bromine to be absorbed by dinaphthyl spread upon a glass plate placed under a bell jar, a little water being also present to absorb the hydrobromic acid formed. The product is treated with boiling alcohol, and the residual white powder is dissolved in hot benzol. It crystallises in thin monoclinic prisms, volatile, without decomposition, melting at 215° , nearly insoluble in alcohol, somewhat more soluble in ether, easily in boiling benzol and carbon bisulphide. It is not altered by alcoholic solutions of potash, potassium cyanide, ammonia, potassium acetate, or silver acetate, even at the boiling heat. It dissolves in fuming nitric acid, forming a nitro-compound precipitable by water.

Hexbromodinaphthyl, $\text{C}^{20}\text{H}^6\text{Br}^6$, is formed by treating dinaphthyl with excess of bromine, and remains on evaporating its solution in carbon bisulphide (previously agitated with soda-ley) as a yellow resinous mass. It dissolves in alcohol, and is for the most part precipitated therefrom by water as a yellow powder. By agitating its solution in aqueous ether-alcohol with sodium-amalgam, it is converted into dinaphthyl.

Hexchlorodinaphthyl, $\text{C}^{20}\text{H}^6\text{Cl}^6$, obtained by saturating a solution of dinaphthyl in carbon bisulphide with chlorine, and purified by agitation with soda-ley and water, is a yellow, resinous, easily fusible mass, which is decomposed by heat, and likewise reduced to dinaphthyl by sodium-amalgam.

Tetranitrodinaphthyl, $\text{C}^{20}\text{H}^4(\text{NO}^2)^4$, is formed by adding dinaphthyl to fuming nitric acid, and separates, on mixing the solution with water, in yellow flocks, which are deposited from solution in hot alcohol as an orange-coloured powder made up of resinous spherules. It melts and detonates when heated, and when treated in alcoholic solution with tin and hydrochloric acid, yields a small quantity of a very unstable base, the salts of which acquire a transient blue or violet colour by the action of potassium chromate.

NAPHTHYL ALCOHOL or **NAPHTHOL**. $\text{C}^{10}\text{H}^8\text{O} = \text{C}^{10}\text{H}^7(\text{OH})$ (Eller, *Zeitschr. f. Chem.* [2] iv. 723; Maikopar, *ibid.* v. 215; Schäffer, *ibid.* 395).—Of this alcohol there are two modifications, α and β , produced by fusing the lead or potassium salts of the corresponding naphthylsulphurous acids with excess of potash. At the

end of the reaction, the fused mass is dissolved in water, the filtered solution is mixed with hydrochloric acid, and the separated naphthol, after recrystallisation from water, is further purified by sublimation. α Naphthol likewise distils over easily with vapour of water, but β naphthol cannot be separated in this manner from the fused mass.

α Naphthol crystallises in small white shining needles, sometimes also in laminae, easily soluble in alcohol, ether, chloroform, and benzene, sparingly soluble in hot, nearly insoluble in cold water. It has a faint odour, like that of phenol, and its vapour excites sneezing. The aqueous solution mixed with chloride of lime assumes a deep violet colour, changing when heated to red-brown, with separation of brown flocks. A deal-shaving dipped into the aqueous solution, then wetted with hydrochloric acid and exposed to the sun, acquires a peculiar green colour, gradually changing to red-brown; the same changes of colour are produced more slowly in diffused daylight. α Naphthol melts at 94° (Schäffer); at 96° and sublimes in needles (Maikopar). It is identical with the naphthol which Griess obtained from diazonaphthalene (v. 1093). β Naphthol is easily soluble in alcohol, ether, chloroform, and benzene, sparingly soluble in hot water, and crystallises therefrom in laminae. Its aqueous solution is coloured yellow by chloride of lime, and deposits yellow flocks when warmed. A deal-shaving moistened with hydrochloric acid is coloured by it nearly in the same manner as by α naphthol, but much more quickly (Schäffer). It melts at 122° (Schäffer); at 123° and sublimes in laminae (Maikopar). A mixture of α and β naphthol melts at a lower temperature than either of the naphthols separately (Maikopar).

Naphthol heated with *potassium* or *sodium*, or with *hydrate of potassium, sodium, or barium*, unites therewith like phenol, but the compounds formed are less soluble than the phenol-compounds, being decomposed, with separation of naphthol, when evaporated over the water-bath or when carbonic acid is passed through them.

Naphthol heated in the water-bath with an equivalent quantity of *phosphorus pentachloride* yields trinaphthyllic phosphate, $\text{PO}(\text{C}^{10}\text{H}^7)^3$, in compact crystalline masses, the α ether thus produced melting at 145° , the β ether at 108° . A small quantity of an oily chlorinated compound is also formed, probably naphthyl chloride (Schäffer).

Dinitronaphthol. $\text{C}^{10}\text{H}^6(\text{NO}^2)^2\text{O}$ (Martius, *Berl. Akad. Ber.* 1867, p. 519; *Zeitschr. f. Chem.* [2] iv. 80. Darmstädter a. Wichelhaus, *Ann. Ch. Pharm.* clii. 298).—This compound is not produced—at least in any available quantity—by direct nitration of free naphthol; but it may be prepared by the action of nitric acid upon naphthol in the nascent state, namely by treating a dilute solution of naphthylamine hydrochloride with potassium nitrite, whereby diazonaphthalene hydrochloride is produced, and boiling this solution with nitric acid. The diazonaphthalene then splits up into nitrogen and naphthol, which latter is immediately converted into the dinitro-compound by the nitric acid present:

The dinitronaphthol separates in yellow needles which may be purified by recrystallisation from alcohol; or better in most cases by solution in ammonia, and repeated crystallisation of the resulting ammonium salt (Martius). See also Balló (*Zeitschr. f. Chem.* [2] vi. 51).

The same compound is obtained by adding a solution of α naphthyl-sulphuric acid (p. 860) to nitric acid; the liquid then turns red even in the cold, and deposits yellow crystalline dinitronaphthol, but the action is greatly facilitated by a gentle heat. The product is most easily purified by crystallisation from chloroform. β Naphthyl-sulphuric acid treated in a similar manner does not yield any nitrated naphthol (Darmstädter a. Wichelhaus).

Dinitronaphthol forms sulphur-yellow crystals, which are especially lustrous and well defined when deposited from chloroform. It melts at 138° (Darmstädter a. Wichelhaus). It is nearly insoluble in boiling water, slightly soluble in alcohol, ether, and benzol; does not volatilise with vapour of water. It is dissolved without alteration by cold nitric acid, but by prolonged boiling therewith it is converted into oxalic and phthalic acids. It is an acid, decomposing carbonates with effervescence, and forming orange-red to minium-coloured salts, soluble in alcohol, and in some instances

soluble in water. The ammonium salt separates on mixing a hot ammoniacal solution of the acid with concentrated solution of sal-ammoniac, as an orange-coloured precipitate which crystallises from boiling water in thin needles. The calcium salt, $[\text{C}^{10}\text{H}^7(\text{NO}^2)_2]\text{Ca} + 6\text{H}_2\text{O}$, forms long orange-yellow needles somewhat sparingly soluble in water, and becoming red, with loss of water, at 120° . The silver salt, $\text{C}^{10}\text{H}^7(\text{NO}^2)_2\text{OAg}$, is a red flocculent precipitate, the solution of which in hot ammonia deposits crystals of the argent-ammonium salt. The ethylic ether, $\text{C}^{10}\text{H}^7(\text{NO}^2)_2\text{O} \cdot \text{C}^2\text{H}_5$, formed by heating the silver salt with ethyl iodide to 100° , crystallises from alcohol in long yellow needles melting at 88° , insoluble in water (Martius).

Dinitronaphthol is one of the most beautiful and permanent of yellow dyes, colouring silk and wool, without the aid of a mordant, in all shades from light lemon to deep gold-yellow. It is isomeric with the yellow naphthalene dye (perhaps β dinitronaphthol) which was patented in this country in 1863 in the name of W. Newton (*London Journal of Arts*, 1863, December, p. 348). This latter, prepared by boiling 100 pts. naphthalene with 200 pts. nitric acid of sp. gr. 1.30, and designated by Martius as *dinitronaphthyllic acid*, is much more soluble in alcohol than a dinitronaphthol, and is converted by reduction with tin and hydrochloric acid into a brown resinous mass, whereas a dinitronaphthol similarly treated yields the basic compound *diamidonaphthol*, $\text{C}^{10}\text{H}^7(\text{NH}^2)_2\text{O}$. The hydrochloric acid solution of this base supersaturated with potash, deposits, on exposure to the air, a yellow crystalline base, $\text{C}^{10}\text{H}^7\text{N}^2\text{O}$, which forms easily crystallisable, finely coloured, permanent salts, and is converted by boiling with water into an indifferant body, $\text{C}^{10}\text{H}^7\text{NO}^2$, crystallising in yellow-red needles:

This latter is converted by boiling with hydrochloric acid (according to the equation $\text{C}^{10}\text{H}^7\text{NO}^2 + \text{H}_2\text{O} = \text{NH}^3 + \text{C}^{10}\text{H}^7\text{O}^2$) into a compound which crystallises in yellow needles or laminae very slightly soluble in water, more soluble in alcohol, very soluble in ether, subliming when heated, and yielding by oxidation oxalic and phthalic acids (Martius & Griess, *Ann. Ch. Pharm.* cxxiv. 375).

Oxynaphthol. $\text{C}^{10}\text{H}^7\text{O}^2 = \text{C}^{10}\text{H}^7(\text{OH})^2$. *Naphthobixyl*.—Produced by fusing disulphonaphthylene-sulphurous acid (v. 568), or its potassium salt, with potash:

After precipitation from the potash solution by hydrochloric acid, and purification from a tarry substance by boiling with water, it crystallises in colourless needles or small rhombohedrons easily soluble in alcohol, ether, and chloroform, less easily in hot water. The solutions (not quite pure) exhibit a remarkable dichroism of blue and brown. Oxynaphthol dissolves easily in potash, the solution instantly turning black in contact with the air, and yielding with acids, after a while, a black precipitate. Heated in a test-tube to 230° it turns yellow and then brown, but does not fuse (Dusart, *Bull. Soc. Chim.* [2] viii. 200. Darmstädter u. Wichelhaus, *Deut. chem. Ges. Ber.* 1869, p. 113).

Dichloroxynaphthol, $\text{C}^{10}\text{H}^7\text{Cl}^2\text{O}^2 = \text{C}^{10}\text{H}^7\text{Cl}^2(\text{OH})^2$, is formed by the action of reducing agents on dichloronaphthoquinone (p. 853):

The reduction is most easily effected by heating in the water-bath with aqueous hydriodic acid and a small quantity of phosphorus, till the yellow crystals of dichloronaphthoquinone become colourless. By washing these crystals with water, dissolving them in alcohol, and evaporating or precipitating with water, dichloroxynaphthol is obtained in colourless crystals which quickly turn reddish on exposure to the air. It is quite insoluble in cold water, only slightly soluble in hot water, easily in alcohol and ether. It melts at 135° – 140° , turns brown and decomposes partially at a higher temperature. Alkalies dissolve it readily, forming a solution which is colourless at first, but soon acquires the colour of the chloroxynaphthalates. Ferric chloride reconverts it into dichloronaphthoquinone (Graebe, *Ann. Ch. Pharm.* cxlix. 5).

Dichlorodiacetoxynaphthol, $\text{C}^{10}\text{H}^7\text{Cl}^2(\text{OC}^2\text{H}^3\text{O})^2$, is formed by heating dichloroxynaphthol with acetyl chloride. After washing and recrystallisation from alcohol, it forms long, colourless, silky needles melting at 236° and subliming in long prisms. It is insoluble in water, dissolves slightly in cold alcohol, easily in hot alcohol and ether. It is not attacked by potash, or oxidised by ferric chloride (Graebe, *loc. cit.*).

Chloro-dioxynaphthalic Acid. $\text{C}^{10}\text{H}^7\text{ClO}^3 = \text{C}^{10}\text{H}^7 \begin{Bmatrix} \text{Cl} \\ \text{OH} \\ (\text{CO}^2\text{H})^2 \end{Bmatrix}$ (Th. Hermann,

Ann. Ch. Pharm. cli. 63; *Zeitschr. f. Chem.* [2] iv. 551; *Jahresb.* 1868, p. 382).—This

acid is obtained, together with other products, by adding potassium chlorate in small portions to a mixture of moderately strong sulphuric acid and naphthalene, whereby chlorous acid is evolved, which then acts upon the naphthalene in the manner shown by the equation :

The product of the reaction consists of a liquid and a yellowish-red buttery mass. The liquid is decanted; the buttery mass repeatedly exhausted with warm water, as long as acid extracts are obtained; the acid liquid is repeatedly exhausted with ether; the ether evaporated; the residue is digested with benzol; the residue left after evaporation of the benzol is exhausted with warm water; and the solution is decolorised with animal charcoal. This solution when left to evaporate deposits the chlorinated acid in oily drops; these are dissolved in benzol, and the solution is left to evaporate in an open vessel. The syrupy liquid thus obtained gradually deposits crystals of phthalic acid, which may be removed by precipitating the very dilute solution with basic lead acetate; and the remaining liquid, freed from lead and again left to evaporate, yields the chlorinated acid. This, when dried over sulphuric acid, is an amorphous slightly coloured substance, moderately soluble in water, easily soluble in alcohol, ether, and benzol. When boiled with water, it very readily exchanges its chlorine for hydroxyl, so that it is not easily prepared in any considerable quantity.

Dioxynaphthalic Acid. $\text{C}^{10}\text{H}^8\text{O}^6 = \text{C}^8\text{H}^4 \left\{ \begin{matrix} (\text{OH})^2 \\ (\text{COOH})^2 \end{matrix} \right.$ (Hermann, *loc. cit.*).—Pro-

duced by boiling the chlorinated acid with water, or more readily with baryta-water. It is most easily purified by converting it several times into the acid barium salt. When first separated from this salt, it forms a viscid substance, which however, when left at rest for some time, or more quickly if rubbed with a glass rod, begins to crystallise, and solidifies in a few days to a radio-crystalline mass. According to Carius, the crystals are moderately oblique monoclinic prisms, tabular from predominance of the face $\infty\text{P}\infty$. The acid is extremely soluble in water, alcohol, and ether; insoluble in benzol. The solution has a strong acid reaction, decomposes carbonates, and reduces silver from the ammoniacal solution of the nitrate at the boiling heat. Nitric acid oxidises it to phthalic acid. When heated it softens below 100° , melts at 126° , and does not resolidify till cooled to a much lower temperature. Heated between watch-glasses, it yields a sublimate of a sparingly soluble acid and a brown residue which at a higher temperature gives off yellow strong-smelling vapours, condensing partly in the crystalline form, partly in oily drops. Heated to 180° with hydriodic acid of 50 p. c., it yields, with separation of iodine, but without evolution of carbon dioxide, a somewhat sparingly soluble acid, which crystallises in rhombic prisms, sublimes like benzoic acid, forms a yellow precipitate with ferric chloride, and in neutral solution, white precipitates with lead and silver salts.

Dioxynaphthalic acid is bibasic. Most of its salts are easily soluble in hot water. The acid salts crystallise more readily than the neutral salts. Lead acetate produces in the cold solution of the neutral barium salt a precipitate easily soluble in acetic acid; ferric chloride forms a yellow-brown precipitate even in the acid solution. The following dioxynaphthalates have been examined :

$\text{C}^{10}\text{H}^7\text{O}^4\text{K}^2$,	very deliquescent, microscopic, rhombic prisms.
$\text{C}^{10}\text{H}^7\text{O}^4\text{K} + \text{H}^2\text{O}$,	spherical groups of needles, or rhombic prisms or pyramids.
$\text{C}^{10}\text{H}^7\text{O}^4(\text{NH}^4)$,	slender needles.
$\text{C}^{10}\text{H}^7\text{O}^4\text{Ba} + 3\text{H}^2\text{O}$,	rhombic prisms; anhydrous at 110° .
$(\text{C}^{10}\text{H}^7\text{O}^4)^2\text{Ba}$,	monoclinic prisms, or nodular groups of needles.
$(\text{C}^{10}\text{H}^7\text{O}^4)^2\text{Ca}(\text{NH}^4)^2 + 2\text{H}^2\text{O}$,	many-sided monoclinic prisms; anhydrous at 120° ; decomposing at 140° .
$(\text{C}^{10}\text{H}^7\text{O}^4)^2\text{Ca}(\text{NH}^4)^2$,	shining monoclinic prisms.
$(\text{C}^{10}\text{H}^7\text{O}^4)^2\text{Cu}(\text{NH}^4)^2$,	blue rhombic prisms.
$(\text{C}^{10}\text{H}^7\text{O}^4)^2\text{Cu}^2\text{H}^2 + 2\text{H}^2\text{O}$,	microscopic monoclinic prisms, obtained by double decomposition of the acid barium salt.
$\text{C}^{10}\text{H}^7\text{O}^4\text{Pb}$,	white amorphous precipitate.
$4\text{C}^{10}\text{H}^7\text{O}^4\text{Pb} \cdot \text{PbH}^2\text{O}^2 + 4\text{H}^2\text{O}$,	monoclinic tables, obtained by boiling the neutral salt with excess of lead acetate.

The solution of this last salt in hot water containing a few drops of nitric acid deposits on cooling, monoclinic prisms of the salt $(\text{C}^{10}\text{H}^7\text{O}^4)^2\text{Pb}^2\text{H}^2 + 16\text{H}^2\text{O}$.

Dioxynaphthalic chloride, $\text{C}^{10}\text{H}^7\text{O}^4\text{Cl}^2$ or $\text{C}^8\text{H}^4 \left\{ \begin{matrix} \text{Cl}^2 \\ (\text{COOH})^2 \end{matrix} \right.$ is formed by the action of

phosphorus pentachloride on potassium dioxynaphthalate. It is an oily liquid decomposed by water with reproduction of the acid, and by alcohol with formation of diethylic dioxynaphthalate, $C^{10}H^6O^4 \cdot (C^2H^5)^2$.

NAPHTHYL CYANIDE. $C^{10}H^7CN$.—Syn. with MONOCYANONAPHTHALENE (p. 847).

NAPHTHYL ETHERS. **Naphthyl Acetates** or **Acetyl-naphthols**, $C^{10}H^7(C^2H^3O)O$, are obtained by treating naphthol with acetyl chloride in a retort with upright condenser ultimately at a gentle heat, distilling off the excess of acetyl chloride, dissolving the residue in alcohol, and evaporating. *a* **Acetyl-naphthol** washed with water and dried in a vacuum over caustic potash forms a clear, yellowish, oily, nearly inodorous liquid, insoluble in water, easily soluble in alcohol, ether, and chloroform. When it is distilled with aqueous vapour, or even when its alcoholic solution is evaporated over the water-bath, it is resolved into naphthol and acetic acid. *β* **Acetyl-naphthol** crystallises from its alcoholic solution by evaporation at a gentle heat. When purified by repeated crystallisation from alcohol, and dried in a vacuum over caustic potash, it forms small, soft, shining, needle-shaped crystals having a faint but agreeable odour of anise, easily soluble in alcohol, ether, and chloroform, but insoluble in water. Melts at 60° . Decomposed by heat, like the *a* other (Schäffer).

Naphthyl Benzoates or **Benzoyl-naphthols**, $C^{10}H^7(C^7H^5O)O$, are obtained by heating naphthol with benzoyl chloride. The *a* compound separates from solution in ether by evaporation as a yellowish oil which solidifies after a few days to a crystalline mass, and when recrystallised from ether-alcohol forms large shining tables and prisms melting at 56° . It dissolves in boiling alcohol, and separates on cooling as an oil which soon solidifies to a crystalline mass. By heating with sulphuric acid it is resolved into benzoic and naphthyl-sulphurous acids. *β* **Benzoyl-naphthol** is sparingly soluble in ether, easily in boiling alcohol, and crystallises therefrom on cooling in modular groups of slender needles melting at 107° . By heating with alcoholic potash it is resolved into benzoic acid and *β* naphthol (Maikopar).

Naphthyl Ethylates or **Ethyl-naphthols**, $C^{10}H^7(C^2H^5O)O$, are produced by heating naphthol with an equivalent quantity of potassium hydrate and excess of ethyl iodide in alcoholic solution, in a retort with upright condenser. On separating the potassium iodide thereby formed, and expelling the alcohol, ethyl-naphthol remains, and may be distilled over with vapour of water.

a Ethyl-naphthol is a yellowish oily liquid which has a peculiar odour, sinks in water, boils at 272° (corr. 280.7°), and does not solidify at -5° . *β* Ethyl-naphthol is at ordinary temperatures a nearly colourless crystalline mass having an agreeable odour like that of pine-apples. It melts at 33° ; dissolves easily in alcohol, ether, chloroform, and benzol, but is insoluble in water (Schäffer).

Naphthyl Phosphate, $PO(C^{10}H^7)^3 = PO(C^{10}H^7O)^3 = \left(\begin{smallmatrix} (PO)^{'''} \\ (C^{10}H^7)^3 \end{smallmatrix} \right) O^3$ (Schäffer,

Ann. Ch. Pharm. clii. 289).—Produced by gently heating naphthol with an equivalent quantity of phosphorus pentachloride, and purified by solution in alcohol, decoloration with animal charcoal, and repeated crystallisation. The formation of the phosphate is probably preceded by that of the monochloride; thus:

and

a Naphthyl phosphate forms small colourless crystals, easily soluble in ether and chloroform, sparingly soluble in alcohol, insoluble in water. Melting point 145° .

β Naphthyl phosphate crystallises in small white inodorous needles, easily soluble in ether and chloroform, sparingly in cold, easily in hot alcohol; insoluble in water. Melting point 108° nearly.

Naphthyl-sulphuric Acids. $C^{10}H^7SO^4 = C^{10}H^7 \left\{ \begin{smallmatrix} OH \\ SO^3H \end{smallmatrix} \right\} O^3 = \left(\begin{smallmatrix} C^{10}H^7 \\ (SO^3)^{'''} \\ H \end{smallmatrix} \right) O^3$ (Schäffer,

Ann. Ch. Pharm. clii. 293).—Produced by heating naphthol with strong sulphuric acid in the water-bath till it is completely dissolved and is no longer precipitated by water, then diluting with water, boiling, and neutralising with lead carbonate. The resulting lead salt, purified by recrystallisation and decomposed by hydrogen sulphide, yields a solution of the acid which may be crystallised by evaporation over the water-bath, and finally in a vacuum over sulphuric acid.

***α* Naphthylsulphuric acid** forms long white radiating needles, unctuous to the touch, very deliquescent, easily soluble in water and in alcohol; melting, with brown coloration, at 101°. It dissolves easily in nitric acid, the solution after some time depositing crystalline dinitronaphthol. Its solution mixed with ferric chloride assumes a deep blue colour, changing to green when heated and becoming blue again on cooling. It is not coloured by chloride of lime. The calcium salt, $(C^{10}H^7SO^3)^2Ca + 3H^2O$, forms small colourless shining laminæ easily soluble in water, less soluble in alcohol, decomposing at 100°. **Lead salts.**—A solution of the acid neutralised with lead carbonate yields two lead naphthyl-sulphates, one containing $C^{10}H^7SO^3Pb$, crystallising in microscopic needles sparingly soluble in water, almost insoluble in alcohol, easily soluble in acidulated water; the other, $(C^{10}H^7SO^3)^2Pb$, crystallising in nodular groups of needles, easily soluble in water, somewhat less soluble in alcohol.

***β* Naphthyl-sulphuric acid** forms small laminar crystals unctuous to the touch, melting at 125°, not deliquescent. With nitric acid it forms in the cold a deep red solution with a tinge of blue; the colour disappears at the boiling heat, but without formation of a separable nitro-compound. The aqueous solution of the *β* acid mixed with ferric chloride assumes a faint green colour in the cold, and deposits brown flocks when heated. With chloride of lime it assumes a yellow colour, becoming somewhat deeper on addition of ammonia. The calcium salt, $(C^{10}H^7SO^3)^2Ca + 5H^2O$, forms very light silky laminæ easily soluble in water and alcohol, giving off their water in a vacuum over sulphuric acid, decomposing at 100°. There is but one lead salt of *β* naphthyl-sulphuric acid, viz. $(C^{10}H^7SO^3)Pb + 6H^2O$, which forms small silvery very light crystalline laminæ easily soluble in water, somewhat less soluble in alcohol.

Naphthylsulphurous Acid. $C^{10}H^8SO^3 = C^{10}H^7 \cdot SO^2H$.—*Naphthalene-sulphuric Acid. Sulphonaphthalic Acid.*—Faraday obtained this acid in two modifications, distinguished from another by the behaviour of their barium salts when heated, the one burning with flame, the other merely smouldering (v. 560). Merz (*Zeitschr. f. Chem.* [2] iv. 393), who distinguishes the former as *α*, the latter as *β* naphthylsulphurous acid, finds that these two acids may be most easily separated by means of their lead salts, the *α* lead salt being much more soluble in water and in alcohol than the *β* salt. All the *α* salts are in fact more soluble than the corresponding *β* salts. **Potassium salts,** $2C^{10}H^7SO^3K + H^2O$.—The *α* salt crystallises from alcohol in laminæ; the *β* salt in needles. The *α* salt dissolves in 13 pts. water and in 108 pts. alcohol at 11°; the *β* salt in 15 pts. water and 115 pts. alcohol at 10°. **Barium salts,** $(C^{10}H^7SO^3)^2Ba + H^2O$.—The *α* salt dissolves in 87 pts. water and in 350 pts. alcohol at 10°; the *β* salt in 290 pts. water and in 1950 pts. alcohol at 10°. **Calcium salts.**—Crystallise in laminæ; the *α* salt, $(C^{10}H^7SO^3)^2Ca + 2H^2O$, dissolves in 16½ pts. water and 19½ pts. alcohol at 10°. The *β* salt forms anhydrous crystals soluble in 76 pts. water and in 137 pts. alcohol at 10°. **Lead-salts.**—The *α* salt crystallises from water or alcohol in shining laminæ soluble in 27 pts. water and in 11 pts. alcohol at 10°. The *β* salt forms scales or crusts containing $\frac{2}{3}$ mol. water or anhydrous, soluble in 115 pts. water and in 305 pts. alcohol at 10°.

α Naphthylsulphurous acid, separated from the lead salt by hydrogen sulphide, is completely resolved, by heating to 200° with hydrochloric acid, into sulphuric acid and naphthalene: $C^{10}H^7SO^2H + H^2O = SO^2H^2 + C^{10}H^8$. The *β* acid similarly treated remains for the most part undecomposed (Merz).

The potassium salts of the two acids heated with potassium cyanide yield *α* and *β* naphthyl cyanide (p. 847).

The following observations apply to the *α* acid and its derivatives:

Naphthylsulphurous chloride, $C^{10}H^7SO^2Cl$, prepared by the action of phosphorus pentachloride on sodium naphthyl-sulphite, is decomposed in alcoholic solution by sodium-amalgam, in such a manner as to yield naphthalene and sulphurous acid:

whereas in acid solution (with zinc and sulphuric acid) it yields naphthyl sulphhydrate:

When sodium-amalgam acts upon the chloride dissolved in pure ether, *naphthylsulphurous hydride*, $C^{10}H^8SO^2 = C^{10}H^7 \cdot SO^2H$, is produced as a thickish oil, slightly soluble in water, easily in alcohol or ether, converted by oxidation in the air into naphthylsulphurous acid, and by treatment with zinc and sulphuric acid into naphthyl sulphhydrate (Otto a. Mories, *Ann. Ch. Pharm.* cxlvii. 164; *Jahresb.* 1867, p. 718).

Bromonaphthylsulphurous Acid. $C^{10}H^7BrSO^2H$.—Of this acid there are three modifications, the first of which is formed by dissolving monobromonaphthalene in

fuming sulphuric acid; when separated from its lead salt it is an asbestos-like crystalline mass, or broad, flat needles melting at 137° – 139° , very soluble in water, alcohol, and ether. The *potassium* and *sodium salts*, the *calcium salt* $(C^{10}H^7BrSO^2)^2Ca + 3H^2O$, and the *barium salt* $(C^{10}H^7BrSO^2)^2Ba + 2H^2O$, crystallise in small laminae soluble in water and alcohol; the *lead salt*, $(C^{10}H^7BrSO^2)^2Pb + 14H^2O$, forms indistinct crystals sparingly soluble in water. The *silver salt* is a white precipitate, blackening at the boiling heat (Otto a. Mories, *loc. cit.*; Darmstädter a. Wichelhaus, *Ann. Ch. Pharm.* clii. 303).—The second modification is formed by treating a naphthylsulphurous acid with bromine, but is at the same time partly converted into dibromonaphthalene, which separates as an oil, gradually solidifying to a crystalline cake. The bromonaphthylsulphurous acid remains in solution, and may be purified by conversion into a potassium salt. When separated therefrom, it forms a dark-coloured syrup, which gradually solidifies under the air-pump to a mass which melts at 104° ; it dissolves easily in water and alcohol, but is nearly insoluble in ether. The *potassium salt* is anhydrous, and forms stellate groups of spicular crystals having a faint yellow colour. The *barium* and *lead salts* are sparingly soluble, slight yellow precipitates.—The third modification is formed in like manner by the action of bromine on β naphthylsulphurous acid, but is not converted into dibromonaphthalene: hence it is obtained in larger quantity. When separated from its potassium salt it forms a microscopically crystalline mass melting at 62° , very soluble in alcohol and water, and likewise in ether, by which last character it is distinguished from the other two modifications. The *potassium salt*, $C^{10}H^7BrSO^2K$, crystallises in faintly yellow tables; the *barium* and *lead salts* are sparingly soluble precipitates (Darmstädter a. Wichelhaus).

Bromonaphthylsulphurous chloride, $C^{10}H^7BrSO^2Cl$, remains on treating the liquefied mixture of the sodium salt of the first modification of bromonaphthylsulphurous acid and phosphorus pentachloride with water, as a yellowish resinous non-distillable mass, insoluble in water, easily soluble in ether, alcohol, and benzol, gradually decomposed by moist air, with evolution of hydrochloric acid; decomposed by alcoholic potash into bromonaphthyl sulphite and chloride of potassium, and by sodium-amalgam into naphthalene and sulphurous acid. With ammonia it forms *bromonaphthylsulphamide*, $C^{10}H^7Br \cdot SO^2NH^2$, which crystallises from water in laminae, from alcohol in needles, and melts at 195° . Bromonaphthylsulphurous chloride is violently attacked by sodium-amalgam, forming *bromonaphthylsulphurous hydride*, $C^{10}H^7BrSO^2H$, which is separated from the aqueous solution of the resulting sodium salt, as a viscid oil having the consistence of turpentine and easily soluble in water (Otto a. Mories).

NAPHTHYL SULPHYDRATE or **NAPHTHYL MERCAPTAN**. $C^{10}H^7(SH)$.—See v. 1093.

NAPHTHYLAMINE. $C^{10}H^7N = C^{10}H^7NH^2$.—According to Böttger (*Dingl. pol. J.* clxxiii. 480), the hydrochloride of this base is easily obtained by mixing an alcoholic solution of nitronaphthalene with an equal volume of hydrochloric acid, and adding a sufficient quantity of zinc-foil to produce a brisk evolution of hydrogen. The filtered solution deposits the hydrochloride in nodular crystals. The sulphate may be obtained in like manner.

Naphthylamine-red or *Naphthalene-red*.—Naphthylamine is converted by many oxidising agents, viz. stannic chloride, mercuric chloride, mercuric nitrate, or nitric acid (which, however, is apt to decompose it altogether) into a violet-red colouring matter, which may be extracted by boiling water containing alcohol or acetic acid, and precipitated from the solution by sodium chloride or carbonate. If a large excess of naphthylamine is used, or if the violet-red body be boiled with naphthylamine, a greyish-blue substance is produced (Scheurer-Kestner, *Rep. Chem. app.* iii. 262, 313; *Jahresb.* 1861, p. 353; see also Ballé, *Zeitschr. f. Chem.* [2] vi. 51).

The solution of this colouring matter (prepared with stannic or mercuric chloride) in boiling alcohol has a deep red colour, and when evaporated deposits beautiful needle-shaped crystals having a green colour and metallic lustre. These crystals are the hydrochloride of a base having the composition $C^{10}H^7N^2$, derived from 3 mol. naphthylamine by abstraction of 3 mol. hydrogen, just as rosaniline is derived from aniline: $3C^{10}H^7N - 3H^2 = C^{10}H^7N^2$. The hydrochloride dried at 100° has the composition $C^{10}H^7N^2 \cdot HCl + H^2O$. The *platinochloride*, also dried at 100° , contains $2(C^{10}H^7N^2 \cdot HCl) \cdot PtCl^4 + 2H^2O$; the *picrate* dried at 100° is $C^{10}H^7N^2 \cdot C^8H^4(NO^2)_4O + H^2O$. As all these salts retain 1 mol. water at 100° , it is probable that the free base, like rosaniline, will also be found to contain water, and to have the composition $C^{10}H^7N^2 \cdot H^2O$. The hydrochloride exhibits a characteristic reaction, which distinguishes it from all the aniline-dyes. On pouring a few drops of its concentrated

solution into a cylindrical vessel filled with alcohol, a liquid is formed, perfectly transparent, with light rose-colour by transmitted light, but exhibiting in reflected light a strong and peculiar fluorescence, giving an appearance of opacity, as if a precipitate were being formed, and diffusing itself through the liquid in clouds of a fiery-red colour.

Naphthylamine-red is also formed by treating azodinaphthyl-diamine with naphthylamine, ammonia being evolved at the same time. In this case its formation from naphthylamine may be represented by the two following equations:

Naphthylamine-red forms splendidly crystallised colouring matters with the iodides of methyl and ethyl (Hofmann, *Deut. chem. Ges. Ber.* 1869, pp. 375, 412; *Zeitschr. f. Chem.* [2] v. 632, 694).

On the action of acids on naphthylamine, see Chapman (*Chem. Soc. J.* [2] iv. 135, 329).

NAPHTHYL-CARBOXYLIC ACID. Syn. with NAPHTHOIC ACID (p. 851).

NAPHTHYL-DIAMINE, $\left(\begin{smallmatrix} \text{C}^{10}\text{H}^7 \\ \text{H}^2 \end{smallmatrix}\right)^m \text{N}^2$, and **NAPHTHYLENE-DIAMINE**, $\left(\begin{smallmatrix} \text{C}^{10}\text{H}^7 \\ \text{H}^1 \end{smallmatrix}\right)^m \text{N}^2$.—Naphthyl-diamine is produced, together with naphthylamine and pyridine (as secondary product), by the action of nascent hydrogen on azodinaphthyl-diamine:

When a saturated alcoholic solution of azodinaphthyl-diamine is digested with tin and strong hydrochloric acid, the decanted yellow solution evaporated, the aqueous extract of the residue freed from tin by hydrogen sulphide, and the filtrate evaporated as much as possible without contact of air, a residue is left, which, after recrystallisation from a small quantity of water, with addition of strong hydrochloric acid, and washing with dilute hydrochloric acid, consists of the hydrochlorides of naphthylamine and naphthyl-diamine; the pyridine salt remains in the mother-liquor. The separation of the two salts is most easily effected by repeated digestion with absolute alcohol, which dissolves chiefly the hydrochloride of naphthylamine, while the naphthyl-diamine salt remains undissolved.

Naphthyl-diamine precipitated from the hydrochloride by ammonia forms splendid shining scales, which on exposure to the air are very quickly converted into a dark green mass. By distillation in a stream of hydrogen it is obtained as a pale yellow oil of very high boiling point, solidifying to a crystalline mass on cooling. It is easily soluble in alcohol, ether, and benzol. The *hydrochloride*, $\text{C}^{10}\text{H}^{10}\text{N}^2 \cdot 2\text{HCl}$, crystallises from hot water in laminae, and is almost completely precipitated from its aqueous solution by hydrochloric acid. The gold and platinum salts form dingy green needles. The *sulphate*, $\text{C}^{10}\text{H}^{10}\text{N}^2 \cdot \text{H}_2\text{SO}_4$, is precipitated by dilute sulphuric acid from the hot-saturated solution of the hydrochloride in long needles, or as a light brown crystalline powder nearly insoluble in cold water and in alcohol. The *nitrate* is a nodular crystalline mass; the *oxalate* crystallises in tufts.

The alcoholic solution of naphthyl-diamine forms with silver nitrate a white precipitate, which quickly decomposes with separation of metallic silver; the precipitate formed with mercuric chloride likewise decomposes in drying. On mixing the alcoholic solution of the base with carbon bisulphide, hydrogen sulphide is gradually evolved, and dark garnet-red crystals separate, sparingly soluble in alcohol, ether, and benzol. Potassium nitrite, ferric chloride, potassium dichromate or ferricyanide, produce, in dilute solutions of naphthyl-diamine salts a splendid green colour; in more concentrated solutions a green flocculent precipitate; this reaction is very delicate and serves to distinguish naphthyl-diamine from naphthylene-diamine (*infra*), which is coloured brown-red or chestnut-brown by the oxidising agents above mentioned. The green substance is coloured violet by ammonia and brown-red by hydrochloric acid; by distillation, either alone or with potash, it reproduces naphthylamine (Perkin, *Chem. Soc. J.* [2] iii. 173).

Naphthylene-diamine hydrochloride, $\text{C}^{10}\text{H}^8(\text{NH}_2)^2 \cdot 2\text{HCl}$, is formed by boiling dinitro-naphthalene with tin and hydrochloric acid, and crystallises from the

solution, freed from tin by hydrogen sulphide and evaporated in an atmosphere of this gas, in dazzling white needles. The *nitrate* forms prismatic needles, becoming dark in course of time. Ammonia added to the concentrated solution of the hydrochloride throws down a white crystalline precipitate of naphthylene-diamine, $C^{10}H_8(NH^2)^2$, melting at 175° . *Dibromonaphthylene-diamine*, $(C^{10}H_4Br^2)(NH^2)^2$, is precipitated on mixing the warmed aqueous or alcoholic solution of naphthylene-diamine hydrochloride with bromine, and crystallises from alcohol. By the prolonged action of bromine on the hot solution, *tribromonaphthylene-diamine* is obtained. Potassium nitrite added to the solution of naphthylene-diamine hydrochloride, throws down a violet body, $C^{20}H^{15}N^3O^3$, which dissolves slowly in hydrochloric acid, with evolution of nitrogen, and when boiled with tin and hydrochloric acid is converted into naphthylamine hydrochloride (Holleman. *Zeitschr. f. Chem.* [2] i. 555).

The isomeric base regarded by Perkin as naphthyl-diamine is probably also a naphthylene-diamino, and might be distinguished as *iso-namylene-diamino*.

NARCEINE. $C^{23}H^{20}O^2$.—According to Hesse (*Ann. Ch. Pharm.* cxxix. 250), this alkaloid crystallises from boiling water, alcohol, or dilute sulphuric acid in long white prisms, melting at 145.2° , solidifying to an amorphous mass, and giving off at higher temperatures vapours which smell like herring-pickle. 1 pt. narceine dissolves at 13° in 1285 pts. water, 915 pts. alcohol of 85 p. c., and about 800 pts. of dilute acetic acid. Strong sulphuric acid colours it (not green as stated by Anderson), but black, and in thinner layers violet. According to Dragendorff (*Jahresb.* 1864, p. 728), it forms with pure strong sulphuric acid a blood-red solution, becoming dark brown to garnet-coloured at 150° , and light red on cooling after addition of nitric acid. *Narceine sulphate* crystallises in small prisms decomposed slowly by cold, instantly by hot water into narceine and sulphuric acid. The *picrate* forms an oily yellow mass, easily soluble in boiling water; the *tannate*, grey-white flocks. The *mercuriochloride* is oily at first, but ultimately crystallises in concentric groups of short prisms. The *platinochloride*, $2(C^{23}H^{20}NO^2 \cdot HCl) \cdot PtCl_4 + 2H_2O$, is an amorphous precipitate which soon becomes crystalline; the *aurochloride* is a yellow precipitate separating as an oil from boiling water.

Narceine Periodides.—A *sesqui-iodide*, $(C^{23}H^{20}NO^2)_2I_2$, is formed when a solution of the hydrochloride, diluted with water till it is no longer precipitated by potassium periodide, is mixed with that reagent, and the mixture is left to itself for some weeks in a loosely covered vessel. The solution then becomes filled with slender needles of the sesqui-iodide. A *tri-iodide*, $C^{23}H^{20}NO^2 \cdot HI_3$, is gradually deposited in beautiful needles from an alcoholic solution of the sesqui-iodide mixed with iodine (Jürgensen, *Deut. chem. Ges. Ber.* 1869, p. 460).

Soc. J. [2] vi. 257; Matthiessen, *Proc. Roy. Soc.* xvii. 337; Matthiessen u. Wright, *ibid.* 340).—When narcotine is heated with excess of hydrochloric acid for about two hours, methyl chloride is formed, and 1 at. hydrogen substituted for CH^3 in the narcotine:

If the reaction be continued for some days, 2 at. CH^3 are in like manner replaced by 2 at. H, forming the base $C^{20}H^{18}NO^2$; and when narcotine is heated with fuming hydriodic acid, 3 at. CH^3 are replaced by 3H, yielding the base $C^{17}H^{15}HO^2$ (iv. 27).

The last of these bases is called normal narcotine, or more shortly *normar-cotine*; the other two, and ordinary narcotine itself, are its three methyl-derivatives:

Ordinary narcotine heated to a little above 200° *per se*, or for a considerable time in contact with water, splits up into meconin and cotarnine:

Dimethyl-nornarcotine heated above 100° with water in sealed tubes likewise undergoes decomposition, apparently thus:

Hydrochloride of dimethyl-norcotinine treated with *ferric* or *platinic chloride*, forms methyl-noropianic acid and cotarnine; thus:

Methyl-norcotinine heated with water yields in like manner normeconin and cotarnine:

with oxidising agents, noropianic acid and cotarnine:

and norcotine yields with heated water and with oxidising agents, normeconin or noropianic acid respectively, and cotarnimide:

The following table exhibits a comparative view of the physical properties and reactions of norcotine and its methylated derivatives, and of cotarnine:

Characters of Narcotine, &c.

	Trimethyl-norcotinine (ordinary narcotine), $C^{10}H^{15}NO^+$	Dimethyl-norcotinine, $C^{10}H^{13}NO^+$	Methyl-norcotinine, $C^{10}H^{11}NO^+$	Norcotine, $C^{10}H^9NO^+$	Cotarnine, $C^{11}H^{11}NO^+$

* All these precipitates decompose on boiling with excess of platinum chloride.

According to Gobley (*J. Pharm.* [4] ii. 156), narcotine may be extracted from opium—together with a fatty oil and a substance resembling caoutchouc—by digestion with oil of turpentine at 100°.

Narcotine Tri-iodide, $C^{22}H^{23}NO^7HI^3$, is formed by mixing an alcoholic solution of narcotine with hydrochloric acid, adding the calculated quantity of iodine, and then water till a permanent turbidity is produced. On stirring the liquid, the tri-iodide separates in shining laminae, and an additional quantity may be obtained by adding more water. This compound is moderately soluble in alcohol, but undergoes a remarkable alteration when boiled therewith, the solution on cooling depositing the tri-iodide of a new base, tarconine, $C^{22}H^{11}NO^3$, containing 2 at. hydrogen less than cotarnine:

(Jörgensen, *Deut. chem. Ges. Ber.* 1869, 460; *Zeitschr. f. Chem.* [2] v. 673).

NEPHRITE. For analyses of this mineral from the pile-buildings of the Swiss lakes and other localities, see Fellenberg (*Jahresb.* 1865, p. 880); Damour (*Compt. rend.* lxi. 313, 357; *Jahresb.* 1865, p. 880).

NEPHROLYMASE. This name is applied by Béchamp (*Bull. Soc. Chim.* [2] iii. 213) to a soluble ferment existing in the urine of man, the dog, and the rabbit, and capable of converting starch into sugar.

NEURINE. Syn. with CHOLINE (p. 448).

NICKEL. The atomic weight of this metal has been redetermined by Russell (*Chem. Soc. J.* [2] vii. 294) by measuring the volume of hydrogen evolved on dissolving a known weight of the pure metal in hydrochloric acid. (See ANALYSIS OF GASES, p. 142.) The mean of four closely agreeing experiments gave for the atomic weight of nickel the number 58.70, which is very nearly the same as that which Russell formerly obtained (iv. 40) by reducing the pure monoxide with hydrogen, viz. 58.74.

Different but less trustworthy results have been obtained by Sommaruga (*Jahresb.* 1866, p. 244) and by Winkler (*ibid.* 1867, p. 289). The former, by analysis of niccolo-potassic sulphate, $(SO^4)^2NiK^2 + 6H^2O$, obtained the number 58; the latter, by reducing a neutral solution of sodio-auric chloride with metallic nickel, and weighing the gold precipitated, found Ni = 59.06.

Detection of Nickel.—A solution of a nickel salt mixed with sodium acetate and hypochlorite, and heated to the boiling point, deposits a deep blue, nearly black peroxide forming a specular coating on the glass; the reaction is extremely delicate, and every trace of nickel is thereby removed from the liquid (Popp, *Ann. Ch. Pharm.* cxxxi. 363; see also Wicke, *Zeitschr. f. Chem.* [2] i. 86; *Jahresb.* 1865, p. 267). Sodium hyposulphite added to nickel salts at the boiling heat throws down black nickel sulphide, probably also forming trithionate and chloride of sodium:

The precipitate is not attacked by strong sulphuric or boiling hydrochloric acid, but is oxidised by nitric acid to nickel sulphate (W. Gibbs, *Sill. Am. J.* [2] xxxvii. 346).

Potassium sulphocarbonate colours a nickel solution crimson-brown, or, if very dilute, rose-red. The solution to be tested is first freed from cobalt by potassium nitrite, and the filtrate is made alkaline with ammonia, mixed with sal-ammoniac, and precipitated with a little colourless ammonium sulphide. The filtrate from this precipitate yields, when strongly concentrated by evaporation, a precipitate of nickel sulphide. This precipitate is washed on a filter, dried, ignited, treated with a little nitric acid, and evaporated. The saline residue is dissolved in water and added to about 50 c. c. water containing 1 or 2 drops of the solution of sulphocarbonate (prepared by saturating one half of 250 c. c. potash-ley containing 5 p. c. K^2O with hydrogen sulphide, adding the other half, gently warming the liquid for two days with 10 c. c. carbon bisulphide, and then decanting from the uncombined CS^2). If nickel is present, the rose-red or crimson colour will be produced. This reaction suffices to distinguish $\frac{1}{10}$ milligram of nickel in 1 c. c. of liquid. The nickel-compound dissolved in the alkaline sulphocarbonate exhibits in dilute solution distinct absorption-bands; concentrated solutions stop the light almost completely (C. D. Braun, *Zeitschr. f. Chem.* [2] v. 309).

For other methods of detecting nickel in presence of cobalt, and for separating the two metals, see COBALT.

NICOTINE. On the preparation of this base see Pribram (*Bull. Soc. Chim.* [2] viii. 276). De Luynes (*Compt. rend.* lxvii. 656) describes a compound of nicotine and orcin, as an oil soluble in excess of narcotine. According to Huber (*Ann. Ch. Pharm.* cxli. 271), nicotine oxidised with potassium chromate and sulphuric acid yields an amidated acid, $C^9H^9NO^2$, from which by distillation with lime an oily base, C^9H^9N , soluble in water is obtained.

NITRATES. 1. **Hydrogen Nitrate or Nitric Acid.**—Exact determinations of the specific gravity of aqueous nitric acid of various strengths have been published by J. Kolb (*Ann. Ch. Phys.* [4] x. 136). The percentage p of hydrogen nitrate, HNO^3 , was determined in each case by adding a weighed and excessive quantity of pure calcium carbonate, and weighing the undissolved portion. The values directly determined are distinguished in the following table by an asterisk :

P	Density		Contraction	P	Density		Contraction
	at 0°	at 15°			at 0°	at 15°

Detection and Estimation of Nitric Acid.—P. Holland (*Chem. News*, xvii. 219) modifies Pelouze's method of estimating nitric acid (by oxidation of a ferrous salt, iv. 87) by performing the oxidation in a vacuum.

Chapman (*Chem. Soc. J.* [2] vi. 172) estimates nitric acid by reducing it with aluminium (a method first suggested by Fr. Schulze, *Jahresb.* 1861, p. 835), and distilling off the ammonia thereby produced. The quantity of ammonia, if somewhat considerable, is determined by titration; if very small, as in ordinary waters, by Nessler's test, the depth of colour produced being compared with that developed in a similar manner in a standard solution of ammonia. (See WATER-ANALYSIS, v. 1032.)

According to E. Schulze (*Zeitschr. anal. Chem.* vi. 379), the estimation of nitric acid by reduction with aluminium (or zinc) is not applicable to vegetable juices, or any liquids containing large quantities of organic matter, whereas that of Schlösing, depending on the reducing action of ferrous chloride (iv. 88), gives good results. Fr. Schulze (*Zeitschr. f. Chem.* [2] iv. 296) now recommends that such liquids be first distilled with dilute potash to remove ammonia, the organic matter then destroyed by heating the alkaline solution with potassium permanganate, the excess of permanganate decomposed with a salt of formic acid, and the nitric acid determined in the neutralised and concentrated filtrate by reduction with aluminium.

Schenk a. Chapman (*Laboratory*, i. 152) find that Pugh's method of estimating nitric acid by converting it into ammonia with stannous chloride, and determining the excess of the latter volumetrically, is not applicable to water-analysis, because organic matters of all kinds likewise convert stannous into stannic chloride, ammonia being also formed if the organic matter is nitrogenous.

C. Nöllner (*Zeitschr. anal. Chem.* vi. 375; vii. 355) estimates nitric acid in saltpetre and saltpetre-lyes by means of the solubility of ammonium nitrate in alcohol. 1 grm. of the salt is heated with ammonium sulphate and a little water; absolute alcohol is then added; and the liquid filtered from the sulphates is mixed with an alcoholic solution of pure potash, whereby potassium nitrate is precipitated, and may be washed with alcohol and weighed.

The following process for the detection of nitric and nitrous acids, founded on an observation of Hofmann (*Ann. Ch. Pharm.* xlvii. 60), is given by C. D. Braun (*Zeitschr. anal. Chem.* vi. 71): 1 c. c. of pure strong sulphuric acid is mixed on a watch-glass by drops with $\frac{1}{2}$ c. c. of a solution of aniline sulphate, and a drop of the liquid to be tested is brought on the end of a glass rod to the edge of the acid liquid. If only a trace of the nitric acid is present, deep carnation-red streaks and curves make their appearance as the liquids slowly mix, and the entire liquid becomes rose-red, or, if the quantity of nitric acid is rather larger, carmine-red to brown-red or brown-yellow. In this manner nitric acid may be detected in common sulphuric acid and in spring or river water.

On the reduction of nitric acid by tin and hydrochloric acid, see HYDROXYLAMINE (p. 722).

According to Schönbein (*J. pr. Chem.* cv. 208; *Jahresb.* 1868, p. 179), those organic substances which decompose hydrogen dioxide catalytically have also the power of reducing nitrates in solution to nitrites, and completely decomposing the latter. This reaction has been especially noticed with fresh confervæ, yeast, and fungi in general, also with blood-corpuscles.

2. Metallic Nitrates. Copper Nitrates.—A tetracupric salt, $4\text{CuO} \cdot \text{N}^2\text{O}^6 + 3\frac{1}{2}\text{H}^2\text{O}$, is precipitated from a boiling solution of the normal nitrate by an acetate of alkali-metal, magnesium, manganese cobalt, nickel, zinc, cadmium, copper, or lead, also by many propionates and valerates, also on mixing a solution of cupric acetate with the nitrates of many of the bases just mentioned; ammonium nitrate gives no precipitate (Casselmann, *Jahresb.* 1865, p. 274).

Indium Nitrate.—See INDIUM (p. 732).

Iron Nitrates.—Ferrous nitrate is most readily prepared by dissolving ferrous sulphide in cooled nitric acid of sp. gr. less than 1.12. The solution, made as neutral as possible, carefully concentrated by evaporation, and then exposed to a winter temperature, deposits the salt in crystals, which appear to consist of $(\text{NO}^3)^2\text{Fe} + 6\text{H}^2\text{O}$. These crystals may be preserved in the moist state at low temperatures; but when separated from the mother-liquor they are quickly converted into red-brown basic ferric nitrate. 100 pts. of the crystallised salt dissolve in 50 pts. water at 0° , in 40.8 pts. at 15° (sp. gr. of solution 1.48), and in 33.3 pts. at 25° (sp. gr. of solution 1.50 (Ordway, *Sill. Am. J.* [2] xl. 325).

Cubic ferric nitrate, $\text{Fe}^2\text{O}^3 \cdot 3\text{N}^2\text{O}^6 + 12\text{H}^2\text{O}$ or $(\text{Fe}^3)^4(\text{NO}^3)^6 + 12\text{H}^2\text{O}$, is always obtained when the solution is so composed that it may be regarded as containing

equivalent quantities of the crystallised salt and the hydrate of nitric acid, $\text{N}^2\text{O}^4 \cdot 3\text{H}^2\text{O}$. If it contains less water, no crystals are formed; if more, the cubic salt is always associated with the clinorhombic salt, containing $18\text{H}^2\text{O}$ (iv. 93). The latter is formed exclusively when the solution has a constitution represented by the formula $(\text{Fe}^2\text{O}^3 \cdot 3\text{N}^2\text{O}^3 + 18\text{H}^2\text{O}) + n(\text{N}^2\text{O}^4 \cdot 4\text{H}^2\text{O})$. The cubic salt also crystallises out when the clinorhombic salt is heated till it has lost 14 p. c., and the liquid is mixed with an equal volume of fused hydric nitrate, (NO^2H) , or when 1 mol. of the fused clinorhombic salt is mixed with rather more than 4 mol. NO^2H . During the cooling and crystallisation the liquid must be protected from atmospheric moisture (Ordway).

The same method serves also for the preparation of other nitrates in the crystalline state, especially those of *chromium, glucinum, zinc, and manganese*; the glucinum salt crystallises in quadrate octohedrons (Ordway).

On commercial nitrate of iron, see *Lonsson (Zeitschr. f. Chem. [2] vi. 284)*.

Lead Nitrates.—The *diplymbic salt*, $\text{Pb}(\text{NO}^3)^2 \cdot \text{PbO} + 4\text{H}^2\text{O}$, is precipitated from a solution of potassium nitrate or normal lead nitrate by a slight excess of basic lead acetate. The *triplymbic salt*, $\text{Pb}(\text{NO}^3)^2 \cdot 2\text{PbO}$, is formed by mixing the aqueous solutions of triplymbic acetate and potassium nitrate (the precipitate redissolves in excess of the basic acetate); it is slightly soluble in cold water, more soluble than the diplymbic salt, is precipitated therefrom in the crystalline form by alcohol, and crystallises from the hot-saturated solution in small hard prisms. It has been obtained with quantities of water varying from 1 to $\frac{1}{2}$ mol. The *septymbic salt*, $\text{Pb}(\text{NO}^3)^2 \cdot 5\text{PbO} + \text{H}^2\text{O}$, is separated from the solution of either of the preceding salts by excess of ammonia, as a fine white perfectly insoluble precipitate (*J. Löwe, Zeitschr. anal. Chem. iv. 388; J. pr. Chem. xcvi. 385*).

Sodium Nitrate. NaNO^3 .—This salt occurs native, not in Chile, as commonly stated, but in the province of Tarapaca, Dep. Moquegua, in Peru. The following analyses are by D. Forbes (*Phil. Mag. [4] xxxii. 139*): *a.* Comparatively pure selected crystals from the bed of La Noria, about 30 miles east of Iquique, and 3052 feet above the sea-level.—*b.* Fine-grained saline mass from a hill on the Sal de Ohispo, west of the port of Pisagua:

NaNO^3	NaCl	CaCl^2	KI	Na^2SO^4	MgSO^4	$\text{Al}^2(\text{SO}^4)^3$	Insol.
76.69	21.63	0.45	—	0.92	—	—	0.31 = 100
21.01	55.27	0.33	0.87	4.74	5.93	9.81	2.04 = 100

Thallium Nitrates.—See **THALLIUM** (v. 754, 756). According to Carstanjen (*Jahresb. 1867, p. 280*), thallous nitrate is decomposed at a bright red heat, giving off a volatile thallium-compound, and leaving a mixture of thallous nitrite and thallic oxide.

3. Nitric Ethers (Chapman a. Smith, *Chem. Soc. J. [2] v. 576; vi. 174*).—*Amyl Nitrate*, $\text{C}^5\text{H}^{11}\text{NO}^3$, is best prepared by gradually pouring 150 c. c. of a mixture of 1 vol. nitric acid (sp. gr. 1.36) and 3 vol. strong sulphuric cooled with ice and salt into 50 c. c. amyl alcohol, through a funnel reaching to the bottom of the vessel, the liquid being stirred all the while. The amyl nitrate then rises to the surface as an oily layer, which may be purified by washing with weak potash-ley and water, drying over calcium chloride, and rectification.

It boils constantly at 147° – 148° ; between 7° and 8° it has exactly the same specific gravity as water, but is lighter above and heavier below that temperature. The inhalation of its vapour produces headache and restlessness for several hours. It is quite insoluble in water, soluble in ethylic, methylic, and amylic alcohols, benzol, and glacial acetic acid, insoluble in concentrated formic acid, hydrochloric acid, cold nitric and sulphuric acids, and is not attacked by hydrochloric, acetic, formic, or oxalic acid, even at the boiling heat. At its boiling point it dissolves considerable quantities of sulphur and phosphorus. It is not attacked by trichloride or pentachloride of phosphorus; but with the oxychloride it gives off hydrochloric acid, and forms chlorinated substitution-products of intolerable odour. With sodium methylate and alcoholic potash it behaves like amyl nitrite (p. 870). Sodium introduced into well-cooled amyl nitrate acquires a strong silvery lustre, and forms, with violent reaction, sodium amylate and sodium nitrate: $\text{C}^5\text{H}^{11}\text{NO}^3 + \text{Na}^2 = \text{C}^5\text{H}^{11}\text{NaO} + \text{NaNO}^3$. If the amyl nitrate is diluted with an equal volume of ether, sodium acts very violently on it, even in the cold.

Amyl nitrate is not acted upon by *zinc-ethyl* when the two are mixed in an atmosphere of carbon dioxide; but on bringing the mixture for a moment in contact with the air, it explodes with vivid incandescence. If heated to about 40° it explodes with extraordinary violence. By dilution with ether the reaction may be moderated; it then begins at about 100° , yielding products of deep decomposition.

Ethyl Nitrate, $\text{C}^2\text{H}^5\text{NO}^3$, may be prepared like the amyl compound, and reacts in

a similar manner with the chlorides of phosphorus; it likewise dissolves sulphur and phosphorus, and is decomposed by potassium acetate into ethyl acetate and potassium nitrate; with sodium it forms ethylate and nitrate of sodium.

Methyl Nitrate resembles the ethyl compound, distils over sodium without alteration, and is decomposed by it only when the two are heated together in a sealed tube and in presence of ether.

(On the nitrates of isobutyl and isopropyl see BUTYL and PROPYL COMPOUNDS.

(On the reduction of nitric ethers by tin and hydrochloric acid, see HYDROXYLAMINE (p. 722).

Action of Fatty Acids on Nitric Ethers in Presence of Sulphuric Acid.—When amyl nitrate is added by drops to a warm mixture of 20 pts. glacial acetic acid and 1 pt. strong sulphuric acid, carbon dioxide and methyl nitrite are given off, while amyl acetate remains in solution:

Butyl nitrate and ethyl nitrate act in a similar manner. With methyl nitrate the reaction appears to be as follows:

Similar reactions are also produced when valeric acid is used instead of acetic acid, but the butyl nitrite thereby produced suffers immediate decomposition. Amyl nitrate and formic acid in presence of sulphuric acid yield amyl formate, nitrogen monoxide, carbon dioxide, and water, red vapours being also given off.

NITRILES. See CYANIDES, ALCOHOLIC (pp. 522–528).

NITRITES. For the preparation of *potassium nitrite*, *Stahlschmidt* (*Pogg. Ann.* cxviii. 466; *Jahresb.* 1866, p. 153) recommends the following process, founded on the fact that potassium nitrate in presence of free alkali is quickly reduced by the action of zinc-powder, even at ordinary temperatures, to nitrite, and partly to caustic potash, with evolution of nitrogen. A solution of potassium nitrate saturated at 30°–40° is mixed with about one-tenth of its volume of aqueous ammonia; and zinc-powder is added by small portions, with frequent agitation and cooling, to keep the temperature below 50°, till the greater part of the nitrate is decomposed (which may be known by a sample of the liquid, boiled to expel ammonia and filtered from precipitated zinc oxide, no longer giving a perceptible precipitate when mixed with 4 or 5 vol. alcohol). The clarified solution is then decanted from the zinc, boiled to volatilise the ammonia, then filtered, and treated with carbon dioxide at the boiling heat to decompose the metallic nitrites. The solution thus freed from zinc and cadmium is lastly neutralised with nitric acid, and the potassium nitrite is separated by evaporation and crystallisation. A similar process may be applied to the preparation of other nitrites. *Erdmann* (*Jahresb.* 1866, 154) prepares potassium nitrite by melting saltpetre in a cast-iron crucible at a moderate red heat, with several times its weight of iron filings or turnings, till a sample dissolved in water and treated with sulphuric acid gives off abundance of nitrous acid. The cooled mass is then lixiviated with water; the solution somewhat concentrated till the undecomposed nitrate crystallises out, then super-saturated with nitrous acid (evolved from starch and nitric acid), and evaporated at a gentle heat.

Nitrites of Nickel and Cobalt (*Erdmann, J. pr. Chem.* xcvi. 385; *Jahresb.* 1865, p. 717; 1866, p. 245).—Nickel solutions quite free from cobalt or calcium yield on addition of a large quantity of potassium nitrite, a red-brown precipitate of potassium-nickel nitrate (iv. 74); but when calcium chloride is added to a solution of this double salt, or to a mixture of nickel chloride and potassium nitrite, a yellow crystalline precipitate of the triple salt, $NiCaK^2(NO^2)^4$, is formed, very slightly soluble in cold water, but dissolving easily, with green colour, in boiling water. Barium chloride and strontium chloride form in like manner yellow or reddish-yellow triple salts of analogous constitution, which separate from hot solutions in microscopic cubes or combinations of the cube with octohedral faces. Cobalt salts mixed with chloride of barium, strontium, or calcium, yield with potassium nitrite blackish-green precipitates of corresponding composition; they are formed, however, only in concentrated solutions, and decompose during filtration and washing. It appears from these results that the separation of nickel from cobalt by potassium nitrite (i. 1045) cannot be effected in presence of calcium salts.

A neutral solution of cobalt chloride forms with excess of potassium nitrite a yellow crystalline precipitate of the salt $3NiK^2(NO^2)^4 + H^2O$; a solution mixed with a large excess of acetic acid yields double salts of more complex constitution.

When $NiCaK^2(NO^2)^4$ is gradually deposited from a mixture

of nickel acetate and ammonium nitrite in small, shining, cherry-red, apparently monoclinic crystals. A double salt of tetrammonio-cobaltic nitrite with potassium nitrite, $4\text{NH}_4\cdot\text{Co}^2(\text{NO}_2)^6 + 2\text{KNO}_2$, is obtained by mixing a solution of cobalt chloride with a large quantity of sal-ammoniac and excess of potassium nitrite; the liquid then deposits at a gentle heat shining yellow scales of potassium-cobalt nitrite, and afterwards brown vitreous rhombic prisms of the double salt just mentioned. The potassium in this salt may be replaced by equivalent quantities of other metals: thus its solution forms with silver nitrate a yellow or orange-coloured precipitate of the salt $4\text{NH}_4\cdot\text{Co}^2(\text{NO}_2)^6 + 2\text{AgNO}_2$. A neutral solution of cobalt chloride mixed with neutral ammonium nitrite yields by slow evaporation brown rhombic prisms of the double salt $4\text{NH}_4\cdot\text{Co}^2(\text{NO}_2)^6 + 2\text{NH}_4\text{NO}_2$.

On the estimation of nitrous acid by means of potassium permanganate, see Kübel (*J. pr. Chem.* cii. 222; *Zeitschr. f. Chem.* [2] iv. 314).

Nitrous Ethers. *Amyl nitrite*, $\text{C}^5\text{H}^{11}\text{NO}_2$, is formed, together with nitric acid, by the action of nitrogen tetroxide on amyl alcohol:

When nitrous acid vapour (from starch and nitric acid) is passed into amyl alcohol, ammonium nitrate is produced, as well as amyl nitrite, probably because the nitrous acid vapour is a mixture of [or is resolved into] the tetroxide and dioxide of nitrogen:

(N. Bunge, *Zeitschr. f. Chem.* [2] ii. 82, 225; *Bull. Soc. Chim.* [2] vi. 482).

Amyl nitrite added by drops to a hot mixture of *potassium dichromate* and *dilute sulphuric acid* is oxidised to nitric acid, valeric acid, and amyl valerate. Strong sulphuric acid acts violently on it, sometimes setting it on fire; sulphuric acid diluted with 2 pts. water decomposes it at 100° , forming sulphurous oxide, nitrogen dioxide, and amyl valerate:

Amyl nitrite dropped into a gently warmed mixture of concentrated *hydriodic acid* and *phosphorus* is decomposed, with formation of nitrogen dioxide and amyl iodide. Treated with excess of *phosphoric anhydride*, it is violently attacked, forming a brown solid mass, probably containing the cyanide of an alcohol-radicle of the allyl series, $\text{C}^4\text{H}^7\cdot\text{CN}$, formed according to the equation $\text{C}^5\text{H}^{11}\text{NO}_2 = \text{C}^4\text{H}^7\text{N} + 2\text{H}_2\text{O}$ (Chapman, *Chem. Soc. J.* [2] iv. 333, 336).

Amyl nitrite (boiling at $98^\circ\text{--}99^\circ$) heated to 106° with *sodium methylate* is resolved into methyl-amyl oxide and sodium nitrite:

With *sodium ethylate*, it yields in like manner, ethyl-amyl oxide; with an alcoholic solution of potash, it forms amyl alcohol and ethyl-amyl oxide in proportions varying with the quantity of water present. Heated with *ammonia* to 130° , it is resolved into amyl alcohol, nitrogen, and water:

Strong aqueous *hydrochloric acid* decomposes it only when heated, and even then not completely; but when saturated with hydrochloric acid gas and heated, it yields amyl alcohol, nitrogen dioxide, and chlorine:

if water is altogether absent, amyl chloride and its chlorinated derivatives are also formed. With *hydrobromic acid*, amyl bromide and nitrous acid are formed: $\text{C}^5\text{H}^{11}\text{NO}_2 + \text{HBr} = \text{C}^5\text{H}^{11}\text{Br} + \text{HNO}_2$; with *hydriodic acid*, iodine is separated, and ammonia is frequently formed:

Boiled with *glacial acetic acid*, it gives off red vapours, then pure nitrogen dioxide, and forms amyl acetate:

Heated with *formic acid*, it reacts according to the equation:

Heated with a concentrated solution of *zinc chloride*, it gradually dissolves, with abundant evolution of gas and formation of valeraldehyde and amyl valerate:

and

Zinc acts but slowly on amyl nitrite at the boiling heat, forming *zinc amylate*, with continuous evolution of nitrogen dioxide:

Sodium acts but slowly at first on amyl nitrite, but the reaction quickly becomes violent and sometimes explosive; if the liquid be sufficiently diluted with ether, the action goes on more quickly, with evolution of nearly pure nitrogen if the sodium is in excess, chiefly of nitrogen monoxide in the contrary case, and formation of amylate and oxide of sodium, but only a small quantity of nitrite:

and

(Chapman a. Smith, *Chem. Soc. J.* [2] v. 576).

NITRO-COMPOUNDS. On the formation and general properties of organic compounds formed from others by substitution of NO^2 for H , see Engelhardt a. Latschinoff (*Zeitschr. f. Chem.* [2] vi. 225).

NITROGEN OXIDES. *Monoxide.* N^2O .—According to R. Weber (*Berl. Akad. Ber.* 1866, 588; *Jahresb.* 1866, p. 140), both nitrous and nitric acids are reduced to nitrogen monoxide by the action of sulphurous acid. The monoxide is also produced, though very slowly, by the action of sulphurous acid on the dioxide, as formerly observed by Pelouze. Nitrogen monoxide is sometimes formed in sulphuric acid chambers, giving rise to loss of nitric acid and disturbance of the process. It is formed chiefly from the nitrous acid (and to a less extent from the nitric acid) when this acid is in contact with excess of sulphurous acid and a large quantity of water. This reduction may therefore be avoided by the introduction of a sufficient quantity of nitric acid, and by having a certain quantity of dilute sulphuric acid (which also interferes with the reduction) constantly present in the chamber.

Salts of Nitrogen Monoxide, or Hyponitrites, are formed by the action of sodium-amalgam on the nitrates of the alkali-metals. The sodium salt is alkaline to test-paper, and gives with silver nitrate a yellow precipitate having the composition NOAg (Divers, *Proc. Roy. Soc.* xix. 425; *Chem. Soc. J.* [2] ix. 484).

Dioxide. NO or N^2O^2 .—According to Chapman (*Chem. Soc. J.* [2] v. 166), this oxide is slowly reduced by concentrated hydriodic acid, with formation of ammonia and separation of iodine. It is oxidised by permanganates to nitric acid, with separation of manganese dioxide if the solution is neutral. The trioxide and tetroxide are oxidised to nitric acid in the same manner, but the monoxide is not attacked.

Trioxide. N^2O^3 .—On the action of water on this compound and on nitrous acid, see Frémy (*Compt. rend.* lxx. 61; *Zeitschr. f. Chem.* [2] vi. 138).

Tetroxide. NO^2 or N^2O^4 = $\frac{\text{NO}^2}{\text{NO}^2}$.—Deville a. Troost (*Compt. rend.* lxiv. 257;

Jahresb. 1867, p. 177) have determined the vapour-density of this compound by Dumas' process for temperatures above its boiling point. To obtain a series of determinations for increasing temperatures, the water-bath, or oil-bath for temperatures above 100° , was heated by a gas-flame 5° to 10° higher in each experiment than in the preceding; the glass globe of the capacity of 84.68 cub. cent. was immersed in the bath with its point still unbroken; kept in it about half an hour at a uniform temperature; then opened carefully and without loss; sealed again after the escape of gas had ceased; then weighed, &c. &c. The results of the experiments are given in the following table, in which P denotes the weight of the vapour contained in the globe at the variable temperature t ; K the expansion-coefficient of the glass; β the expansion-coefficient of nitrogen tetroxide between two successive values of t , and therefore $\frac{\alpha(1+kt)}{P}$ the

volume occupied by 1 gram of vapour at t° ; D denotes the density calculated on the assumption that nitrogen tetroxide is a perfect gas, so that $\beta = 0.00367$, the normal coefficient of expansion, and that the density varies with the pressure according to Mariotte's law:

Vapour-density of Nitrogen tetroxide.

t	D	P	$\frac{v(1+kt)}{P}$	100 β
26.7°	2.65	2.604	320.36	
35.4	2.53	2.419	345.12	0.888
39.8	2.46	2.358	360.42	1.008
49.6	2.27	2.108	403.33	1.215
60.2	2.08	1.870	454.95	1.207
70.0	1.92	1.688	505.85	1.137
80.6	1.80	1.530	556.37	0.946
90.0	1.72	1.426	597.22	0.781
100.1	1.68	1.354	629.23	0.531
111.3	1.65	1.291	660.29	0.441
121.5	1.62	1.240	688.74	0.422
135.0	1.60	1.180	723.87	0.378
154.0	1.58	1.118	764.40	0.367
183.2	1.57	1.037	824.77	

The coefficient β exhibits a maximum value at the temperature of 40°, and does not become constant till the temperature rises above 100°.

The nitrogen tetroxide with which the preceding experiments were made was prepared by direct combination of the dioxide with pure oxygen. It solidified constantly at -10°, but when once fused remained liquid even at -21.3°. The yellow colour of the liquid and vapour becomes darker as the temperature rises; at 22° the gas is reddish, and at 183° rather black than red.

Deville a. Troost infer from their experiments that the vapour-density of nitrogen tetroxide is constant and equal to 1.589, and therefore that the quantity represented by the formula NO^2 occupies 2 volumes (= H^2).

Salet, on the other hand (*Compt. rend.* lxvii. 488; *Jahresb.* 1868, p. 177), adduces an experimental argument in favour of the view that at comparatively low temperatures the quantity of the vapour of nitrogen tetroxide contained in two volumes is N^2O^4 , and that as the temperature rises, the compound is more and more resolved into two molecules, NO^2 , each occupying two volumes. Firstly, from the relations

$$\begin{aligned} a + b &= D; & \frac{a}{23} + \frac{b}{46} &= 1, \\ a &= 46 - D; & b &= 2D - 46 \end{aligned}$$

(in which D is the density of the mixed vapour referred to hydrogen as unity, a and b the quantities by weight of NO^2 and N^2O^4 contained in it, 23 the theoretical density of NO^2 , 46 that of N^2O^4), he calculates, from the vapour-densities determined by Deville and Troost, the amount of dissociation at the various observed temperatures, according to the formula $\frac{a}{D}$, which expresses the weight of NO^2

contained in the unit of vapour. Secondly, assuming that the vapour of N^2O^4 is colourless, and that of NO^2 coloured, he calculates the lengths which a column of the vapour at 26.7° must have in order to exhibit a depth of colour equal to that of a column of constant length regarded as unity at the temperatures given in the following table. On the other hand, having ascertained that a short hot column and a longer cold column of the vapour, which exhibit equal depths of colour, also exhibit similar absorption-spectra, he determines the required lengths of the columns by a peculiar mode of observation. The near agreement of the experimental results thus obtained with theory is exhibited in the following table, in which the column headed 'Calculated

lengths' contains the values obtained by the formula $x = \frac{a}{D} \cdot \frac{P}{3.1214 \times 20.26}$ (P

denoting the weight of the unit of volume at 1°):

Temperature	A Weight P of a litre of vapour	$\frac{a}{D}$	B Lengths of Column	
			calculated	observed
26.7°	8.1214	20.26 p. c.	1	1
35.4	2.8975	25.8	1.182	1.18
39.8	2.7745	29.6	1.299	1.28
49.6	2.4793	40.5	1.588	1.28
60.2	2.1980	53.3	1.852	1.9
70.0	1.9768	66.1	2.066	1.9
80.6	1.7973	76.9	2.185	2.2
90.0	1.6744	85.1	2.253	2.2
100.1	1.5892	89.7	2.254	2.8
111.3	1.5144	93.3	3.234	2.25
121.5	1.4519	96.6	2.218	2.24
135.0	1.3814	99.1	2.165	2.20
154.0	1.3082	101.7 *	2.104	2.12
200.0			1.9	1.95
225.0			1.8	1.95
250.0			1.7	1.95
275.0			1.6	1.6
300.0			1.56	1.62

These numbers show that the depth of colour increases rapidly with the temperature at first, attains a maximum when the decrease of density balances the increase of coloration, and afterwards diminishes when the diminution of the density exerts a predominating influence.

A. Naumann (*Ann. Ch. Pharm. Suppl.* vi. 203) has also calculated, from the experimental results of Deville and Troost, the amount of dissociation of the molecule N_2O_4 which may be supposed to take place at the several temperatures observed. The calculations are based upon the formula

$$p = \frac{100(d - D)}{(a - 1)D},$$

in which d is the theoretical specific gravity of a body susceptible of dissociation, D the observed sp. gr. of the gaseous mixture at any temperature, a the number of molecules into which a molecule of the original compound is resolved by dissociation, and p the number of parts per cent. of the dissociated compound.

Temperature	Vapour-density of Nitrogen tetroxide	Percentages of Decomposition	Increase per. cent. of decomposition for temperature in- tervals of 10°
26.7°	2.65	19.96	
35.4	2.53	25.65	6.5
39.8	2.46	29.23	8.1
49.6	2.27	40.04	11.0
60.2	2.08	52.84	12.1
70.0	1.92	65.57	13.0
80.6	1.80	76.61	10.4
90.0	1.72	84.83	8.8
100.1	1.68	89.23	4.4
111.3	1.65	92.67	3.1
121.5	1.62	96.23	3.5
135.0	1.60	98.69	1.8
154.0	1.58		
183.2	1.57		

These numbers afford an explanation of the apparent maximum of the expansion-coefficient observed by Deville and Troost, inasmuch as they exhibit a dissociation of the vapour gradually increasing with the temperature.

* Corresponding to the somewhat too low density observed.

On the spectra of the vapours of nitrogen trioxide and tetroxide, see Luck (*Zeitschr. f. Chem.* [2] vi. 287).

Pentoxide or Nitric Anhydride. N_2O_5 .—This oxide is most readily prepared by passing the vapour of nitryl chloride, NO_2Cl , over well-dried silver nitrate heated to $60^\circ\text{--}70^\circ$, and condensing the product by a freezing mixture. The anhydride then collects in colourless prismatic or needle-shaped crystals having exactly the properties described by Deville (Odet a. Vignon, *Compt. rend.* lxi. 1142; *Zeitschr. f. Chem.* [2] vi. 81).

NITROSO-COMPOUNDS. The formation of these compounds by the action of nitrous acid on azotised bodies appears to depend essentially on the presence of the imidogen group NH in the latter, the reaction consisting in an interchange between the group NO of the nitrous acid and the H of the imidogen; thus:

(Baeyer, *Zeitschr. f. Chem.* [2] vi. 215).

NITRYL CHLORIDE, NO_2Cl , is produced by the action of phosphorus oxychloride on lead nitrate, or better on silver nitrate. It is a liquid having a faint yellow colour, boiling at $+5^\circ$, remaining liquid at -31° , and converted by water into nitric and hydrochloric acids (Odet a. Vignon).

NONANE or NONYL HYDRIDE, C^9H_{20} , is produced by heating cumene, C^9H_{12} , with 80 pts. of saturated aqueous hydriodic acid (Berthelot); also, according to H. Vohl (*Jahresb.* 1865, p. 841), when tetradecane, $\text{C}^{14}\text{H}_{30}$, is passed through red-hot wrought-iron tubes.

NONYLENE, C^9H^{18} , is found among the hydrocarbons produced by decomposition of the lime-soap of Menhaden oil (p. 814). Boiling point, 253° (Warren a. Storer).

NUCITANNIN or NUCITANNIC ACID. A peculiar tannin occurring in the episporm of walnuts. It dissolves in water and alcohol, is precipitated by basic lead acetate, and is resolved by dilute acids into sugar and a red acid substance, *rufic acid*, soluble in ammonia and in alcohol. The nucitannin is likewise accompanied by considerable quantities of gallic and ellagic acids, which greatly impede its purification. *Rufic acid* is a brown-red amorphous substance easily soluble in alcohol, forming soluble salts with the alkali-metals, insoluble or slightly soluble coloured salts with calcium, lead, and silver (Phipson, *Chem. News*, xx. 116).

NUTRITION. Frankland (*Phil. Mag.* [4] xxxii. 182; *Chem. Soc. J.* [2] vi. 33) has determined the heat of combustion of muscular substance, urea, and other substances which play an essential part in the transformation of tissue in the animal body, by burning them with a mixture of potassium chlorate and manganese dioxide. The mean results are as follows:

1 gram of substance dried at 100°	developed by combustion	
	Heat-units	Corresponding units of force: Metre-kilograms
Beef-muscle, purified by repeated washing with ether	5103	2161
Purified albumin	4998	2117
Beef-fat	9069	3841
Hippuric acid	5383	2280
Uric acid	2615	1108
Urea	2206	934

Dried muscle and albumin, in passing through the organism, yield about a third of their weight of urea. Hence it may be calculated that these substances, when oxidised in the animal body, yield the following amounts of heat and force:

	Heat-units	Metre-kilograms
Beef-muscle	4368	1848
Albumin	4263	1803

Frankland has also determined the quantities of heat produced by the combustion of various articles of food with potassium chlorate. The following table gives the mean values in heat-units for 1 gram of the undried substances, together with the mechanical equivalents in metre-kilograms:

1 gram of undried substance	Water p. c.	Develops when burnt in oxygen		When oxidised in the animal body.
		Heat-units	Met.-kil. of force	Met.-kil. of force

The question as to how far the production of muscular force depends on the oxidation of nitrogenous materials, has been examined experimentally by Fick and Wislicenus (*Phil. Mag.* [4] xxxi. 485). These observers estimated the quantities of albuminous substances oxidised in their own bodies, on a purely non-nitrogenous diet, both at rest and during muscular exertion (in an ascent of the Faulhorn), taking as a measure of this oxidation the amount of nitrogen excreted in the urine. These amounts were as follows: (a) During 11 hrs. 50' rest, previous to the ascent; (b) during the ascent, 3 hrs. 10'; (c) during 5 hrs. 40' rest after the ascent; (d) during the following 11 hrs. (night) after a full meat diet. The numbers marked I. give the results for Fick (weighing 66 kilograms); those marked II. for Wislicenus (76 kilograms):

	Urea	Amount of nitrogen in the urea	Amount of Nitrogen in the Urine		Corresponding quantity of albuminoids oxidised *
			Total	Per hour	Total
a { I.	12.4820	5.8249	6.9153	0.63	46.1020
II.	11.7614	5.4887	6.6841	0.61	44.5607
b { I.	7.6330	3.2681	3.3130	0.41	22.0867
II.	6.6973	3.1254	3.1336	0.39	20.8907
c { I.	5.1718	2.4151	2.4293	0.40	16.1953
II.	5.1020	2.3809	2.4165	0.40	16.1100
d { I.			4.8167	0.45	32.1113
II.			5.3482	0.51	35.6412
e + c { I.			5.7432		37.1700
II.			5.5501		37.0007

* Calculated on the assumption that albuminoids contain 15 p. c. N.

The quantities of albuminoids oxidised during the ascent of the mountain (1956 metres high) were therefore: I. 37.17 grms., and II. 37.0 grms. Comparing these numbers with Frankland's estimate of the amount of force generated by the oxidation of 1 gram of albumin, we obtain, for I. 68,690 metre-kilograms, for II. 688,376 metre-kilograms of force generated during the ascent by the oxidation of albuminous substances in the body.

Further, Fick and Wislicenus conclude—from calculations for which we must refer to their memoir—that the work expended in raising the body through the height of 1956 metres, and in the action of the heart and respiratory organs during the same time (neglecting that expended in other bodily movements), was for I. 159,637, and for II. 184,287 metre-kilograms. Since, however, of the total energy generated in a given time by the process of oxidation in the organism, only a fraction is expended in mechanical force—this fraction, according to Haidenhain, not exceeding one-half in the most favourable case—these values must be doubled in order to obtain the total amount of energy developed by the oxidising process. We have then as the final result:

	I. Metre- kilograms.	II. Metre- kilograms.
Maximum expenditure of force during the ascent	319,274	368,574
Maximum of force generated by oxidation of muscular substance	68,690	68,376
